Neil R. Carlson

William Buskist

Psychology

The Pearson logo consists of the word "PEARSON" in white, uppercase, sans-serif font, centered within a dark blue rectangular box. A thin, curved yellow line is positioned directly beneath the text.

PEARSON

We work with leading authors to develop the strongest educational materials in psychology, bringing cutting-edge thinking and best learning practice to a global market.

Under a range of well-known imprints, including Allyn and Bacon, we craft high quality print and electronic publications which help readers to understand and apply their content, whether studying or at work.

To find out more about the complete range of our publishing, please visit us on the World Wide Web at: www.pearsoned.co.uk

Psychology

Fourth Edition

G. Neil Martin

Middlesex University, UK

Neil R. Carlson

University of Massachusetts, USA

William Buskist

Auburn University, USA

Allyn & Bacon
is an imprint of

PEARSON

The publisher's policy is to use paper manufactured from sustainable forests.

Brief contents

Preface to the fourth edition	xvii
Guided tour	xx
The authors	xxvi
Acknowledgements	xxviii
1. The science of psychology	2
2. Research methods in psychology	47
3. Evolution, genetics and behaviour	75
4. Psychology and neuroscience	113
5. Sensation	167
6. Perception	213
7. Learning and behaviour	257
8. Memory	291
9. Consciousness	337
10. Language	375
11. Intelligence and thinking	431
12. Developmental psychology	493
13. Motivation and emotion	553
14. Personality	609
15. Social cognition and attitudes	647
16. Interpersonal and group processes	679
17. Health psychology	727
18. Abnormal psychology	773
Appendix: Understanding research results	A1
Glossary	G1

1 The science of psychology

<i>What you should be able to do after reading Chapter 1</i>	3
<i>Questions to think about</i>	3

What is psychology?

Psychology defined	3
<i>Cutting edge: How much of a science is psychology?</i>	3
<i>Controversies in Psychological Science:</i>	4
<i>Is psychology common sense?</i>	4
Explaining behaviour	7
Established and emerging fields of psychology	8
<i>Psychology in action: How to detect a liar</i>	10
<i>Cutting edge: I'm your biggest fan ... What makes a celebrity worshipper worship?</i>	13
<i>Psychology in action: Psychology in the witness box</i>	14
<i>Psychology – An international perspective</i>	16

Psychology: a European perspective

Psychological training and status of psychology in Europe	18
European views of psychology and psychologists	18

Psychology: the development of a science

Philosophical roots of psychology	20
-----------------------------------	----

Modern psychology: from the Leipzig laboratory to the cognitive revolution

Structuralism: Wilhelm Wundt	24
Memory: Hermann Ebbinghaus	24
Functionalism: William James and James Angell	25
Evolution and heritability: Charles Darwin and Francis Galton	25
Psychodynamic theory: Sigmund Freud	26
Behaviourism: Edward Thorndike and Ivan Pavlov	27
Behaviourism: John B. Watson	28
Radical behaviourism: Edward Tolman and Clark Leonard Hull	29
Radical behaviourism: Burrhus Frederic Skinner	30
Genetic epistemology: Jean Piaget	30
Gestalt psychology: Max Wertheimer	31
Humanistic psychology	31
The personality psychologists: Gordon Allport,	32
Raymond Cattell, Hans Eysenck, Walter Mischel,	32
Paul Costa and Robert McCrae	33
The social psychologists	33

The cognitive revolution: beyond behaviourism	34
The biological revolution	35
Cognitive neuroscience: the future of the biology of the 'mind'?	38

Conceptual and historical issues in psychological science

<i>Chapter review</i>	39
<i>Suggestions for further reading</i>	40
<i>Journals to consult</i>	41
<i>Website addresses</i>	42
<i>Addresses: major international professional psychology organisations and societies</i>	42
	43

2 Research methods in psychology

<i>What you should be able to do after reading Chapter 2</i>	47
<i>Questions to think about</i>	47

The process of discovery in psychology: the scientific method

Stages in experimentation	48
Communicating the results of scientific research	48
<i>Cutting edge: Stories conquer statistics</i>	49
<i>Controversies in Psychological Science: Psychology and the media</i>	50
Identifying the problem: getting an idea for research	51
Quantitative research methods: designing an experiment	52
<i>Psychology in action: The Barnum effect</i>	55
<i>Controversies in Psychological Science: How representative are samples in psychological research?</i>	59
<i>Response bias – An international perspective</i>	60
Correlational studies	63
Single-case studies	64
Generalising from data	64
Application of psychological research	65
Qualitative analysis	65

Ethics

Research with human participants	68
Informed consent	68
<i>Controversies in Psychological Science: Can research with animals help us to understand human behaviour?</i>	70
<i>Chapter review</i>	71
<i>Suggestions for further reading</i>	72
<i>Journals to consult</i>	72
<i>Website addresses</i>	73

3 Evolution, genetics and behaviour

What you should be able to do after reading Chapter 3
Questions to think about

The development of evolutionary theory

In the beginning: the voyage of the *Beagle*
The Origin of Species
 Natural selection and evolution
 Human evolution
 Natural selection and human evolution

Heredity and genetics

The basic principles of genetics
 Genetic diversity
 Influences of sex on heredity
 Mutations and chromosomal aberrations
 Epigenetics
 Genetic disorders
Psychology in action: The psychological consequences of genetic counselling
 Heredity and behaviour genetics
Controversies in Psychological Science: Are attitudes genetically inherited?

Sociobiology

Reproductive strategies and the biological basis of parenting
Physical attraction – An international perspective
Cutting edge: Can I have your number?
Cutting edge: Jealousy, infidelity and the brain
Infidelity – An international perspective
 Altruism and kin selection
 Sociobiology and evolutionary psychology as an explanation for human behaviour?
Chapter review
Suggestions for further reading
Journals to consult
Website addresses

4 Psychobiology and neuroscience

What you should be able to do after reading Chapter 4
Questions to think about

Psychobiology and neuroscience

The nervous system: the brain and its components

The central nervous system
 The peripheral nervous system
 Cells of the nervous system
 Neurotransmitters
 Myelination
 The action potential
 Synapses

Excitation and inhibition 120
 A simple neural circuit 122
 Neuromodulators: action at a distance 123

Techniques in psychobiology and neuroscience 124

76 Lesioning 124
 77 Studying brain injury: clinical neuropsychology 126
 77 Rehabilitation after brain damage 126
 78 *Psychology in action: Using brain activity to overcome physical disability* 128
 81 Psychophysiology: measuring CNS activity 129
 82 Psychophysiology: measuring activity outside the CNS 130
 84 *Cutting edge: James Bond and the bloody consequences of Mortal Kombat* 133
 85 Neuroimaging techniques 134
 87 *Cutting edge: Love, friendship and neuroscience* 138
 87 *Cutting edge: The magic of neuroscience* 138
 89 Caveats 140
 90 *Controversies in Psychological Science: Can brain scanners detect deception?* 140
 92 Modern brain stimulation: transcranial magnetic stimulation (TMS) 141
 93

Control of behaviour 143

95 Organisation of the cerebral cortex 144
 96 Temporal sequencing of events 144
 96 Lateralisation of function 144
 98 Vision: the occipital lobe 146
 100 Audition: the temporal lobe 146
 103 Somatosensation and spatial perception: the parietal lobe 147
 105 Planning and moving: the frontal lobe 148
 106

Control of internal functions and automatic behaviour 149

108 The brain stem 149
 109 The cerebellum 149
 111 Subcortical structures 150
 111

Drugs and behaviour 154

Stimulating or inhibiting the release of transmitter substances 154
 113 Stimulating or blocking postsynaptic receptor molecules 154
 113 Inhibiting reuptake 155
 Sedatives 155
 114 *Controversies in Psychological Science: What is drug addiction?* 156
 Stimulants 158
 114 Drugs and altered states of consciousness 158
 114 Drug classification 160
 115 *The psychology of cannabis use – An international perspective* 160
 117 *Chapter review* 162
 118 *Suggestions for further reading* 164
 118 *Journals to consult* 165
 119 *Website addresses* 165

5 Sensation

What you should be able to do after reading Chapter 5
Questions to think about

Sensation and behaviour

Sensory processing

Transduction
 Sensory coding
 Psychophysics
 The principle of the just-noticeable difference

Vision

Light
 The eye and its functions
 Transduction of light by photoreceptors
 Adaptation to light and dark
 Eye movements
 Colour vision
 Defects in colour vision
Psychology in action: Red light = danger?
 Synaesthesia

Audition

Sound
 The ear and its functions
 Detecting and localising sounds in the environment
 The interaction between audition and vision
 Audition and the temporal cortex
Cutting edge: Hearing voices
 Deafness

Gustation

Taste receptors and the sensory pathway
 The four or more qualities of taste
 The development of taste preference

Olfaction

Cutting edge: Cheese, body odour and the orbitofrontal cortex
Odour perception – An international perspective
 Anatomy of the olfactory system
Controversies in Psychological Science: Do human pheromones exist?
 The dimensions of odour
 Sex differences

The somatosenses

The skin senses
 The internal senses
 The vestibular senses
Chapter review
Suggestions for further reading
Journals to consult
Website addresses

6 Perception

What you should be able to do after reading Chapter 6
Questions to think about

168 The nature of perception 214

168 Definition of perception 214

168 Perception of form 214

168 Figure and ground 214
 170 Organisation of elements: the principles of Gestalt 215
 170 Models of pattern perception 217
 173 Top-down processing: the role of context 220
 173 Direct perception: Gibson's affordances 221
 173 Face perception 222

177 Perception of space and motion 227

177 Depth perception 227
 178 *Psychology in action: CCTV and face perception* 231
 178 Distance and location 232
 182 Constancies of visual perception 233
 183 Visual perception across cultures 233
 184 *Controversies in Psychological Science: How does language influence visual perception?* 235

185 Perception of motion 237

185 *Cutting edge: Content over style?* 237
 186 *Perception and the environment – An international perspective* 239
 187 *The psychology of art – An international perspective* 240

191 Brain mechanisms of visual perception 241
 191 The primary visual cortex 241
 192 How different are imagining and perceiving visual stimuli? 242
 The visual association cortex 243

193 Brain damage and visual perception 244

193 Perceptual disorders 246
 195 *Psychology in action: How does brain injury affect artists?* 250
 196 *Chapter review* 252

197 *Suggestions for further reading* 253

197 *Journals to consult* 254

Website addresses 255

7 Learning and behaviour

What you should be able to do after reading Chapter 7
Questions to think about

203 The purpose of learning 258

203 Habituation 258

206 Classical conditioning 258

206 Pavlov's serendipitous discovery 259
 207 The biological significance of classical conditioning 260
 208 Basic principles of classical conditioning 260
 209 Conditional emotional responses 261
 210 What is learned in classical conditioning? 263
 Neurobiological correlates of Pavlovian conditioning 263

After behaviourism

Hull's computational approach to learning
Tolman and the cognitive map

Operant conditioning

The law of effect
Skinner and operant behaviour
The three-term contingency
Reinforcement, punishment and extinction
Other operant procedures and phenomena

Conditioning of complex behaviours

Aversive control of behaviour
Psychology in action: Flavour aversions
Applications of operant conditioning to human behaviour
Controversies in Psychological Science: What is insight?
Recent approaches to learning: computational modelling and neural networks

Learning in practice: being a student

Deep v. shallow learning
Learning style
Cutting edge: Personality and academic success
Confidence
The best way to understand a textbook
Can the internet be used to teach successfully?
Studying psychology – An international perspective
Chapter review
Suggestions for further reading
Journals to consult
Website addresses

8 Memory

What you should be able to do after reading Chapter 8
Questions to think about

Memory: an introduction

Types of memory

Sensory memory

Iconic memory
Echoic memory

Short-term memory

Working memory
Primacy and recency effects
The limits of short-term and working memory
Loss of information from short-term memory

Learning and encoding in long-term memory

The consolidation hypothesis
Levels of processing
Mnemonics
Cutting edge: Something to chew over

263 Long-term memory: episodic and semantic memory

264
265 *Autobiographical Memory – An international perspective*
Explicit and implicit memory

266

Remembering

266
267 *Psychology in action: Using odours to retrieve memories*
267 Reconstruction: remembering as a creative process
268 *Psychology in action: How long does memory last?*
270 The malleability of memory
Eyewitness testimony
272 Eyewitness identification
273 *Cutting edge: Unbelievable accents*
275 Interference
275 State-dependent memory: the effect of mood on recall
276 Flashbulb memories

279 The biological basis of memory

Before memory: learning
281 Where are long-term memories formed?
281 Chemical modulation of long-term potentiation
282 Amnesia
282 *Psychology in action: Memory at the movies ...*
283 The role of the hippocampus in memory
283 Neuroimaging and memory
284 Memory-enhancing drugs
285 *Controversies in Psychological Science:*
286 *Do 'smart drugs' work?*
287 Chapter review
287 *Suggestions for further reading*
288 *Journals to consult*
Website addresses

9 Consciousness

291
291 *What you should be able to do after reading Chapter 9*
Questions to think about

292

Consciousness: an introduction

292 Philosophical approaches to consciousness
292 The meaning of 'consciousness'

Theories of consciousness

293 Neurobiological theories
293 Cognitive theories

Selective attention

294
297 Dichotic listening
298 The cocktail-party phenomenon
299 *Controversies in Psychological Science: Does mobile phone use impair your driving?*
300 Background noise
300 *Noise – An international perspective*
301 Models of selective attention
304 Visual information
Inattention blindness

Divided attention
Brain mechanisms of selective attention
Control of consciousness

Hypnosis

Psychology in action: Attention and pain
The induction of hypnosis
Characteristics of hypnosis
Theories of hypnosis
Controversies in Psychological Science: Can hypnosis reduce pain and stress?

Sleep

The stages of sleep
Cutting edge: Evening types are more creative but are more maladaptive
Functions of sleep
Sleep deprivation
Sleep-dependent memory consolidation
Psychology in action: How sleep loss affects behaviour
Dreaming
Functions of dreams
Role of REM sleep in brain development
Brain mechanisms of sleep
Sleep disorders
Chapter review
Suggestions for further reading
Journals to consult
Website addresses

10 Language

What you should be able to do after reading Chapter 10
Questions to think about

The use of language

Psycholinguistics: the study of language acquisition and meaning
Perception of speech
Recognition of speech sounds
Production of speech
Recognition of words: the importance of context
Understanding the meaning of speech
The relationship between semantics and syntax
Knowledge of the world
What is meaning?
Is there a universal language?

Reading

Psychology in action: Sex differences in communication
Scanning text
Phonetic and whole-word recognition
The process of reading
The dual-route model of reading
Psychology in action: How children learn to read
Understanding the meanings of words and sentences
On the relative importance of consonants and vowels

350 Language acquisition by children 392

351 Perception of speech sounds by infants 392
352 *The pre-speech period and the first words – An international perspective* 393
353 Infant communication 394
353 How adults talk to children 394
354 Acquisition of adult rules of grammar 395
354 Acquisition of meaning 396
355 Bilingualism 398
Is there a language acquisition device? 398
356 *Controversies in psychological science: Can other primates acquire language?* 400

357

357 Brain development and language 403

The case of Genie 403
360 Plasticity and language development 403
360 Is half a brain enough? 404

361 The neuropsychology of language and language disorders 404

364 Language disorders 404
364 Aphasia 405
366 *Psychology in action: The man who lost his language* 409
366 Specific language impairment 411
367 Dyslexia 413

371 Word recognition and production: neuroimaging studies 418

372 Is there a visual word form area? 419
Cutting edge: Irony – a look inside the brain 419
Neuroimaging and language – An international perspective 420
375 Braille and Sign language 421
375 Neuropsychological models of language: a summary 422
Caveats and complications 423
376 Handedness 424
Chapter review 425
Suggestions for further reading 427
Journals to consult 428
Website addresses 428

378 11 Intelligence and thinking

What you should be able to do after reading Chapter 11 431
Questions to think about 431

381 What is intelligence? 432

383 Theories of intelligence 432

383 Spearman's two-factor theory 432
384 Evidence from factor analysis 433
385 Sternberg's triarchic theory of intelligence 434
386 Gardner's multiple intelligences theory 436
387 Emotional intelligence 436
387 *Estimating intelligence – An international perspective* 438
389 Are there consistent sex differences in cognitive ability? 440
391 Sex differences in general knowledge 444

Intelligence testing

Early intelligence tests
Modern intelligence tests
Reliability and validity of intelligence tests

The roles of heredity and environment

Cutting edge: Do you have to be smart to be rich?
The meaning of heritability
Sources of environmental and genetic effects
during development
Results of heritability studies
If intelligence is inherited, how does inheritance occur?
Giftedness
Psychology in action: Can low intelligence be improved?
IQ and nutrition
Cutting edge: The effect of intelligence on health
*Controversies in Psychological Science: Is there a relationship
between race and intelligence?*

Intelligence, thinking and ageing

Ageing and cognitive ability
What is ageing?
Why does cognitive ability decline?
Dementia
Dementia of the Alzheimer type
Clinical features of DAT
Memory decline in Alzheimer's disease
Dementia and the novelist: the case of Iris Murdoch
Treatment for DAT

Thinking

Classifying
Formal and natural concepts
Deductive reasoning
Syllogistic reasoning – An international perspective
Inductive reasoning
Logical errors in inductive reasoning
Cutting edge: Who believes in spoon bending?
Cutting edge: How eBay works
Psychology in action: Jury decision-making
Problem-solving
Where in the brain does decision-making occur?
Reasoning and the brain
Creative thinking
Cutting edge: Creativity and romance
Case studies in creativity
*Controversies in Psychological Science: Are creativity and
psychopathology related?*
Cutting edge: The key to creativity – shut up!
Chapter review
Suggestions for further reading
Journals to consult
Website addresses

12 Developmental psychology

444 *What you should be able to do after reading Chapter 12* 493
445 *Questions to think about* 493
447

Developmental psychology 494

Prenatal development 494

448 Stages of prenatal development 494
449 Threats to normal prenatal development 496

Physical and perceptual development in infancy and childhood 497

Controversies in Psychological Science:
Does foetal learning exist? 497
Brain development 498
Does the environment affect brain development? 499
Motor development 501
Perceptual development 501

Cognitive development in infancy and childhood 505

457 Development of memory 505
457 Knowing where things are – spatial development
460 at 2 years old 507
462 The development of cognition: Jean Piaget 508
462 Vygotsky's sociocultural theory of cognitive development 513
464 Developmental models of information processing
465 in cognitive development 514
467
468

Social and emotional development in infancy and childhood 516

468 Infant attachment 516
468 The nature and quality of attachment 518
469 Predictors of secure attachment 519
471 Relationships with siblings 520
472 Relationships with others 520
474 *Social organisation – An international perspective* 521
474

Disorders of social cognition and emotion 521

477 Autism 521
478 *Cutting edge: Loneliness and autistic tendency* 523
480 Asperger's syndrome 525
481 *Theory of mind – An international perspective* 525
482 Conduct disorder/attention deficit hyperactivity disorder 526
484 Disorders of emotional regulation 526
484

Development of sex roles in childhood 528

485 Development of sexual identity 528
487

Moral development 530

489 Piaget's theory of moral development 530
490 Kohlberg's theory of moral development 530
490 Evaluation of Piaget's and Kohlberg's theories of moral
development 531
Alternative models of moral development 532

Adolescence

Physical development
Sexual maturation
Behavioural effects of puberty
How do adolescents view puberty?
Changes in leisure activities reflect the move into young adulthood
Psychology in action: Adolescence and the internet
Social development, peer relations and delinquency
Friendship
Psychology in action: Bullying
Relations with parents

Adulthood: beyond adolescence

Middle adulthood: a period of contentment?
Parenthood
Work
Late adulthood and the menopause
Old age
Death and bereavement
Chapter review
Suggestions for further reading
Journals to consult
Website addresses

13 Motivation and emotion

What you should be able to do after reading Chapter 13
Questions to think about

Motivation

Biological needs
Physiology of reinforcement

Ingestion: drinking and eating

Thirst
What starts a meal?
What stops a meal?
Sensory-specific satiety
Obesity
Psychology in action: The problem of obesity and its treatment
Controversies in Psychological Science: Can the bitter gene cause obesity?
How emotion affects food intake
Cutting edge: Mood food
Anorexia nervosa
Bulimia nervosa
Aetiology of anorexia and bulimia nervosa
Body dissatisfaction in healthy and eating-disordered women
Cutting edge: Body size, television size and other peoples attractive size
Eating disorders – An international perspective

533 Sexual behaviour

533 Effects of sex hormones on behaviour
533 Sexual orientation
534 Neurobiological correlates of sexual behaviour
535

Aggressive behaviour

535 Ethological studies of aggression
536 Hormones and aggression
537 Testosterone: status, relationships and empathy
537 Imitation and aggression
538 *Psychology in action: Aggression at work*
539

Emotion

540 Basic emotions
540 The biology of emotion
541 *Controversies in psychological science: What is the key to enduring happiness?*
542 *Emotion – An international perspective*
543 Emotional experience: anger and disgust
546 Using display rules
547 Facial feedback hypothesis
550 *Cutting edge: A slump in mental fortune*
551 Facing emotion
551

Theories of emotion

Physiological theories
Evolutionary theories
553 Cognitive theories
553 *Cutting edge: Keeping your emotional distance*
Controversies in Psychological Science: Dark clouds gathering, sunny spells later ...
554 Emotion without cognition?
555 *Chapter review*
Suggestions for further reading
557 *Journals to consult*
Website addresses

14 Personality

562 *What you should be able to do after reading Chapter 14*
Questions to think about

562

Towards a definition of personality

Trait theories of personality

567 Personality types and traits
567 Identification of personality traits
568 *Cutting edge: Personality and music preference*
569 *Cutting edge: How extraverted is 'honeybunny22@hotmail.de'?*
569 *Personality – An international perspective*
571 Stability of personality traits across the lifespan
572 *Cutting edge: Sex and profession differences in personality*
How we view ourselves in the past and the present
Cutting edge: Do you get better looking each day?

Heritability of personality traits

Neurobiological basis of personality
Cutting edge: Personality and birth order
Controversies in Psychological Science: The state you're in

The social learning approach

Expectancies and observational learning
 Reciprocal determinism and self-efficacy
 Person variables
 Locus of control
Controversies in Psychological Science: Do traits or situations best predict behaviour?
Psychology in action: Personality and romance

The psychodynamic approach

The development of Freud's theory
 Structures of the mind: id, ego and superego
 Defence mechanisms
 Freud's psychosexual theory of personality development
 Further development of Freud's theory: the neo-Freudians
 Evaluation of psychodynamic theory and research

The humanistic approach

Maslow and self-actualisation
 Evaluation of the humanistic approach

Assessment of personality

Objective tests of personality
 Projective tests of personality
Controversies in Psychological Science: Are projective tests reliable and valid?
Chapter review
Suggestions for further reading
Journals to consult
Website addresses

15 Social cognition and attitudes

What you should be able to do after reading Chapter 15
Questions to think about

Social psychology

Doing social psychology

Social cognition and social knowledge

Forming impressions of people
 Schemas and categories
 Group schemas and stereotypes
 When good intentions backfire: stereotypes, influence and behaviour
 Facing racial stereotypes
Cutting edge: Sexist humour: does it make you sexist?

618 Conceptual and historical issues in psychological science

619
 619
 621

Self and identity

Self-knowledge 657
 Orientations of self-knowledge 657
 Self-awareness 659
 Types of self and identity 659
 Social identity 659
 Self motives 660
 Self-esteem 660
Cultural differences in self and identity – An international perspective 660

630 Social inference

Causal attribution 661
 Implications and extensions of attribution theory 662
 Attributional biases 662
Psychology in action: Attributional processes in relationships 665
 Heuristic judgements 666

636 Attitudes and attitude change

The nature of attitudes 668
 Attitudes and behaviour 669
 Attitude change and persuasion 670
 Cognitive dissonance 672
 Self-perception 674
Chapter review 675
Suggestions for further reading 676
Journals to consult 677
Website addresses 677

16 Interpersonal and group processes

What you should be able to do after reading Chapter 16 679

Preface to the fourth edition

Here's an apparently simple question: What made you pick up this book and read it? You might be a psychology student and spotted this book in your library or bookshop. It might be the recommended text on your course. You may have been at a friend's house, become bored and begun leafing through this book lying on a table. You may have been attracted to the cover. You may even have liked the authors' other books so much that you had to read this one as well.

This simple exercise illustrates the essence of psychology – the scientific study of why and how humans (and animals) behave in the way that they do. Psychology is the science of behaviour and, being a science, it approaches the understanding of behaviour in a specific way. Everyone has an opinion on psychology and on what motivates people and what brings people to react and behave in the way that they do. We are all quasi-psychologists, in a way. Trained psychologists, however, attempt to understand behaviour through careful experimentation and empirical observation. They do this because it is the best method of gaining useful and reliable information about behaviour and the causes of behaviour. This book, the fourth edition of *Psychology*, introduces you to the scientific approach to understanding human behaviour and each chapter reviews the current state of knowledge about behaviour – from intelligence and emotion to child development and prejudice – based on sound scientific study.

Let's go back to the opening paragraph. The reason you are reading this book is probably because it was recommended on your psychology course or because you have spotted it in the library or bookshop and think that it will give you good value for money. As a student of psychology, you are studying the most fascinating and complex subject matter in science – human behaviour. You study not just how individuals develop language, perceive visual images, reason, feel, respond to others and learn, but also the biological bases of these behaviours. You will learn about the various methods that psychologists adopt when studying behaviour and how people evolved to do the things that they do (although scientists do have disagreements over the best method of study to adopt – the one certain fact you will learn in psychology is that no finding is ever 'cut and dried', there is always discussion and controversy).

Psychology is one of the most popular degree courses in Europe and in North America – it is the third most popular degree subject in the UK, based on student applications to study. The subject matter is intrinsically interesting and its study allows students to develop what are called, in management-speak, 'transferable skills' – skills such as operating a computer, writing laboratory reports, producing clear and evaluative written work, performing statistical operations, using statistical software packages, designing projects, communicating,

material to an audience ... all of these, in addition to understanding specific aspects of human behaviour such as how children learn to read, why we perceive in the way that we do, how we influence others, how the brain works, how we reason and so on.

The fourth edition – pedagogical features

The fourth edition of *Psychology* continues where the last three editions left off. It is designed to give you a flavour of what modern psychology is about. It describes every major field of psychology and includes up-to-date information and clear evaluation of controversial findings, theories and models in psychology. One of the best ways to learn about psychology is to keep abreast of new developments in the field. As a beginning student, you clearly need to know and understand the basics, but you also need to know how those basic findings are being modified and challenged. As a result, the new edition has over 430 new references, reflecting the extensive nature of the updated content and its emphasis on presenting you with up-to-date information from the psychology research literature (it also reflects how prolific psychologists are).

This fourth edition, like the previous three, has several features to help you understand the applications and controversies in psychology and to make you think more deeply about psychological issues and psychological research. Here's a brief summary:

Conceptual and Historical Issues in Psychological Science

Understanding the history of a discipline and the context in which research emerged is important for any discipline. Throughout the book, at the relevant point, a CHiPS symbol will appear next to the text which will flag up any issues related to a major conceptual or historical milestone in psychology. When you come across one of these icons, pause and think about issues surrounding the topic being described and evaluated.

An International Perspective

Every chapter has a section headed 'An International Perspective', which allows you to see how psychology is, and has been, studied across nations and cultures. An important issue in psychological research is whether findings are universal or specific to a group being studied. If you find that someone behaves in a particular way in one group in one culture or country, would a similar person behave in the same way, under the same conditions in another culture or country? This section provides an international perspective on topics such as

emotion, personality, memory, cannabis use, physical attraction, infidelity, sex bias, language and brain activation, prejudice, eating disorders, mental illness and many others.

MyLab

At various points in the text, you'll find this symbol: 

This will alert you to one of the major interactivities in MyLab, your online course in introductory psychology that helps you test your knowledge and understanding of the material in each chapter. The interactivities come in various forms – multiple choice questions, true or false questions. Most, however, will involve you applying your knowledge and understanding via interactive exercises.

The chapters in MyPsychLab correspond to those in your book. When you are ready to explore the resources for a chapter you will need to log in to MyPsychLab, to the relevant chapter and click on to the study guide. From here, you can watch and work through animations, exercises, interactions, tests and much more to help further and consolidate your understanding.

Cutting Edge

The Cutting Edge feature reviews a recent study or series of studies that are novel, important or make a really significant contribution to our knowledge and understanding of psychology. Some of these include research on: why celebrity worshippers worship (Chapter 1), how stories are more persuasive than statistics (Chapter 2), whether a woman's fertility influences her acceptance of a date (Chapter 3), jealousy and brain activity (Chapter 3), the neurobiological correlates of behaving like James Bond (Chapter 4), predictors of university success (Chapter 7), the effect of chewing gum on memory (Chapter 8), how evening and morning types differ (Chapter 9), the role of the brain in interpreting irony (Chapter 10), the effect of intelligence on wealth and health (Chapter 11), how eBay works (Chapter 11), loneliness and autistic tendency (Chapter 12), how posture influences emotion (Chapter 13), how emotion affects food intake (Chapter 13), whether your email address reflects your personality (Chapter 14), whether different States show different personalities (Chapter 14), whether sexist humour makes us sexist (Chapter 15), how obedience to authority has not changed for decades (Chapter 16), the relationship between ostracism and our perception of our environment (Chapter 16), the relationship between your name and your success (Chapter 16), the role of telomeres in stress (Chapter 17), and the effect of commuting distance on stress (Chapter 17). There are 44 new Cutting Edge sections in this edition.

Controversies in Psychological Science

Each chapter contains at least one section which focuses on a controversy in psychological science. The best advice I was given by one of my tutors as an undergraduate was, 'question everything'. By this, he did not mean criticising studies or theories for the sake of it. He meant that psychology was a live, constantly evolving science

which, like all sciences, progresses by contradiction: somebody reports a finding; another refines this finding by showing that it applies only to certain contexts, people, conditions and so on. Most introductory texts can appear biblical: unquestionable towers of knowledge. But, although a great deal of fact is presented in this text, it also shows you how facts can be interpreted in different ways.

The Controversies in Psychological Science sections are made up of three parts. The first part (the issue) outlines the controversy; the second part (the evidence) describes and evaluates the data that give rise to the controversy; finally, the third part (conclusion) briefly suggests what we can conclude from the evidence available. One aim of the Controversies in Psychological Science sections is to engage you in critical thinking by presenting you with a controversial topic, theme or idea in psychology and take you through evidence for and against a topic, theme or idea. Some of these controversies are well known: Is intelligence racially determined? Can primates learn language? Are psychiatric patients violent? Others are not so well known but cast some light on some aspect of psychology and behaviour: Is psychology common sense? Does the weather influence mood and thinking? Do 'smart' drugs work? Can neuroimaging detect deception? And so on. The material covered in the Controversies sections will give you a hint of the liveliness of debate surrounding some issues in psychology and could form the basis of discussion with your fellow students or with colleagues in tutorials or seminars.

Psychology in Action

Research in psychology is aimed at exploring, defining and predicting the causes of behaviour. Some of it is also aimed at using such research in an applied, practical setting. The Psychology in Action sections review the evidence for the application of psychological principles to a 'real-life' issue: for example, using closed-circuit television (CCTV) to identify criminals; jury decision-making; road traffic accident reduction; the use of brain technology to help the seriously ill to communicate; differences between men and women in the ways they use language, and so on. Chapter 18 on mental disorders is almost a whole PiA section in itself because it describes the study and treatment of mental illness. These sections aim to show you how principles from psychology can be used to help us to understand why we behave in the way that we do.

What you should be able to do after reading the chapter

At the beginning of each chapter there is a brief description about what you should be able to do after reading the chapter. This section provides you with a set of goals that you should try to achieve during the course of reading the chapter. The items in these sections are, in essence, your learning objectives.

Questions to think about

The beginning of each chapter also presents you with a series of questions to think about. The Questions to Think About feature has been designed to help you ask questions about your knowledge of

psychology and to probe what you have learned from the topic you have read. There are further questions for you to think about embedded throughout each chapter.

Chapter reviews

At the end of each chapter there is a summary of the information that has gone before. The summary has been bullet-pointed to make it easy to read and understand.

Glossary

Important terms that are defined in the text and which appear in bold also appear, alphabetically, in a glossary at the end of the book.

Suggestions for further reading

As an intelligent reader of an introductory textbook you will be hungry for more psychological knowledge after having tasted this starter. The suggestions for further reading are designed to satisfy your appetite. All the recommended readings come with comments and these should help you to decide on what further reading is best for you. Some of the reading is quite advanced; other readings are less demanding. You should try to consult at least a few of these per chapter because the further reading will lead you into more detailed description and discussion of psychological topics.

Journals to consult

In addition to the further reading, we have added a list of journals for you to consult. About 90 per cent of the facts, theories and ideas that you read about in this book have been published in science journals and there are many different types of journals in psychology. This is where original research, theories and methods in psychology are published. If you want to go direct to the source of psychological research then journals are the place to go. You might find much of the material in them deeply unattractive, incomprehensible or abstruse. However, you will also find material that is original and new. Textbook

authors are a little like journalists reporting the events and people that they think readers will be interested in. Of course, textbook authors have few of the failings of journalists but they can only give you a brief glimpse of the events that they report. The beauty of psychology is that you can consult the source yourself, and the journals listed should help you do this.

Website addresses

Following the annotated suggested reading, we have included, for each chapter, the internet addresses of some websites which are worth visiting. Some of these give you more information about the general or specific issues raised in the chapter; some provide you with online tutorials, experiments, virtual libraries or bibliographies.

All of these features, together with the extensive revision of the text to make it up-to-date and comprehensive, should provide you with an effective learning tool. To familiarise yourself with these features and how they will benefit your study of this text, they are reproduced and described in the guided tour which follows.

I very much hope that you will learn a lot about psychology from the fourth edition of *Psychology*. I also hope that you enjoy what you learn and that the book will take you to places you had not thought of exploring. This is the beauty of psychology. Opening one door will lead you to several others. If you like what you have read, then please do let me know. One of the joys of teaching and researching is obtaining feedback about the work that you produce. If you have any comment to make or suggestion for improvement, then please write to me, G. Neil Martin, Department of Psychology, School of Health and Social Sciences, Middlesex University, The Burroughs, Hendon, London, NW4 4BT, UK, or email me at: n.martin@mdx.ac.uk. You can also visit my website at: <http://www.mdx.ac.uk/hssc/staff/profiles/academic/martinn.htm>.

*G. Neil Martin, FRSA
London, 2009*

Guided tour

This book is accompanied by **MyPsychLab**, which contains a wealth of interactive learning tools to enrich your experience of the text, including a study plan, multiple choice questions, animations, interactions and questions. Log on to <http://www.mypsychlab.co.uk> and follow the registration instructions inside the access card at the back of this book to access these valuable resources.

Each chapter of **Psychology** begins with an extract introducing you to the topic by using a real world example. **Questions to think about** encourage you to reflect on the key issues in the chapter, while the list of **What you should be able to do** helps you to track your learning as you read. The **MyPsychLab** feature also suggests some of the interactive resources available to support your understanding of these topics. [

Throughout the text you'll see this icon, which indicates that there is a relevant resource in **MyPsychLab** to enable fuller understanding of the topic.

Luck can change your life

Ms V is a compulsive gambler. It wrecked her marriage and drained her wallet long ago. Her kids don't like her because she is always barely scraping by – and borrowing money from them – waiting for the next big win that she hopes will give her all the cash she needs to escape her current mess.

How did it all begin? The answer lies in the schedules of reinforcement. At college, one of her boyfriends liked to bet on the horses and V went along one day. She bet £50 on a filly named Flo and won £300. What a rush! Luck brought her a giant reinforcer without much effort – with no 'down side' in sight. Her boyfriend was excited, too. V saved the money and went back to the track several more times over the next several weeks – sometimes alone, sometimes with her boyfriend – making more £50 bets. Most lost. A few made small wins. But the betting was exciting, and there was lots of sensory stimulation when her horse took one of the front positions.

When V's £300 was about half gone, she bet on a long shot with big odds. No one expected Viceroy to win, but V put down £75 on a hunch. Viceroy... won by a nose. V walked away with £4,500 in her pocket. Early periods of generous reinforcement can have a big effect on our later behavioural decisions.

Source: adapted Baldwin and Baldwin (1998)

WHAT YOU SHOULD BE ABLE TO DO AFTER READING CHAPTER 7

- Describe the concept of habituation and the phenomena of classical conditioning and operant learning.
- Understand the principles underlying classical conditioning.
- Understand the principles underlying operant conditioning.
- Describe and explain conditioned aversions.
- Describe the nature of insight.
- Apply the principles of learning theory to behaviour.
- Describe some of the factors that influence academic learning.

QUESTIONS TO THINK ABOUT

- Do different aspects of learning have different underlying principles? Is learning to ride a bike governed by different principles from those used for learning to find your way around college or university or learning a foreign language?
- Does all learning have to be intentional? Can you learn something without knowing it or without wanting to learn it?
- Is learning a process that depends on innate ability, the ability to adopt successful learning strategies or both?
- What factors do you think enhance and promote the process of learning?
- What psychological factors can enhance (or impair) your academic learning?
- In what way is the brain like a computer (and vice versa)?

Explore the accompanying videos, simulations, and animations on MyPsychLab. This chapter includes activities on: Acquisition of conditioned responses • Stimulus generalisation and stimulus discrimination • Classical conditioning of Little Albert • Schedules of reinforcement • Check your understanding and prepare for your exams using the multiple choice, short answer and essay practice tests also available

Psychology in action – Continued

(a) Leonard Shelby, played by Guy Pearce in the film *Memento*, is one of the few successful cinematic portrayals of amnesia. The most successful, however, appears to be Dory (b), in *Finding Nemo*. Source: (a) Universal Entertainment/The Kobal Collection Ltd; (b) W. Disney/Disney Pixar Features.

sticky strings spurring from his wrists, to cheer for a group of hobbits, to bow an authentic, black-helmeted villain, or to see a boy in spectacles railing on a known in a firing context. Really becomes important, however, if the reality is meant to be accurately portrayed. Dustin Hoffman's character in *Rain Man*, for example, although an extreme example, is an attempt at a serious portrayal of the social debilitation experienced by a person with Asperger's Syndrome. (The man who inspired the Hoffman character appears in Chapter 12.)

The general lesson, however, is this: don't go to the movies expecting to learn much about psychology. In fact, as this section demonstrates, you might as well forget it...

The role of the hippocampus in memory

The hippocampus, like many structures of the brain, is not fully mature at birth. In fact, it is not until a child is 2–3 years old that most of these structures are fully developed. As a result, many cognitive activities, such as the formation of semantic memories, are not particularly well developed until this age (Lisak and Kagan, 2002). One reason that few people remember events that occurred during infancy may be the immaturity of the hippocampus.

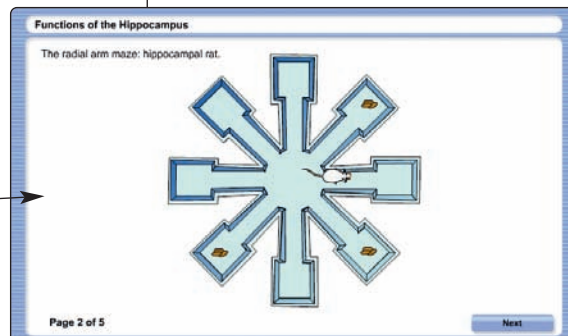

The hippocampus receives information from all association areas of the brain and sends information back to them. In addition, the hippocampus has two-way connections with many regions in the interior of the cerebral hemispheres. Thus, the hippocampal formation is in a position to 'know' – and to influence – what is going on in the rest of the brain (Gluck and Myers, 1995). Presumably, it uses this information to influence the establishment of explicit long-term memories.

The structure appears to be very important for navigating or exploring our way around a spatial environment or in forming representations of the locations of objects (O'Keefe and Nadel, 1978; Morris *et al.* (1982), for example, placed rats in a pool of milky water that contained a platform just underneath the water.

In order to avoid swimming constantly, the rats had to find the platform hidden beneath the milky water.

Eventually, through trial and error, the rats would find the platform. Then, the researchers performed a series of experimental ablations. One group of rats received lesions to the hippocampus, another received lesions to the cerebral cortex and another received no lesion. When the rats were then allowed into the pool, the pattern of behaviour seen in Figure 8.21 was observed. Notice how those rats with the hippocampus lesion had extremely poor navigation compared with the cortex lesion and control group. Similarly, when rats had learned that there was a platform under water and were then allowed to explore the water with the platform removed, those with an intact hippocampus would spend longer in the part of the maze where the platform had been previously positioned. Those rats with hippocampal lesions, however, did not engage in this 'dwelt time' in the quadrant where the platform once was (Gerlai, 2001). This suggests an important role for the hippocampus in spatial learning.

Both rodents and primates show deficits in what has been called spatial memory (Redish and Touretzky, 1997). Spatial memory, the ability to encode and retrieve information about locations and routes is, like memory itself, not a unitary function. Kesckes *et al.* (2001), for example, note that there is a difference between memory

This new edition is richly illustrated with diagrams and photographs.

Psychology in action uses fascinating, real-life examples to show how psychology is applied in the real world.

Cutting edge introduces you to some of the most interesting new subjects of study in contemporary psychology.

An International Perspective allows you to explore global differences in psychological research, attitudes, policies and methods.

To be a true psychologist it is vital to understand the conceptual and historical issues that shape the field. Watch out for this icon as you read, which will help you remember key milestones in the development of psychological science.

Psychology in action – Red light = danger?

According to some anthropologists, the colour red is seen as a sign of dominance in non-human species. Of course, what applies in the animal kingdom does not necessarily apply to the human kingdom. A study from researchers at the University of Durham, UK, however, suggests that it might.

In a novel study, the researchers examined the success and failure of sportsmen and women who wore red or blue costumes (Hill and Barton, 2005). In the 2004 Olympic Games, contestants in the combat sports, boxing, taekwondo, Greco-Roman wrestling and freestyle wrestling, were randomly given either red or blue costumes to wear. When Hill and Barton (2005) analysed the win rate of contestants, those in red costumes won more fights than those in blue costumes.

They then further extended this research by examining the win rate of players in the Euro 2004 international football competition. The performance of five teams that wore red was compared with the performance of the same teams when they

in the sports studied (Blewett et al., 2005). Some have also questioned the bias of the referee. The colour might influence the perception of performance, regardless of actual performance.

In an ingenious test of this hypothesis, Hagemann et al., (2008) asked 42 experienced football referees to watch a videotape of five different sparring competitions. The competitors' heads and trunks were covered in red or blue material. When asked to award points to these competitors, the red ones were given 13 per cent more points (as previous research would predict). Then, and this is the ingenious twist, the experimenters electronically switched the colours of the competitors – the actual competitors remained the same, as did their performance, but the colour they wore changed. When this happened, the points awarded to the red competitors increased. Those who had been given the points in the previous study (and were now dressed in blue) were awarded fewer. These results, according to the authors, suggest 'need a change to the rules (i.e., to forbid red sports attire) and support referees by providing electronic decision making only'.

Does the colour of a team's kit influence their success? Source: Chris Coleman/Newsweek United

women who are yellow and blue; red and green both look yellowish. Figure 5.22 shows one of the figures from a commonly used test for defective colour vision. A person who confuses red and green will not be able to see the '5'.

The most serious defect, called protanopia (literally, 'first-colour defect'), appears to result from a lack of the photoreceptors for red cones. The fact that people with protanopia have relatively normal acuity suggests that

British psychologist Hans Eysenck noted in this chapter's opening quote, most people believe that they are experts in human behaviour. And to some extent we are all lay scientists, of a kind, although generally unreliable ones.

Psychological research, however, frequently contradicts people's assumed expertise as the Controversies section below illustrates.

Cutting edge – How much of a science is psychology?

Psychology is a young science and the discipline has tried hard to earn and demonstrate its scientific spurs. Chemistry, physics or biology seem to have no such problems: their history is testament to their status as a science. A new study, however, suggests that psychology is gaining ground.

Simonton (2004) compared the scientific status of psychology with that of physics, chemistry, sociology and biology. He identified a number of characteristics that typified a general science including:

- the number of theories and laws mentioned in introductory textbooks (the higher the ratio of theory to law, the 'softer' – i.e. less scientific – the discipline);
- publication rate (the more frequent, the more scientific the discipline);
- the appearance of graphs in journal papers (the 'harder' the discipline, the greater the number of graphs);
- the impact made by young researchers (the more scientific the discipline, the greater the agreement that a researcher's contribution is significant);
- how peers evaluated 60 of their colleagues in their own disciplines, and how often single papers are cited (referred to in research papers).

Simonton also looked at other measures of scientific standing: 'lecture diffusivity' (the number of pause words such as 'uh', 'er' and 'um' these are more common in less formal, less structured and less factual disciplines); the extent to which

references in journal articles were recent; the age at which a person received the Nobel prize; and perceived difficulty of the discipline. Simonton combined these measures to provide a composite measure of scientific status.

Based on the first set of indicators, Simonton found that the natural sciences were judged to be more 'scientific' than were the social sciences. Psychology fell right on the mean – at the junction between natural and social sciences, as Figure 1.1 shows. However, psychology's score was much closer to biology than to sociology. The biggest gap in scores was found between psychology and sociology, suggesting that the discipline is closer to its natural science cousins than its social science acquaintances.

Figure 1.1 According to Simonton's study, psychology's scientific status was more similar to that of biology than other disciplines traditionally associated with it, such as sociology. Source: D.R. Simonton, 'Psychology's status as a scientific discipline: its empirical placement within an implied hierarchy of the sciences', *Review of General Psychology*, 2004, 8, 1, p. 65 (Fig. 2).

Suicide – Continued

Suicide attempts in adolescence are associated with heavy or frequent drinking and illegal drug taking (Shaffer and Pfeffer, 2001; Gould et al., 2003). A group of Norwegian researchers monitored the correlation between substance use and suicide in two surveys (in 1992 and 2002) of 23,000 13–19-year-olds

(Rossow et al., 2005). There was a significant relationship between increased substance use and suicide, but only in girls. For boys, the effect of substance use seemed to be less pronounced in 2002 than in 1992. For both sexes, the substance most significantly associated with suicide attempts was alcohol.

Controversies in Psychological Science – Does mobile phone use impair your driving?

The issue

The sale of mobile phones has been one of the marketing successes of the past few years: approximately 1 billion of them were in use worldwide in 2002 and it is estimated that 2.6 billion will be in use by the end of 2009. Mobile phones are portable, convenient and handy. So handy, that people often use them while doing other things. Surveys suggest that around 80 per cent of mobile phone users report having used the device while driving, despite the use of such devices being illegal in many countries (Goodman et al., 1999). In 2003, for example, the UK passed an amendment to the Road Vehicles Act which made it an offence to drive a motor vehicle on a road while using a hand-held telephone (although not hands-free sets). The rationale for the ban is that factors such as holding the phone or dialling a number cause significant distraction and lack of control over the vehicle. Is there scientific evidence for this assumption?

The evidence

Strayer and Johnson (2001) have suggested that it is not the physical handling of mobile phones that leads to accidents but the conversations people have on them. They measured the errors made by drivers in a simulated driving task. These drivers either listened to a radio, listened to a book on tape, performed a word shadowing exercise on a mobile phone, held a conversation on a mobile phone or held a conversation using a hands-free set. The authors cite previous studies that have shown a relationship between phone use and driving accidents. Redelmeier and Tibshirani's study (1997) of the phone records of those involved in driving accidents found that 24 per cent of people used their

A hands-free set causes less distraction than a hand-held phone, when driving, but research suggests that it is the conversation you have that causes distraction.
Source: Corbis/Bettmann

phones within the 30 minutes before the accident. They argued that this rate suggested a danger that was as great as having excess alcohol in your bloodstream. Strayer and Johnson suggest that while the relationship appears causal, there may be other factors, such as the personality and disposition of the drivers, which caused the accident. Furthermore the study did not consider the conversational aspect of telephone use, although a study by Beem and Indman (1995) suggested that holding a simple conversation did not significantly impair the ability to stay on the road.

Strayer and Johnson tested two hypotheses. The peripheral-interference hypothesis attributes driving accidents to non-conversational uses of the mobile phone such as holding and dialling. The attentional hypothesis attributes any driving impairment to the nature of the conversation taking place on the mobile phone.

In their simulated driving experiment, 48 undergraduates used a joystick to operate a cursor which they moved to follow a moving target on a computer screen. The target would move unpredictably, although not suddenly. Sporadically a green or red light would appear. If a green light appeared, the participant was asked to continue; if the red light appeared they were told to press a button which represented the brake on the joystick. The participants either conversed with a confederate on a mobile phone – they discussed President Bill Clinton's potential impeachment, and the Salt Lake City Olympic Committee bribery scandal – or conversed with a hands-free set or listened to a radio broadcast (which they could choose). The researchers found that the probability of missing a red light almost doubled when participants talked on the phone – whether hands-free or hand-held – compared with when they listened to the radio. There was no significant difference in the error rate between the two phone groups. Not only was the miss rate higher in these two groups, they were also slower to respond to the lights, as Figure 9.5 shows. People drove more poorly during the 'talking' portion of the conversation than the 'listening' portion.

To check that participants were listening to the material in the control condition – the authors did not assess this in their first experiment – and to ensure that the control condition was speech rather than music and speech-based, a second experiment required participants to complete the same simulated driving task but one group listened to a book on tape. This group did not perform significantly worse than the phone groups, suggesting that attending to verbal material is not enough to impair driving: active engagement in conversation is necessary for errors to be committed.

Chapter review

Prenatal development

- The three stages of prenatal development span the time between conception and birth. In just nine months, the zygote grows from a single cell, void of human resemblance, into a fully developed foetus, complete with physical features that look much like yours and mine, except in miniature.
- Sex is determined by the sex chromosomes. Male sex organs are produced by the action of a gene on the Y chromosome that causes the gonads to develop into testes.
- The testes secrete androgens, a class of hormones that stimulates the development of male sex organs. If testes are not present, the foetus develops as a female.
- The most important factor in normal foetal development is the mother's nutrition; malnutrition leads to abnormal development and impaired cognition.
- Normal foetal development can be disrupted by the presence of teratogens, chemicals which can cause mental retardation and physical deformities; one teratogen is alcohol – when consumed by a pregnant woman, this may lead to foetal alcohol syndrome.
- There is evidence that the human foetus is capable of discriminating between sensory stimuli while in the womb, suggesting that it is capable of a rudimentary form of cognition.

Physical and perceptual development in infancy and childhood

- A newborn infant's first movements are reflexes that are crucial to its survival. For example, the rooting, sucking and swallow reflexes are important in finding and consuming food.
- Sophisticated movements, such as crawling and standing, develop and are refined through natural maturation and practice.
- A newborn's senses appear to be at least partially functional from birth. However, normal development of the senses, like that of motor abilities, depends on experience.
- The brain appears to develop throughout infancy and adolescence, with myelination being the key characteristic of maturation.
- Because the infant lacks language, most studies of motor or perceptual development examine the child's non-verbal response to stimulation. These responses include movements involving the head, mouth and eyes.
- If an infant is deprived of the opportunity to practise them during a critical period, these skills may fail to develop, which will affect the child's performance as an adult.
- Before the age of 2 years, infants seem to be more concerned with the contours of visual stimuli – a phenomenon called external effect.

Cognitive development in infancy and childhood

- The first step in a child's cognitive development is learning that many events are contingent on its own behaviour. This understanding occurs gradually and is controlled by the development of the nervous system and by increasingly complex interactions with the environment.
- By around 18 months, the infant shows awareness of changes in its environment. By 6 months, it is able to remember temporal order of stimuli. At 8 months, it is able to recognise words spoken in a story that it heard a while before.
- Over the course of development from 1 to 2 years the number of sequences of actions that the child can remember increases.
- Three factors seem to account for the child's ability to recall information better with age: the formation of memory-related structures, the development of language, and the development of metacognition – the realisation that using memory strategies will help the child to think and behave.
- According to Piaget, as children develop they acquire cognitive structures – mental representations or rules that are used for understanding and dealing with the world and for thinking about and solving problems. The two principal types of cognitive structures are schemas (mental representations or sets of rules that define a particular category of behaviour) and concepts (rules that describe properties of environmental events and their relations to other concepts).

Suggestions for further reading

Personality – general reading

- Allen, B. (2004) *Personality Theories: Development, growth and diversity* (5th edn). Harlow: Pearson Education.
- Carver, C.S. and Scheier, M.F. (2001) *Perspectives on Personality* (6th edn). Boston: Allyn & Bacon.
- Cicouret, S.C. (2008) *Theories of Personality* (5th edn). Boston: Prentice Hall.
- Cox, P. and McCus, R.R. (2005) *Personality in Adulthood*. New York: Guilford Press.
- Gregory, R.J. (2007) *Psychological Testing* (5th edn). Boston: Allyn & Bacon.
- Lombardo, G.P. and Fossati, R. (2002) The European origins of 'personality psychology'. *European Psychologist*, 7(2), 143–5.
- Mischel, W. (2004) *Toward an integrative science of the person. Annual Review of Psychology*, 55, 1–22.
- Monte, C.F. and Sordani, R.A. (2005) *Beneath the Mask* (7th edn). Chichester: Wiley.
- Pervin, L.A. (2002) *The Science of Personality*. Oxford: Oxford University Press.

Each of the titles in these two sections is a very good introduction to personality.

New **Controversies in Psychological Science** examine recent reports and beliefs about psychological findings, to help develop your skills in critical analysis.

The extensive **Chapter review** enables you to consolidate what you've just learnt and is a great tool to help you revise.

At the end of each chapter, **Suggestions for further reading, Journals to consult** and **Website addresses** provide links to further sources of information, allowing you to broaden your understanding of the topic and providing a great starting point for your own research.

MyPsychLab walkthrough

Log in to <http://www.mypsychlab.co.uk> to access all the additional learning materials that accompany *Psychology*, Fourth Edition.

Study Plan

The **Study Plan** section of MyPsychLab is a comprehensive self-test and revision centre. When you log in to **MyPsychLab** you can select any chapter and take a ‘pre-test’, to check how well you understand the topics in that chapter. This identifies any areas you need to work on and generates a **personal study plan** to help you learn. You can then take a ‘post-test’ after revising the study materials in more depth, to check your progress. The study plan includes:

- Pre-test and post-test questions
- Learning resources including simulations, animations and video
- ‘Quick review’ revision questions
- eText

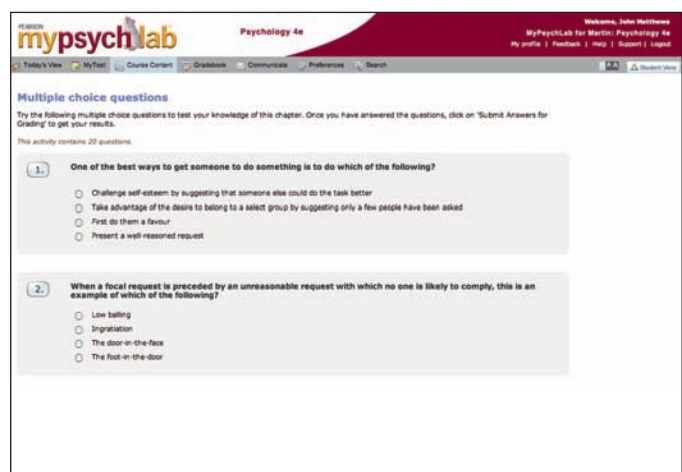

Flashcards are available for all key terms in the book, as well as an easy-to-access online glossary.

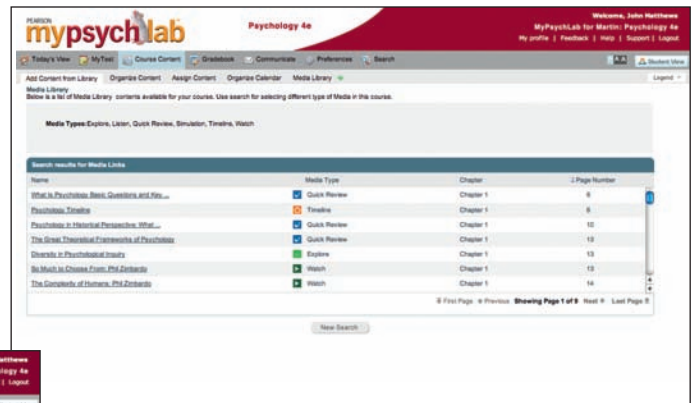

Also accompanying the Fourth Edition of *Psychology* are a range of additional resources to help you learn and revise, such as twice-yearly **research updates** to provide access to the latest psychological literature.

Each chapter contains a large bank of **multiple choice questions** allowing you to test your knowledge of every topic within the book.

Media Library

The MyPsychLab **Media Library** contains a wealth of chapter-specific, rich learning resources to help you assess your knowledge and master key concepts.

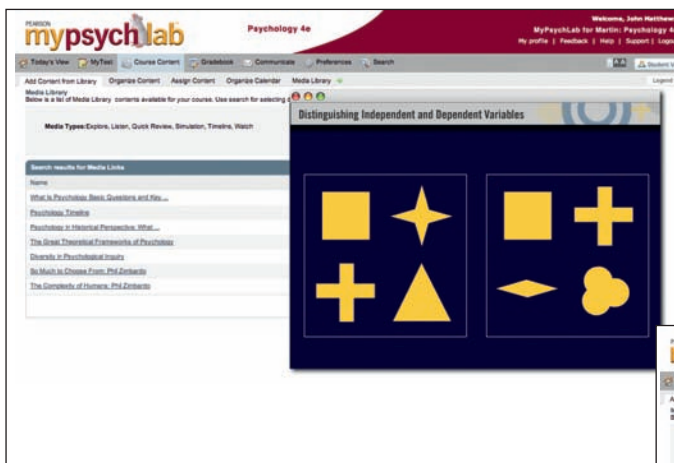

Video

Watch video clips of key experiments and phenomena in psychology and test yourself on what you have observed.

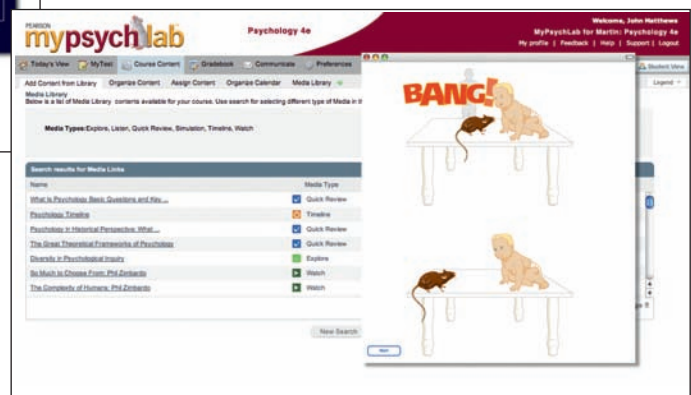

Simulations

Interactive activities that test your understanding in a practical way.

Animations

Fun and interesting animations allow you to watch psychology in action.

The teaching package

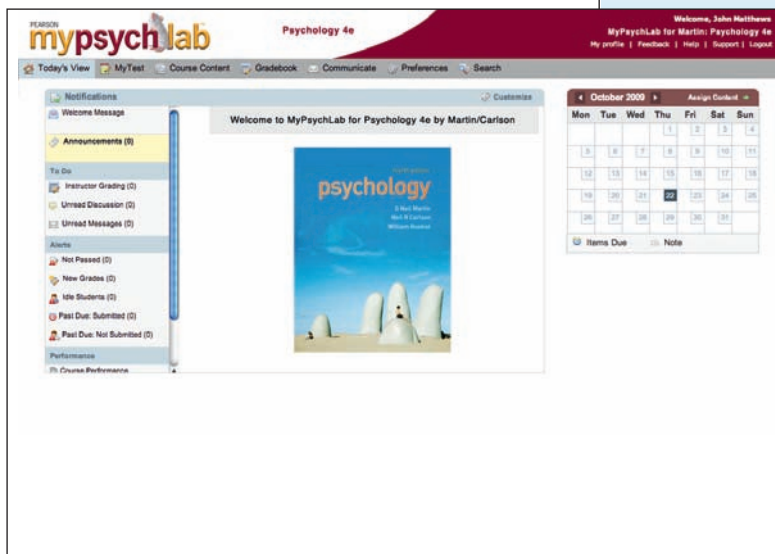

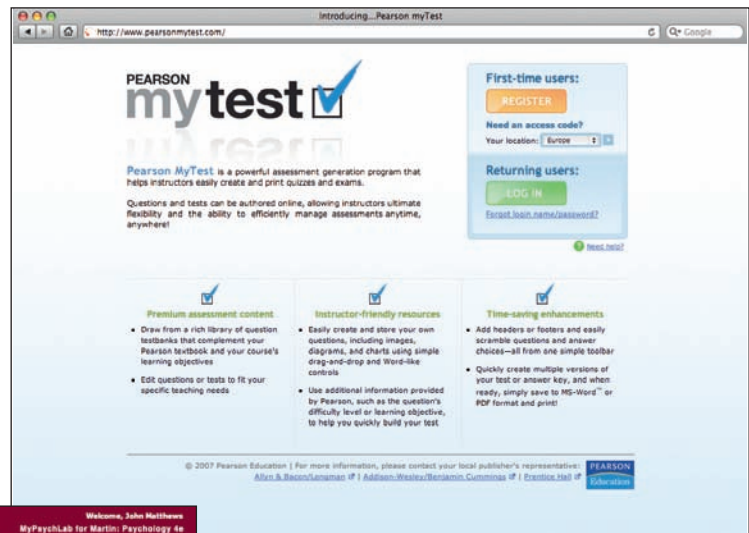

For lecturers a range of supplementary materials is available to help you to plan lectures, create customised tests and set additional, tracked assignments for students. This package includes:

Instructor's Manual

PowerPoint® Slides

MyPsychLab with additional assignments

MyTest testbank

The authors

Dr G. Neil Martin is Reader in Psychology at Middlesex University, UK, a Chartered Scientist, and a Fellow of the Royal Society of Arts. He was educated in Wales, Scotland and England, graduating with a first-class Master of Arts degree in psychology from the University of Aberdeen, where he also won the annual Henry Prize for outstanding undergraduate achievement in psychology. He completed his Ph.D. on psychophysiology and olfactory

perception at the University of Warwick, England.

He is the author of *Psychology – A Beginner's Guide* (Oneworld, 2008); *Human Neuropsychology*, the first European textbook in the field now in its second edition (Pearson Education, 2006); *Essential Biological Psychology* (Hodder Arnold, 2003); *Study Guide – Psychology*, with Nicky Brunswick (Pearson Education, 2005); and the 6th and 7th international editions of *Psychology*, with Neil Carlson and colleagues from the US and Canada (Allyn & Bacon, 2006, 2009). With Nicky Brunswick, he wrote the first European online course in introductory psychology (Pearson Education, 2001, 2003), now in its third edition (Pearson Education, 2006). He is the author of over 150 articles on psychology, has contributed to the *Oxford Companion to Food*, and acts as consultant to industry, business and the media on the psychology of olfaction and humour. He has been an editorial board member of *The Psychologist*, *Journal of Health, Social and Environmental Issues* and the *Annals of Improbable Research* – the satirical journal which awards the annual IgNobel prizes for science that should never be repeated – for which he is also a columnist. He also works as a freelance journalist; his first article for a major national newspaper was entitled 'More than 20 things you needed to know about the nose'.

Dr Neil R. Carlson is Professor of Psychology at the University of Massachusetts, USA. He studied as an undergraduate and postgraduate at the University of Illinois.

He wrote his first textbook, *Physiology of Behavior*, while on sabbatical leave at the University of Victoria in British Columbia. He was the first Allyn & Bacon author to submit a book manuscript on a computer disk.

A few years ago he began to collaborate with Jay Alexander, an artist who works as a laboratory technician at the University of Massachusetts. They prepare all the artwork for Professor Carlson's books.

Dr William Buskist is Professor of Psychology at Auburn University, USA, where he regularly teaches the introductory psychology and the teaching of psychology courses. He has directed Auburn's psychology research laboratories. He also teaches seminars and workshops for undergraduates who are preparing for graduate study in psychology.

He graduated from Brigham Young University in 1981 with a Ph.D. in experimental psychology. Although most of his research has been in the area of human social behaviour, particularly competitive behaviours, Dr Buskist's research now largely focuses on issues in the teaching of psychology.

Dr Michael Hogg is Professor of Social Psychology at Claremont Graduate University, USA, and is a Fellow of the Society for the Psychological Study of Social Issues, the Society for Personality and Social Psychology, and the Academy of the Social Sciences in Australia. He was the foundation director of the Centre for the Study of Group Processes at the University of Queensland, and in 2004 he was a British Academy Visiting Professor at Birmingham University.

Educated at Bristol Grammar School and the University of Birmingham, he received his Ph.D. in 1983 from Bristol University, and has held teaching posts at Bristol University, Macquarie University, the University of Melbourne, the University of Queensland, and Princeton University, and visiting appointments at the University of California, Los Angeles, the University of California, Santa Cruz, the University of California, Santa Barbara, City University, Hong Kong, and the University of Kent, UK.

Michael Hogg's research on group processes, intergroup relations, social identity, and self-conception is closely associated with the development of social identity theory. He has published over 200

scientific books, chapters and articles on these topics. With Graham Vaughan he is the author of *Social Psychology* – one of the leading introductory social psychology texts in Europe and the UK, it was first published in 1995 and is now in its fifth edition. An associate editor of the *Journal of Experimental Social Psychology*, Michael Hogg serves on the editorial board of most of the main social psychology journals, and is foundation co-editor with Dominic Abrams of the journal *Group Processes and Intergroup Relations*, and senior consultant editor for the *Sage Social Psychology Program*. This current research focuses on leadership, deviance, uncertainty reduction, extremism, and subgroup relations. Michael Hogg lives in Los Angeles, but spends substantial time each year in the UK, and in Brisbane, Australia.

Dr Dominic Abrams is Professor of Social Psychology and Director of the Centre for the Study of Group Processes at the University of Kent, Canterbury, UK. He is a Chartered Psychologist, Fellow of the Society for the Psychological Study of Social Issues, and of the Academy of Social Sciences. Following his undergraduate degree at Manchester University and a Masters at the London School of Economics and Political Sciences, he received his Ph.D. in 1984 from the

University of Kent, and held teaching posts at the universities of Bristol and Dundee before returning to Kent in 1989. He has held visiting appointments at the universities of Melbourne, Queensland and Urbana-Champaign, Illinois.

This research on intergroup relations and the self-concept has concentrated on social identity, and spans childhood to old age, and

groups defined by gender, ethnicity, language, faith, sexuality and disability. He has been associate editor for the *British Journal of Social Psychology*, and special issue editor for the *Journal of Community and Applied Psychology* and the *International Journal of Behavioral Development*. He is foundation editor, with Michael Hogg, of *Group Processes and Intergroup Relations*, and serves on the editorial boards of *Journal of Personality and Social Psychology* and the *European Review of Social Psychology*. He has recently been chair of the British Psychological Society Research Board, and now chairs the Joint Committee for Psychology in Higher Education in the UK. His current research focuses on the social psychology of social inclusion and exclusion, societal indices of prejudice, the development of group understanding, and the role of intergroup contact in prejudice reduction.

Dr Nicky Brunswick is Senior Lecturer in Psychology at Middlesex University, UK. She studied for her Ph.D. in the psychophysiology of dyslexia at the University of Warwick and completed her postdoctoral training with Chris and Uta Frith at the Wellcome Department of Cognitive Neurology, Institute of Neurology, London. She researches in the areas of health psychology and developmental dyslexia and her research on reading and dyslexia has appeared in the journals, *Brain*, *Nature Neuroscience* and *Science*. She is the author of *Dyslexia – A Beginner's Guide* (Oneworld, 2009).

Acknowledgements

In the course of writing and revising *Psychology*, I have had the good fortune to call on the expertise and detailed knowledge of a number of people. These include colleagues who reviewed my proposal for a revision of this text, members of Prentice Hall Europe's Special Editorial Board for the first edition of *Psychology*, and my colleagues at Middlesex University and elsewhere. Their contribution is very gratefully acknowledged below. In addition, there are one or two people in particular I would like to thank for contributing to this and previous editions.

From the first and second editions

From Pearson Education, I would like to thank (in chronological order), Christina Wipf-Perry who originally suggested the idea of a European adaptation and who has continued to take an interest in this blossoming pedagogy; Tim Pitts, for his unfailing philosophical outlook; Sue Phillips, development editor for the first edition; Liz Tarrant, production editor for the first edition; Jane Powell, who commissioned the first set of research updates for the website; Matthew Smith, an author's editor; and John Yates, the very tall and charming publisher who helped to launch the first edition. Finally, I would like to thank my current editors and publishers: Ruth Haggerty, Louise Lakey, Karen McLaren and the incomparable Morten Fuglevand. The second edition was written as *Fame Academy* reached its denouement. I would like to thank the inmates, especially Ainslie and David, for many hours of terpsichorean entertainment.

I would like to thank for the following colleagues who either reviewed draft manuscripts or chapters or assisted in the completion of the book in many other invaluable ways.

From the third edition

Thanks, as ever, go to the indomitable Morten Fuglevand who was the guiding hand in this, and other, projects. His influence was enormous. Thanks, too, to Janey Webb for carrying on the Psychology torch, getting the third edition into shape and for assorted treats; Sarah Wild (for all the sterling help with figure queries); Stephen Jeffrey and Nada Jolic (for all the help with MyLab); Robert Chaundy and Jonathan Price for the punctillious copy-editing and proofing; Sarah Busby, Geoff Chatterton, Georgina Clark-Mazo, Nicola Shortt, Alun Swift, Maggie Wells, and the UK and AU marketing teams for all their hard work.

Thanks to the following for all their feedback and advice on the first, second and third editions.

The science of psychology

It appears to be an almost universal belief that anyone is competent to discuss psychological problems, whether he or she has taken the trouble to study the subject or not, and that while everybody's opinion is of equal value, that of the professional psychologist must be excluded at all costs because he might spoil the fun by producing some facts which would completely upset the speculation and the wonderful dream castles so laboriously constructed by the layman.

Explore the accompanying videos, simulations, and animations on MyPsychLab. This chapter includes activities on: Behaviourism • Little Albert • The Skinnerian learning process • Fixed-interval and Fixed-ratio scheduling • Check your understanding and prepare for your exams using the multiple choice, short answer and essay practice tests also available.

WHAT YOU SHOULD BE ABLE TO DO AFTER READING CHAPTER 1

- Define psychology and trace the history of the discipline.
- Be aware of the different methods psychologists use to study behaviour.
- Distinguish between the branches of psychology and describe them.
- Understand what is meant by the 'common-sense' approach to answering questions about psychology and outline its flaws.
- Describe and understand historical developments in psychology such as structuralism, behaviourism and the cognitive revolution.
- Be aware of how psychology developed in Europe and across the world.

QUESTIONS TO THINK ABOUT

- Before you read this chapter, think about your own definition of psychology. Once you have finished reading Chapter 1, see whether your view has changed.
- What types of behaviour do you think a psychologist studies?
- Are there any behaviours that a psychologist cannot or should not study?
- Can psychologists use data from animal experiments to draw meaningful conclusions about human behaviour?
- What do you think psychologists mean when they say they adopt the 'scientific approach'?
- Should psychological research always be carried out to help people?
- Do you think that much of what we know from psychology is 'common sense'? Why?
- Are some psychological phenomena universal, i.e. they appear across nations and cultures?
- How does psychology differ from other disciplines, such as biology, sociology and physics? Which discipline/subjects do you think it is closest to and why?

What is psychology?

If you asked this question of several people, you would probably receive several, very different answers. In fact, if you asked this question of several psychologists, you would still not receive complete agreement on the answer. Psychologists engage in research, teaching, counselling and psychotherapy; they advise industry and government about personnel matters, the design of products, advertising, marketing and legislation; they devise and administer tests of personality, achievement and ability. And yet psychology is a relatively new discipline; the first modern scientific psychology laboratory was established in 1878 and the first person ever to call himself a psychologist was still alive in 1920. In some European universities the discipline of psychology was known as ‘mental philosophy’ – not psychology – even as late as the beginning of the twentieth century.

Psychologists study a wide variety of phenomena, including physiological processes within the nervous system, genetics, environmental events, personality characteristics, human development, mental abilities, health, and social interactions. Because of this diversity, it is rare for a person to be described simply as a psychologist; instead, a psychologist is defined by the sub-area in which they work. For example, an individual who measures and treats psychological disorders is called a clinical psychologist; one who studies child development is called a developmental psychologist; a person who explores the relationship between physiology and behaviour might call themselves a neuropsychologist (if they study the brain) or a biopsychologist/physiological psychologist/psychobiologist (if they study the brain and other bodily processes, such as heart rate). Modern psychology has so many branches that it is often impossible to demonstrate expertise in all of these areas. Consequently, and by necessity, psychologists have a highly detailed knowledge of sub-areas of the discipline and the most common are listed in Table 1.1 on p. 9.

Psychology defined

Psychology is the scientific study of behaviour. The word ‘psychology’ comes from two Greek words, *psukhe*, meaning ‘breath’ or ‘soul’, and *logos*, meaning ‘word’ or ‘reason’. The modern meaning of psycho- is ‘mind’ and the modern meaning of -logy is ‘science’; thus, the word ‘psychology’ literally means ‘the science of the mind’. Early in the development of psychology, people conceived of the mind as an independent, free-floating spirit. Later, they described it as a characteristic of a functioning brain whose ultimate function was to control behaviour. Thus,

the focus turned from the mind, which cannot be directly observed, to behaviour, which can. And because the brain is the organ that both contains the mind and controls behaviour, psychology very soon incorporated the study of the brain.

The study of physical events such as brain activity has made some psychologists question whether the word ‘mind’ has any meaning in the study of behaviour. One view holds that the ‘mind’ is a metaphor for what the brain does; because it is a metaphor it should not be treated as if it actually existed. In his famous book *The Concept of Mind*, the philosopher Gilbert Ryle describes this as the ‘ghost in the machine’ (Ryle, 1949). One might, for example, determine that the personality trait of extroversion exists and people will fall on different points along a dimension from very introvert to very extrovert. But does this mean that this trait really exists? Or is it a label used to make us understand a complex phenomenon in a simpler way? This is called the problem of **reification** in psychology: the assumption that an event or phenomenon is concrete and exists in substance because it is given a name.

The approach adopted by modern psychology is scientific, that is, it adopts the principles and procedures of science to help answer the questions it asks. Psychologists adopt this approach because they believe that it is the most effective way of determining ‘truth’ and ‘falsity’; the scientific method, they argue, incorporates fewer biases and greater rigour than do other methods. Of course, not all approaches in psychology have this rigorous scientific leaning: early theories of personality, for example, did not rely on the scientific method (these are described in Chapter 14). Recent developments in the methodology of psychology have yielded methods that are not considered to be part of the scientific approach: qualitative approaches to human behaviour, for example, reviewed in next chapter.

For the moment, however, consider the value of this approach in psychology. Imagine that you were allowed to answer any psychological question that you might wish to ask: what is the effect of linguistic deprivation on language development, say, or the effect of personality on the stability of romantic relationships? How would you set about answering such questions? What approach do you think would be the best? And how would you ensure that the outcome of your experiment is determined only by those factors you studied and not by any others? These are the types of problem that psychologists face when they design and conduct studies. Sometimes, the results of scientific studies are denounced as ‘common sense’: that they were so obvious as to be not worth the bother of setting up an experiment. The view, however, is generally ill-informed because, as you will discover throughout this book, psychological research frequently contradicts common-sense views. As the late, influential

British psychologist Hans Eysenck noted in this chapter's opening quote, most people believe that they are experts in human behaviour. And to some extent we are all lay scientists, of a kind, although generally unreliable ones.

Psychological research, however, frequently contradicts people's assumed expertise as the Controversies section below illustrates.

Cutting edge – How much of a science is psychology?

Psychology is a young science and the discipline has tried hard to earn and demonstrate its scientific spurs. Chemistry, physics or biology seem to have no such problems: their history is testament to their status as a science. A new study, however, suggests that psychology is gaining ground.

Simonton (2004) compared the scientific status of psychology with that of physics, chemistry, sociology and biology. He identified a number of characteristics that typified a general science including:

- the number of theories and laws mentioned in introductory textbooks (the higher the ratio of theory to law, the 'softer' – i.e. less scientific – the discipline);
- publication rate (the more frequent, the more scientific the discipline);
- the appearance of graphs in journal papers (the 'harder' the discipline, the greater the number of graphs);
- the impact made by young researchers (the more scientific the discipline, the greater the agreement that a researcher's contribution is significant);
- how peers evaluated 60 of their colleagues in their own disciplines, and how often single papers are cited (referred to in research papers).

Simonton also looked at other measures of scientific standing: 'lecture disfluency' (the number of pause words such as 'uh', 'er' and 'um': these are more common in less formal, less structured and less factual disciplines); the extent to which

references in journal articles were recent; the age at which a person received the Nobel prize; and perceived difficulty of the discipline. Simonton combined these measures to provide a composite measure of scientific status.

Based on the first set of indicators, Simonton found that the natural sciences were judged to be more 'scientific' than were the social sciences. Psychology fell right on the mean – at the junction between natural and social sciences, as Figure 1.1 shows. However, psychology's score was much closer to biology than to sociology. The biggest gap in scores was found between psychology and sociology, suggesting that the discipline is closer to its natural science cousins than its social science acquaintances.

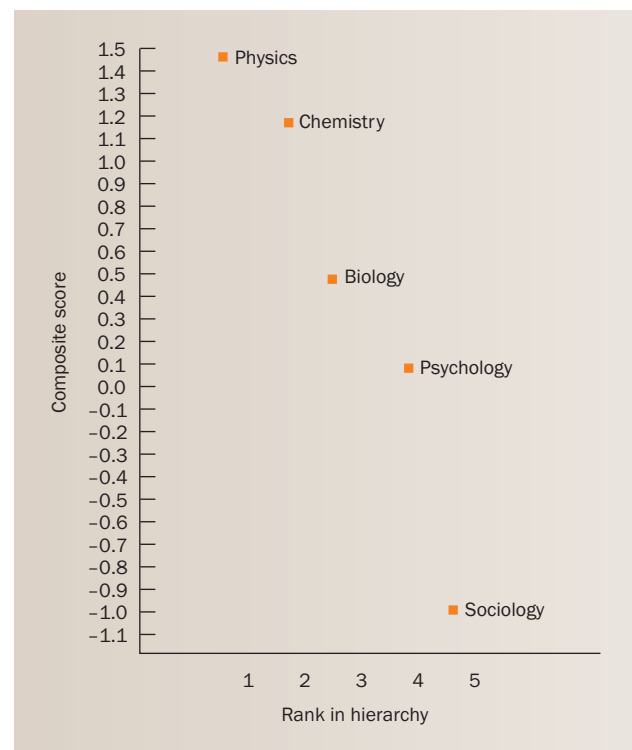

Figure 1.1 According to Simonton's study, psychology's scientific status was more similar to that of biology than other disciplines traditionally associated with it, such as sociology.

Source: D.K. Simonton, 'Psychology's status as a scientific discipline: its empirical placement within an implicit hierarchy of the sciences', *Review of General Psychology*, 2004, 8, 1, p. 65 (Fig. 2).

The stereotypical image of a psychologist (a) and a traditional scientist (b).

Source: (a) Pelaez Inc./Corbis; (b) Tomas de Arno/Alamy Images.

Cutting edge – Continued

A gap also separated chemistry and biology, suggesting that the sciences might be grouped according to three clusters: the physical sciences (chemistry and physics), life sciences (biology and psychology) and social science (sociology).

Simonton concludes with an interesting observation. He argues that psychology's position in this hierarchy does not

really reflect its scientific approach but its subject matter: because the subject matter of psychology can be viewed as not directly controllable or manipulable it may be perceived erroneously, despite its adoption of the scientific method, as neither scientific fish nor fowl.

Controversies in Psychological Science – Is psychology common sense?

The issue

Take a look at the following questions on some familiar psychological topics. See how many you can answer correctly.

- Schizophrenics suffer from a split personality. Is this:
 - true most of the time
 - true some of the time
 - true none of the time, or
 - true only when the schizophrenic is undergoing psychotherapy?
- Under hypnosis, a person will, if asked by a hypnotist:
 - recall past life events with a high degree of accuracy
 - perform physical feats of strength not possible out of hypnosis
 - do (a) and (b), or
 - do neither (a) nor (b)?
- The learning principles applied to birds and fish also apply to:
 - humans
 - cockroaches
 - both (a) and (b), or
 - neither (a) nor (b)?
- Are physically attractive people:
 - more likely to be stable than physically unattractive people
 - equal in psychological stability
 - likely to be less psychologically stable, or
 - likely to be much more unstable?

How well do you think you did? In a study published in 1997, these four questions featured in the ten most difficult questions answered by first-year psychology undergraduates who completed a 38-item questionnaire about psychological knowledge (Martin *et al.*, 1997). In fact, when the responses from first- and final-year psychology, engineering, sociology,

English and business studies students were analysed, no one group scored more than 50 per cent correct. Perhaps not surprisingly, psychologists did significantly better than the other students, with sociologists following close behind. Why should psychology (and other) students perform so badly on a test of psychological knowledge?

The answer lies in the fact that the questionnaire was not really a test of psychological knowledge but of common-sense attitudes towards psychological research. Common-sense mistakes are those committed when a person chooses what they think is the obvious answer but this answer is incorrect. Some writers suggested that 'a great many of psychology's basic principles are self-evident' (Houston, 1983), and that 'much of what psychology textbooks purport to teach undergraduates about research findings in the area may already be known to them through common, informal experiences' (Barnett, 1986). Houston reported that although introductory psychology students answered 15 out of 21 questions about 'memory and learning' correctly, a collection of 50 individuals found in a city park on a Friday afternoon scored an average of 16. The 21 December 2008 edition of *The Sunday Times* featured a full-page article, boldly headed 'University of the bleeding obvious', in which the journalist bemoaned what he perceived to be the triviality of (mostly) behavioural research. 'Why are we,' asked the journalist or his sub-editor, 'deluged with academic research "proving" things that we know already?', citing a string of seemingly irritating, self-evident *bons mots* from various university departments.

Is the common-sense view of psychological research, justified?

The evidence

Not quite. Since the late 1970s, a number of studies have examined individuals' false beliefs about psychology, and students' beliefs in particular. Over 76 per cent of first-year psychology students thought the following statements were true: 'Memory can be likened to a storage chest in the brain into which we deposit

Controversies in Psychological Science – *Continued*

material and from which we can withdraw later', 'Personality tests reveal your basic motives, including those you may not be aware of', and 'Blind people have unusually sensitive organs of touch'. This, despite the fact that course materials directly contradicted some of these statements (Vaughan, 1977).

Furnham (1992, 1993) found that only half of such 'common-sense' questions were answered correctly by 250 prospective psychology students, and only 20 per cent of questions were answered correctly by half or more of a sample of 110 first-year psychology, fine arts, biochemistry and engineering students. In Martin *et al.*'s (1997) study, final-year students answered more questions correctly than did first-year students but there was no significant difference between first- and final-year psychology students. This suggests that misperceptions are slowly dispelled after students undergo the process of higher education and learning, but that studying specific disciplines does nothing to dispel these myths effectively. This is just one explanation.

What, then, is 'common' about 'common sense'? Some have likened common sense to fantastical thinking. This describes ways of reasoning about the world that violate known scientific principles (Woolley, 1997). For example, the beliefs that women can control breast cancer by positive thinking (Taylor, 1983), that walking under a ladder brings bad luck and that touching wood brings good luck (Blum and Blum, 1974) violate known physical laws, but people still believe in doing such things. People often draw erroneous conclusions about psychological knowledge because they rely on small sets of data, sometimes a very small set of data (such as a story in a newspaper or the behaviour of a friend). Take the relationship between a mental disorder such as schizophrenia and murders committed by schizophrenic patients, for example.

Despite the small number of murders committed by schizophrenic patients, the few cases which do receive media attention suggest that people with schizophrenia are uncon-

trollable murderers who should be put out of harm's way (the role of the media in promoting psychology is returned to in the next chapter). As you will see from the chapter on abnormal psychology (Chapter 18) this thinking is blatantly perverse: the majority of schizophrenic individuals will not cause harm to others. It is an example of what social psychologists call the 'under-utilisation of base rate information' (Fiske and Taylor, 1991; you will find more about this in Chapters 11, 15 and 16). It means that individual, vivid, single or a small number of examples are taken to represent the behaviour of an entire group. The base rate information (the actual incidence of behaviour in such groups in general), however, contradicts these single, vivid examples but is either ignored or dismissed. A similar process may be operating when people misperceive some aspects of psychology. Psychologists have discovered that two determinants of fantastical thinking are lack of information and an inability to explain behaviour. It seems likely that these factors could underpin misperceptions about psychology.

Conclusion

As you work through your psychology course and through this book, discovering new and sometimes complicated ways of analysing and understanding human behaviour, you will realise that many of the beliefs and perceptions you held about certain aspects of psychology are false or only half right. Of course, no science is truly infallible and there are different ways of approaching psychological problems (and perhaps, sometimes, some problems are insoluble or we have no good method of studying them satisfactorily). Psychology, however, attempts to adopt the best of scientific approaches to understanding potentially the most unmanageable of subject matter: behaviour. And, for those of you who were wondering, the answers to the questions at the start of the box are c, d, c and a.

Explaining behaviour

The ultimate goals of research in psychology are to understand, predict and change human behaviour: to explain why people do what they do. Different kinds of psychologists are interested in different kinds of behaviour and different levels of explanation. Not all psychologists study humans; some conduct research using laboratory animals or study the behaviour of wild animals in their natural habitat. Research using animals has provided many insights into the factors that affect human behaviour, such as the effect of sensory deprivation on the development of the senses.

How do psychologists 'explain' behaviour? First, they must describe it accurately and comprehensively. We must become familiar with the things that people (or other animals) do. We must learn how to categorise and measure behaviour so that we can be sure that different psychologists in different places are observing the same phenomena. Next, we must discover the causes of the behaviour we observe – those events responsible for its occurrence. If we can discover the events that caused the behaviour to occur, we have 'explained' it. Events that cause other events (including behaviour) to occur are called **causal events** or **determinants**.

For example, one psychologist might be interested in visual perception and another might be interested in romantic attraction. Even when they are interested in the same behaviour, different psychologists might study different levels of analysis. Some look inside the organism in a literal sense, seeking physiological causes, such as the activity of nerve cells or the secretions of glands. Others look inside the organism in a metaphorical sense, explaining behaviour in terms of hypothetical mental states, such as anger, fear, curiosity or love. Still others look only for events in the environment (including things that other people do) that cause behaviours to occur.

Established and emerging fields of psychology

Throughout this book you will encounter many types of psychologist and many types of psychology. As you have already seen, very few individuals call themselves psychologists, rather they describe themselves by their specialism – cognitive psychologist, developmental psychologist, social psychologist, and so on. Before describing and defining each branch of psychology however, it is important to distinguish between three general terms: psychology, **psychiatry** and **psychoanalysis**. A psychologist normally holds a university degree in a behaviour-related discipline (such as psychology, zoology, cognitive science) and usually possesses a higher research degree (a Ph.D. or doctorate) if they are teaching or a researcher.

Those not researching but working in applied settings such as hospitals or schools may have other, different qualifications that enable them to practise in those environments. Psychiatrists are physicians who have specialised in the causes and treatment of mental disorder. They are medically qualified (unlike psychologists, who nonetheless do study medical problems and undertake biological research) and have the ability to prescribe medication (which psychologists do not). Much of the work done by psychologists in psychiatric settings is similar to that of the psychiatrist, implementing psychological interventions for patients with mental illness. Psychoanalysts are specific types of counsellor who attempt to understand mental disorder by reference to the workings of the unconscious. There is no formal academic qualification necessary to become a psychoanalyst and, as the definition implies, they deal with a limited range of behaviour.

Most research psychologists are employed by colleges or universities, by private organisations or by government. Research psychologists differ from one another in two principal ways: in the types of behaviour they investigate and in the causal events they analyse. That is, they explain different types of behaviour, and they explain them in

terms of different types of cause. For example, two psychologists might both be interested in memory, but they might attempt to explain memory in terms of different causal events – one may focus on physiological events (such as the activation of the brain during memory retrieval) whereas the other may focus on environmental events (such as the effect of noise level on task performance). Professional societies such as the American Psychological Association and the British Psychological Society have numerous subdivisions representing members with an interest in a specific aspect of psychology. This section outlines some of the major branches or subdivisions of psychology. A summary of these can be found in Table 1.1.

Psychobiology/biological psychology is the study of the biological basis of behaviour (G. N. Martin, 2003). Other terms for the same branch include physiological psychology and biopsychology. It investigates the causal events in an organism's physiology, especially in the nervous system and its interaction with glands that secrete hormones. Psychobiologists study almost all behavioural phenomena that can be observed in non-human animals, including learning, memory, sensory processes, emotional behaviour, motivation, sexual behaviour and sleep, using a variety of techniques described in Chapter 4.

Psychophysiology is the measurement of people's physiological reactions, such as heart rate, blood pressure, electrical resistance of the skin, muscle tension and electrical activity of the brain (Andreassi, 2001). These measurements provide an indication of a person's degree of arousal or relaxation. Most psychophysiologicalists investigate phenomena such as sensory and perceptual responses, sleep, stress, thinking, reasoning and emotion.

Neuropsychology and **neuroscience** examine the relationship between the brain and spinal cord, and behaviour (Martin, 2006). Neuropsychology helps to shed light on the role of these structures in movement, vision, hearing, tasting, sleeping, smelling and touching as well as emotion, thinking, language and object recognition and perception, and others. Neuropsychologists normally (but not always) study patients who have suffered injury to the brain – through accident or disease – which disrupts functions such as speech production or comprehension, object recognition, visual or auditory perception, and so on. **Clinical neuropsychology** involves the identification and treatment of problems arising from nervous system disorders and injuries. Clinical neuropsychologists typically work in a hospital and collaborate closely with neurologists (physicians who specialise in diseases of the nervous system), although some teach or work in private practice.

Modern neuropsychology also relies on sophisticated brain imaging techniques such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) which allow researchers to monitor the activity of the brains of individuals while they perform some psycho-

Table 1.1 The major branches of psychology

Branch	Subject of study
Psychobiology/Biological psychology	Biological basis of behaviour
Psychophysiology	Psychophysiological responses such as heart rate, galvanic skin response and brain electrical activity
Neuropsychology	Relationship between brain activity/structure and function
Comparative psychology	Behaviour of species in terms of evolution and adaptation
Ethology	Animal behaviour in natural environments
Sociobiology	Social behaviour in terms of biological inheritance and evolution
Behaviour genetics	Degree of influence of genetics and environment on psychological factors
Cognitive psychology	Mental processes and complex behaviour
Cognitive neuroscience	Brain's involvement in mental processes
Developmental psychology	Physical, cognitive, social and emotional development from birth to senescence
Social psychology	Individuals' and groups' behaviour
Individual differences	Temperament and characteristics of individuals and their effects on behaviour
Cross-cultural psychology	Impact of culture on behaviour
Cultural psychology	Variability of behaviour within cultures
Forensic and criminological psychology	Behaviour in the context of crime and the law
Clinical psychology	Causes and treatment of mental disorder and problems of adjustment
Health psychology	Impact of lifestyle and stress on health and illness
Educational psychology	Social, cognitive and emotional development of children in the context of schooling
Consumer psychology	Motivation, perception and cognition in consumers
Organisational or occupational psychology	Behaviour of groups and individuals in the workplace
Ergonomics	Ways in which humans and machines work together
Sport and exercise psychology	The effects of psychological variables on sport and exercise performance, and vice versa

logical task. This approach combines two approaches in psychology: neuroscience and cognitive psychology (see below). Because of this, the area of study is sometimes described as **cognitive neuroscience** (Gazzaniga, 1995) or behavioural neuroscience. A new development in this area has been the study of the psychobiological processes involved in social behaviour, a sub-branch called social neuroscience. Social neuroscientists examine the role of the brain in behaviours such as empathy, turn-taking, seeing things from another person's point of view, social interaction, political outlook, and so on. We look at the work of cognitive/behavioural/social neuroscientists in more detail in Chapter 4 and throughout this book.

Comparative psychology is the study of the behaviour of members of a variety of species in an attempt to explain behaviour in terms of evolutionary adaptation to the environment. Comparative psychologists study behavioural phenomena similar to those studied by physiological psychologists. They are more likely than most other psychologists to study inherited behavioural patterns, such as courting and mating, predation and aggression, defensive behaviours and parental behaviours.

Closely tied to comparative psychology is **ethology**, the study of the biological basis of behaviour in the context of the evolution of development and function. Ethologists usually make their observations based on studies of animal behaviour in natural conditions and investigate topics such as instinct, social and sexual behaviour and cooperation. A sub-discipline of ethology is **sociobiology** which attempts to explain social behaviour in terms of biological inheritance and evolution. Ethology and sociobiology are described in more detail in Chapter 3, as is evolutionary psychology (an approach which interprets behaviour in terms of evolution).

Behaviour genetics is the branch of psychology that studies the role of genetics in behaviour (Plomin and DeFries, 1998). The genes we inherit from our parents include a blueprint for the construction of a human brain. Each blueprint is a little different, which means that no two brains are exactly alike. Therefore, no two people will act exactly alike, even in an identical situation. Behaviour geneticists study the role of genetics in behaviour by examining similarities in physical and behavioural characteristics of blood relatives, whose genes are more similar

than those of unrelated individuals. They also perform breeding experiments with laboratory animals to see what aspects of behaviour can be transmitted to an animal's offspring. Of course, genetic differences are only one of the causes of individual differences. People have different experiences, too, and these experiences will affect their behaviour. Behavioural geneticists study the degree to which genetics are responsible for specific behaviours such as cognitive ability. We examine the work of behavioural geneticists in Chapter 3 and evaluate the contribution of this research to the study of intelligence (in Chapter 11 (and to other topics, such as personality) and throughout the book).

Cognitive psychology is the study of mental processes and complex behaviours such as perception, attention, learning, memory, concept formation and problem-solving (Eysenck and Keane, 1995). To cognitive psychologists, the events that cause behaviour consist of functions of the human brain that occur in response to environmental events. Their explanations involve characteristics of inferred mental processes, such as imagery, attention, and mechanisms of language. Most cognitive psychologists do not study physiological mechanisms, but recently some have begun collaborating with neurologists and other professionals who utilise neuroimaging. A branch of cognitive psychology involves the modelling of human function using computer simulation or 'neural networks'; this is called **cognitive science** and we briefly

examine the contribution of such computer simulations to our understanding of behaviour in Chapters 7 and 10.

Developmental psychology is the study of physical, cognitive, emotional and social development, especially of children (Berk, 2009) but, more broadly, of humans from foetus to death (these psychologists are sometimes called lifespan developmental psychologists). Some developmental psychologists study the effects of ageing on behaviour and the body (a field called gerontology). Most developmental psychologists restrict their study to a particular period of development, such as infancy, adolescence or old age. This field is described and illustrated in more detail in Chapter 12. The development of children's language is described in Chapter 10, and the effects of ageing on cognitive performance are reviewed in Chapter 11.

Social psychology is the study of the effects of people on people. Social psychologists explore phenomena such as self-perception and the perception of others, cause-and-effect relations in human interactions, attitudes and opinions, interpersonal relationships, group dynamics, and emotional behaviours, including aggression and sexual attraction (Hogg and Vaughan, 2007). Chapters 15 and 16 explore these issues and themes in social psychology and the Psychology in Action section here describes some of the recent, counter-intuitive findings from studies of a behaviour that is perennially fascinating but which also has serious consequences: lying.

Psychology in action – How to detect a liar

Take a look at the following behaviours? Which do you think are characteristic of a person who is lying. Think about the reasons for your choices.

- Averting gaze
- Unnatural posture
- Posture change
- Scratching/touching parts of the body
- Playing with hair or objects
- Placing the hand over the mouth
- Placing the hand over the eyes

Which of these did you think predicted lying? According to a standard manual of police interviewing, these features are all characteristic of a liar (Inbau *et al.*, 1986). A study of participants in 75 countries found that 'averting gaze' was described as the best tell-tale sign of lying (Global Deception Research Team, 2006).

Unfortunately, despite the manual's exhortations and the international guesswork, none of these behaviours is actually reliably associated with deception and several studies have shown that general law enforcement officers are usually as poor as the average undergraduate at detecting truth and fal-

sity. Research by psychologists such as Aldert Vrij, for example, has highlighted how bad people are at detecting whether someone is telling the truth or is lying (Vrij, 2000, 2004b). However, it has also identified behaviours which are reliably associated with lying and suggests that the best way of detecting deception is to do so indirectly.

Studies of police officers' and students' ability to detect deception, all report detection rates of between 40 and 60 per cent – a result no better than we would expect by chance (Vrij and Mann, 2001; Vrij, 2000; DePaulo and Pfeifer, 1986). Police officers and people who operate polygraphs – the so-called lie detector which measures skin conductance responses – generally do no better than students (Ekman and O'Sullivan, 1991). The exception to this generally ignominious performance seems to be Secret Service agents – police officers specifically trained to be sensitive to behaviour during interviewing, and criminals (Ekman *et al.*, 1999). These groups tend to perform better than students and general law enforcement officers.

Perhaps the best detectors of dissembling would be those who routinely lie in order to get out of trouble. Researchers from the University of Goteborg, Sweden (Hartwig *et al.*, 2004) found that criminals were significantly better than students at

Psychology in action – *Continued*

These are images of former American President Bill Clinton, British novelist Jeffrey Archer and former American President Richard Nixon. What features might have revealed that they were lying? Clinton claimed not to have had sexual relations with his intern, Monica Lewinsky, Jeffrey Archer was convicted of perjury, and Richard Nixon authorised but denied the tapping of 17 government officials' and reporters' telephones and those of opponents at the Democratic National Committee headquarters at the Watergate apartments.

Source: PA Photos.

detecting liars. However, this finding was coloured by another – the criminals also detected fewer truth-tellers. The lie bias – that criminals are more likely to judge that someone is lying than telling the truth – might stem from the fact that criminals are naturally suspicious (because they are used to being lied to, whether in prison or in the context of their relationships with others) and because they themselves are practised liars (and, therefore, expect the worst of others).

In another study, adult male offenders from a medium security Canadian prison and a group of undergraduates were asked to recall four emotional events from their lives (Porter *et al.*, 2008) but lie about two of them. The researchers measured the number of illustrators (the use of hands to signify something), self-manipulations (touching/scratching the hand, head or body), frequency of head movement and number of smiles and laughs. Verbal indicators were number of words spoken per minute, filled pauses ('umms' and 'ahs'), self-references and pauses longer than two seconds. Illustrators were higher when lying than not telling the truth in both groups. Offenders, however, used more self-manipulations when lying compared with non-offenders, a finding that seems to contradict previous studies. The authors suggest that this may be due to the specific context in which experiments take place, the type of lie, motivation, the consequences of the lie, and so on. The offenders also smiled less than the students when lying about emotional events.

Of course, deception studies are fairly artificial: they usually involve participants watching a videotape of a person, and basing their judgement about the person's truthfulness on

these data. Interviewing suspects, the police would argue, gives you much more information on which to base a judgement. Sadly, research does not support this view. Studies have shown that observers of an interview are better at discriminating between truth-tellers and liars than are the interviewers themselves (Buller *et al.*, 1991; Granhag and Stromwall, 2001). The interviewers also showed evidence of truth bias – the tendency to declare that someone was saying the truth when they were not. People tend to focus on different behavioural cues when deciding on whether a person is telling the truth or lying, with people relying on verbal cues when judging the truthfulness of a story and on non-verbal cues when the story is deceptive (Anderson *et al.*, 1999).

What, therefore, signals that lying is taking place? Two of the most fairly reliable indicators appear to be a high-pitched voice and a decrease in hand movements. People are also better at identifying deception accurately if they are asked about it indirectly. For example, people are less accurate when asked, 'Is this person lying?' than when asked 'Does the person x sincerely like the person y?' (Vrij, 2001). When people are questioned indirectly they tend to focus on those behavioural cues that have been found to predict deception, such as decreased hand movement, rather than those that do not (Vrij, 2001).

New research on lying is presenting us with some counter-intuitive and challenging findings about psychology and human behaviour. Often as you saw in the Controversies in Psychological Science section earlier, these studies contradict 'received wisdom' and 'common sense'.

Individual differences is an area of psychology which examines individual differences in temperament and patterns of behaviour. The primary focus of individual differences research is on how large groups can be further subdivided into more meaningful groups. For example, instead of examining a group's response to the effect of mild alcohol intake on task performance, a psychologist might decide to examine differences between men and women or people who are extraverted or introverted. Some examples of individual differences studied by psychologists include personality, intelligence, hand preference, sex and age. (The Cutting Edge section below looks at the role of personality in a behaviour that some have associated with mental ill-health: celebrity worship.)

Cross-cultural psychology is the study of the impact of culture on behaviour (Segall *et al.*, 1998). The ancestors of people of different racial and ethnic groups lived in different environments which presented them with different problems and opportunities for solving those problems. Different cultures have, therefore, developed different strategies for adapting to their environments. These strategies show themselves in laws, customs, myths, religious beliefs and ethical principles as well as in thinking, health beliefs and approaches to problem-solving.

In each chapter of the book, you'll find a section entitled, '... An international perspective'. This takes a topic in psychology and examines how it has been studied cross-culturally, e.g. Are personality traits universal?, Is the recognition of emotion culture-specific?, Do culture-specific mental illnesses exist?, and so on. But throughout every chapter, you will discover how studies from research laboratories and centres across the world have contributed to our understanding of behaviour.

A similar – but different – term, **cultural psychology**, has been used to describe the study of variations within cultures (not necessarily across cultures). The assumption in cultural psychology is that cultures, and their processes and contents, are variable and not universal (Miller, 1997).

Forensic and criminological psychology applies psychological knowledge to the understanding, prediction and nature of crime and behaviour related to crime. There is a distinction between criminological and forensic psychology. Forensic psychologists can be commissioned by courts to prepare reports on the fitness of a defendant to stand trial, on the general psychological state of the defendant, on aspects of psychological research (such as post-traumatic stress disorders), on the behaviour of children involved in custody disputes and so on. Criminological psychology refers to the application of psychological principles to the criminal justice system (Blackburn, 1996). The terms, however, are often used interchangeably. One example of the way in which criminological psychologists can apply their research to crime is in the study of eyewitness testimony. Eyewitness testi-

mony is a highly unreliable source of information and psychologists have helped show how flawed this method of memory retrieval is and have suggested alternative methods of prompting witnesses' memory of crime. We examine some of these methods in Chapter 8.

The Psychology in Action section below also shows you some of the ways in which the work of psychologists has been useful to the criminal justice system, either by improving police detection techniques or by advising on the reliability of testimony. Many psychologists' work can help to solve or understand pressing human problems such as drug and alcohol abuse, stress, susceptibility to illness, mental disorder, developmental disorders, work inefficiency, witness memory, eyewitness testimony, crowd control and so on.

Clinical psychology 'aims to reduce psychological distress and to enhance and promote psychological well-being by the systematic application of knowledge derived from psychological theory and data' (BPS Division of Clinical Psychology, 2001). It is an applied branch of psychology because clinical psychologists do not work in the laboratory under well-controlled experimental conditions but out in the field, applying the knowledge gained from practice and research. Most clinical psychologists are specially trained practitioners who attempt to assess and treat people's psychological problems.

The remainder represent scientists who investigate a wide variety of causal events, including genetic factors, physiological factors and environmental factors such as parental upbringing, interactions with siblings and other social stimuli. Clinical psychologists can work in private practice (on their own or as part of a joint practice), in hospitals and mental health clinics, as part of government services, in work organisations, and sometimes as lecturers in colleges and universities. Chapter 18 describes some of the problems seen by clinical psychologists.

Perhaps two of the greatest bugbears for psychologists have been the misrepresentation of research and the inaccurate reporting of research, such as the portrayal of mental illness. A research team from the University of Auckland, New Zealand, for example, analysed a week's worth of children's programmes on two television stations to see how mental illness was portrayed (Wilson *et al.*, 2000). Forty-six different programmes were analysed representing 128 different episodes: 60 per cent were made in the USA and over 80 per cent were cartoon animations. Characters were defined as mentally ill if they were referred to by other characters as having a mental illness.

Of the 128 episodes, over 45 per cent contained reference to mental illness. Most of these programmes were cartoons. The most common terms for mental illness were 'crazy', 'mad' and 'losing your mind', although 'mad' and 'crazy' were interchangeably used to mean 'angry'. Other terms included 'driven bananas', 'wacko', 'nuts', 'loony',

Cutting edge – I'm your biggest fan... What makes a celebrity worshipper worship?

Shakespeare, in his day, probably had fans whose responses were a little overenthusiastic, but the explosion of media available in the twenty-first century means that people can now gorge themselves on as much information about their favourite celebrities as they want. According to research, fans (or 'celebrity worshippers') tend to be adolescents or young adults and enjoy 'game-playing' in romantic relationships. They appear to be no more or less shy or lonely than is normal but their degree of worship has been associated with psychological disorder. Some fans can cross the conventional line between worshipping at a distance and becoming overly-obsessed by their idol.

Maltby, McCutcheon and their colleagues have described celebrity worship as having three components (Maltby *et al.*, 2001; McCutcheon *et al.*, 2002). Low levels of worship are characterised as having entertainment-social value (e.g. 'My friends and I like to discuss what my favourite celebrity has done'). Intermediate levels are expressed in attitudes such as 'I

consider my favourite celebrity to be my soul mate' (intense-personal value). Extreme levels, called borderline-pathological, are expressed in views such as 'If I were lucky enough to meet my celebrity, and he/she asked me to do something illegal as a favour, I would probably do it'. Those expressing low levels of worship tend to be extravert (sociable, lively, active, etc.), those expressing intermediate levels tend to be neurotic (tense, moody, emotional), and those showing evidence of borderline-pathological attitudes express some of the traits seen in the psychoticism scale, such as impulsivity and antisocial behaviour (Maltby *et al.*, 2003).

In a study of the relationship between celebrity worship, personality and mental health, Maltby *et al.* (2004) found that in their sample of over 350 participants, 15 per cent were classified as expressing entertainment-social attitudes; 55 per cent expressed intense-personal attitudes; and 1 per cent expressed pathological attitudes. The researchers found that, as predicted in their previous study, the three levels of

The two faces of celebrity. Mark Chapman was obsessed with J.D. Salinger's *The Catcher in the Rye* and assassinated former Beatle John Lennon outside the Dakota Hotel in New York. In 2002, Japanese businessman Masahiko Shizawa was issued with a restraining order because he was 'abnormally obsessed' with Britney Spears.

Cutting edge – Continued

worship were significantly correlated with personality type. Celebrity worshippers who followed their idols for entertainment or social reasons were extravert, sought information and support and were open in showing their emotions. Those who followed their idols for intense or personal reasons were neurotic. Those at the extreme end were more likely to use humour to cope with life, to use drink and drugs and to be non-religious.

Surprisingly, only one level of worship was associated with mental health problems. Those celebrity worshipping for intense-personal reasons had poorer general health (depression, anxiety and social dysfunction), expressed more negative affect (stress and low life satisfaction) and did not cope effectively with everyday life events. The researchers suggest that these problems may be underpinned by personality style (neuroticism) – one that reflects a disengagement from life.

‘cuckoo’ and ‘freak’. Mental illness was frequently portrayed as reflecting a loss of control. Characters at the receiving end of these epithets were routinely and invariably seen as negative, as objects of amusement or derision or as objects of fear. The characters were either comical or villainous. You’ll see in the last chapter how psychologists have identified views such as these and proposed ways of changing them.

Psychology in action – Psychology in the witness box

Recent years have seen a surge of interest in forensic or criminological psychology. Forensic psychology refers to the branch of psychology which involves the ‘collection, examination and presentation of evidence for judicial purposes’ (Haward, 1981; Blackburn, 1996). The British Psychological Society has its own division of criminological and legal psychology and a European Association for Psychology and Law has been established (Blackburn, 1996). Several popular accounts of the forensic psychologist’s work have been published (for example, Canter, 1994; Britton, 1997) and the day-to-day work of the profession has been fictionalised (not entirely accurately) in programmes and films such as *Criminal Minds*, *Cracker*, *The Silence of the Lambs* and *Hannibal*.

The application of psychology to law, however, is a recent phenomenon. The first psychologist to give expert testimony in court was the German Albert Schrenk-Notzing in 1896. Schrenk-Notzing became involved in the trial of a Munich man accused of murdering three women (Bartol and Bartol, 1987). His contribution helped the court to understand the concept of retroactive memory falsification – the confusion that arises between what witnesses say they saw and what actually happened. A little later, in the USA, the advice of Hugo Munsterberg, one of the pioneers of forensic psychology, was sought in two murder trials (Colman, 1995). His work on the reaction time between rifle shots was cited in the case relating to the assassination of John F. Kennedy (Haward, 1979; Colman, 1995).

The psychologists most often consulted by lawyers are clinical and educational psychologists (Lloyd-Bostock, 1988;

Gudjonsson, 1996a). Prison psychologists might also be consulted to assess offenders and give supporting evidence in court; occupational psychologists might be called on in cases involving personal injury or discrimination; academic psychologists might be asked to advise on specialised areas of psychology, such as factors which could influence face identification (Lloyd-Bostock, 1988); clinical neuropsychologists might be asked to determine whether a defendant is malingering, i.e. feigning mental disorder or intellectual incompetence (Martin, 2006). See Table 1.2.

Table 1.2 The types of evidence provided by forensic psychologists

Types of evidence provided	Percentage recorded
Interview with client	97
Studying relevant documents	87
Psychometric test results	85
Interview with informants	79
Behavioural assessment	64
Other (e.g. reviewing audio/video material, conducting research reviews/psychophysiological measurements)	20

Psychology in action – Continued

At the trial stage of criminal proceedings, psychologists may assess an individual's state of mind and determine whether the offence was intentional. Much of the empirical research in psychology could also be applied at this stage – especially research that can inform jurors' understanding of behaviours such as witness memory and eyewitness identification (Loftus, 1986). In North America, and also in England and Wales in particular, the legal and police systems have taken steps to issue guidelines on, for example, eyewitness testimony and its reliability, such as the *Memorandum of Good Practice on Video-recorded Interviews with Child Witnesses for Criminal Proceedings* (1992) in the UK, and *Eyewitness Evidence: A Guide for Law Enforcement* (1999) in the US (Wells *et al.*, 2000).

One tool associated with criminological psychology, and which has given it some cinematic glamour, is **offender profiling**, a technique that dates back to the 1950s (Brown, 1998). The purpose of offender profiling is to present a composite description of a perpetrator, based on biographical and behavioural cues, that can lead to the apprehension of that perpetrator. It can also be used to narrow the focus of an investigation (by specifying the perpetrator's age or sex, or where he/she lives) or to provide suggestions for interviewing suspects (McCann, 1992). By collating data and evaluating evidence, such techniques have led to the arrest of serious criminals, such as the British criminal, John Duffy, who murdered his victims near railways (Canter, 1989). However, even psychologists who have used – and pioneered – such techniques suggest caution in using this technique. The romantic, insightful detective who uses implicit learning to make his deductions dates back to Sherlock Holmes. In a review of offender profiling, a leading forensic psychologist, David Canter from the University of Liverpool, has argued that, 'Much of what passes for "offender profiling" in practice and as reported in the factual and fictional media has no basis in empirical research' (Canter, 2000). He criticises the 'implicit reasoning' approach, popularised by Conan Doyle in his Holmes stories, using an interesting illustration. Holmes's approach involved using experience or logic to draw inferences about the criminal.

In a real-life example cited by Canter, a victim had noticed that the assailant had short fingernails on the left hand and long ones on the right hand. Someone with information about guitar playing suggested that this was a characteristic of serious guitar players and the search was on for a guitarist. When the offender was eventually arrested, he was found to have no connection with guitars. He had asymmetrical fingernails because of his job as a tyre repairman.

'I can never bring you to realise the importance of sleeves, the suggestiveness of thumbnails, or the great information that may hang from a bootlace,' said the great Sherlock Holmes in *A Case of Identity*. Modern crime detection, however, would suggest that Holmes's strategy would convict more innocent people than guilty.

Source: 20th Century Fox/Kobal Collection Ltd.

Canter also describes a team of northern European profilers who mistakenly assumed that because a murdered woman's face had been severely beaten, the offender knew his/her victim and was exacting some form of revenge (<http://www.liv.ac.uk/InvestigativePsychology/invpub.htm>). The murdered woman was a teacher and attention was quickly focused on those pupils who may have been ignored or spurned by her. The murderer turned out to be a drug addict who killed the woman when she disturbed him burgling her house.

Canter suggests adopting a more statistical approach to offender profiling: collecting bits of data so that consistencies between crimes can be highlighted. Although an individual crime will differ from crime to crime, there may be a consistent theme running through that series of crimes. Canter argues that this systematic, clinical approach is more likely to be successful in profiling offenders than is that of the lone detective working on hunches.

Health psychology is the study of the ways in which behaviour and lifestyle can affect health and illness (Sarafino, 2002). For example, smoking is associated with a number of illnesses and is a strong risk factor for death. Health psychologists study what makes people initiate and maintain unhealthy behaviour and can help devise strategies to reduce it. Health psychologists are employed in a variety of settings including hospitals, government, universities and private practice. The work of health psychologists is described in Chapter 17.

Educational psychology is another branch of applied psychology. Educational psychologists assess the behavioural problems of children at school and suggest ways in which these problems may be remedied. For example, the educational psychologist might identify a child's early inability to read (dyslexia) and suggest a means by which this may be overcome through special training. The educational psychologist might also deal with all aspects relevant to a child's schooling such as learning, social relations, assessment, disruptive behaviour, substance abuse, bullying and parental neglect.

Consumer psychology is the study of the motivation, perception, learning, cognition and purchasing behaviour of individuals in the marketplace and their use of products once they reach the home. Some consumer psychologists take a marketer's perspective, some take a consumer's perspective, and some adopt a neutral perspective, especially if they work at a university.

Organisational or occupational psychology is one of the largest and oldest fields of applied psychology and involves the study of the ways in which individuals and groups perform and behave in the workplace (Huczynski and Buchanan, 2006). Early organisational psychologists concentrated on industrial work processes (such as the most efficient way to shovel coal), but organisational psychologists now spend more effort analysing modern plants and offices. They are involved in the administration and development of personality aptitude tests and can also be involved in stress management. Most are employed by large companies and organisations, but almost one-third are employed in universities.

Ergonomics or human factors psychology focuses mainly on the ways in which people and machines work together (Shackel, 1996). They study machines ranging from cockpits to computers, from robots to MP3/4 players, from transportation vehicles for the disabled to telephones. If the machine is well designed, the task can be much easier, more enjoyable and safer. Ergonomists help designers and engineers to design better machines; because of this, the terms ergonomics and engineering psychology are sometimes used interchangeably (Stanton, 1996).

Sport and exercise psychology applies psychological principles to the area of sport. It also involves the study of the effects of sport and exercise on mood, cognition, well-being and physiology. This area is examined in more detail in Chapter 17.

Psychology – An international perspective

Behind almost all research endeavours in psychology is a common aim: to discover a psychological universal. According to Norenzayan and Heine (2005), **psychological universals** are 'core mental attributes shared by humans everywhere'. That is, they are conclusions from psychological research that can be generalised across groups – ways of reasoning, thinking, making decisions, interpreting why people behave in the way that they do, recognising emotions and so on, are all examples of core mental attributes. A sound case for a psychological universal can be made if a phenomenon exists in a large variety of different cultures.

However, as might be obvious to you, some differences may be more obvious in some groups than others – men and women, for example, the young and the old, the mentally ill and the mentally healthy, and so on. At this level of analysis, we cannot say that people in general behave in a particular way, but that a spe-

cific group of people behave in a particular way. Nowhere is this more relevant than when considering the role of culture in psychological studies. A variety of behaviours are absent or are limited in a variety of cultures and nations. Some recent research, for example, has highlighted significant differences between Western and Asian cultures in the types of autobiographical memory they recall, the parts of a landscape and photograph they focus on, and the way in which they draw and take a photograph. Table 1.3 summarises some of these differences.

One approach to demonstrating a psychological universal is to examine a behaviour in three or more cultures, two of which are very different, with a third falling between them, and see how each differs from, or is similar to, the other. The best way, however, is to examine a variety of cultures, as Daly and Wilson (1988) did. Their research examined sex differences in the international rates of homicide and found that men were more

Psychology – Continued

Table 1.3 Behaviours which have been reported to vary across cultures, or which may be less evident in certain cultures. Unfamiliar terms are defined in the chapters referred to in brackets

- Memory for and categorisation of focal colours
- Spatial reasoning (see Chapter 8)
- Autobiographical memory
- Perception of the environment
- Appreciation of art
- Some types of category-based inductive reasoning (see Chapter 11)
- Some perceptual illusions
- Some ways of approaching reasoning
- Aspects of numerical reasoning
- Risk preferences in decision-making (see Chapter 11)
- Self-concept (see Chapters 15 and 16)
- Similarity-attraction effect (see Chapters 15 and 16)
- Approach-avoidance motivation (see Chapter 13)
- The fundamental attribution error (see Chapters 15 and 16)
- Predilection for aggression
- Feelings of control
- High subjective well-being and positive affect
- Communication style
- Prevalence of major depression
- Prevalence of eating disorders (see Chapter 13)
- Mental illness (those that appear in some cultures but not others – see the Controversies in Psychological Science section in Chapter 18)
- Noun bias in language learning (see Chapter 10)
- Moral reasoning
- Prevalence of different attachment style (see Chapter 12)
- Disruptive behaviour in adolescence
- Personality types (see Chapter 14)
- Response bias (see Chapter 2)
- Recognition of emotion
- Body shape preference

Source: Adapted from Norenzayan and Heine (2005).

likely to kill men than women were to kill women. Debate then ensues as to why this universal should be (and that debate is often heated, as most in psychology are).

A related approach is to examine the degree to which a psychological phenomenon is present – personality type is a good example of this. As Chapter 14 will show you, the dominant approach in personality views us as differing along five major personality dimensions. Cross-cultural research has highlighted (i) the universality of these five dimensions but also (ii) the differences or ‘variation’ which exist between and within cultures

within each dimension – so some cultures or states may express more or less of a personality type such as extraversion or conscientiousness, for example.

In the book, examples of universals (and exceptions) are described in the sections: ‘. . . An international perspective’. These will help you put the findings you read about into some form of cultural or international context. They should also help demonstrate that although studies sometimes report findings as being absolute and generalisable to populations in general, sometimes these findings are not.

Psychology: a European perspective

Psychology is one of the most popular degree courses in Europe. In 2008, psychology was the third most popular UK University degree in terms of applications (70,295, pipped only by law and pre-clinical medicine, see Table 1.4). It is estimated that 1 in 850 people in the Netherlands has a degree in psychology (Van Drunen, 1995), and no course is more popular in Sweden (Persson, 1995).

Modern psychology has its origins in Europe: the first psychological laboratory was established in Europe and some of the first designated university degrees in psychology were established there. Research in North America and Europe accounts for the majority of psychological studies published in the world (Eysenck, 2001) and there continues to be debate over whether these two fairly large ‘geographical’ areas adopt genuinely different approaches to the study of psychological processes (G. N. Martin, 2001).

Psychology as a discipline occupies a different status in different European countries and each country has established its own degrees and societies at different times, for historical or political reasons. Almost all countries have a professional organisation which regulates the activity of psychologists or provides psychological training or licensing of psychologists. The first such association in Denmark was founded in 1929 (the Psychotechnical Institute in Copenhagen) and what we would now call educational psychology formed the basis of the professional training it provided: the job of the institute was to select apprentices for the printing trade (Foltveld, 1995). The Netherlands’ first psychological laboratory was founded in 1892 at Gröningen, Denmark’s in 1944 at the University of Copenhagen and Finland’s in 1921 by Eino Kaila at the University of Turku (Saari, 1995). Coincidentally, 1921 was also the year in which The Netherlands passed a Higher Education Act allowing philosophy students to specialise in psychology.

4 English studies	50,251
5 Management studies	49,447
6 Nursing	47,051
7 Teacher training	43,896
8 Business/admin studies	42,816
9 History	41,917
10 Business studies	41,583

The British Psychological Society (BPS) was formed in 1901, with laboratories established at the University of Cambridge and University College London in 1897, closely followed by the establishment of laboratories in Aberdeen, Edinburgh and Glasgow (Lunt, 1995). Sweden’s professional association was founded in 1955 (Sveriges Psykologforbund), with the Netherlands’ pre-dating that in 1938 (Nederlandsch Instituut van Practizeerende Psychologen, or NIPP). Portugal is one of the younger psychology nations – the first graduates in psychology left university in 1982 (Pereira, 1995). Because of the history of the country, psychology was not acknowledged as a university subject in Portugal until after the democratic revolution of 1974.

Psychological training and status of psychology in Europe

The types of career that psychology graduates pursue are similar across most European countries. Figures 1.2(a) and (b) show you the employment destination of psychologists in Denmark and The Netherlands. You can see from these figures that most psychologists are employed in the public sector, with the majority of those working in the clinical, educational or organisational fields. Around 90 per cent of psychologists are employed in the public sector in Finland and 70 per cent of these work in health, clinical or social work-related areas (Saari, 1995). A similar pattern is seen in Sweden (Persson, 1995).

Training for psychologists varies between countries and controversy surrounds the licensing or the legalisation of the profession. For example, psychologists in almost all countries wish for formal statutory regulation of the profession (the medical and legal professions are regulated). In Denmark, the title of psychologist was legally protected in 1993 so that no one could call themselves a psychologist unless they had received specified training. In Greece, a law was passed in 1979 licensing psychologists to practise (Georgas, 1995). These enlightened views have not extended to some other countries, however, despite the attempts of professional organisations in lobbying their legislators. Finland and the UK have faced obstacles in legalising the profession.

The BPS has its own regulatory system so that applied psychologists need to undergo an approved route of training (to go on to practise as forensic, clinical, educational, health psychologists, for example) before they are recognised as qualified professional psychologists by the Society. Most of these individuals choose to register themselves as Chartered Psychologists – a person using the services of a psychologist designated chartered can, therefore, be assured that the person is a recognised professional psychologist.

European views of psychology and psychologists

Non-psychologists' views of what psychology is and what psychologists do are encouragingly positive and generally, accurate although their knowledge of psychological research (as you saw earlier) is flawed. Table 1.5 shows you the responses of an Austrian sample to the question, 'What do you expect a psychologist to do?', and to the sentence, 'Psychologists can . . .' (Friedlmayer and Rossler, 1995).

A Finnish study which asked adults to rate which of a number of professions was more knowledgeable about human nature, found that 53 per cent believed doctors were more knowledgeable, with psychologists following behind in second place (29 per cent) (Montin, 1995). A Norwegian study, however, found the opposite: 49 per cent chose psychologists and 23 per cent chose doctors (Christiansen, 1986). Figures 1.3 (a)–(d) give some of the other illuminating responses to the other questions asked in the Finnish survey. These not only reveal how people

receive or obtain their information about psychology but also show that the discipline is still shrouded in some mystery – 49 per cent declare knowing only ‘a little’ about psychology. Mercifully, 75 per cent of respondents disagreed that psychologists could read minds.

You will find the addresses of professional associations and organisations of psychology in Europe at the end of the chapter. You can contact them for more information about postgraduate courses and training opportunities in psychology.

Psychology: the development of a science

Although philosophers and other thinkers have been concerned with psychological issues for centuries, the science of psychology is comparatively young. To understand how this science came into being, it is useful to trace its roots back through philosophy and the natural sciences. These disciplines originally provided the methods we use to study human behaviour and took many centuries to develop.

Philosophical roots of psychology

Animism

Each of us is conscious of our own existence. Furthermore, we are aware of this consciousness. Although we often find ourselves doing things that we had not planned to do (or had planned not to do), by and large we feel that we are in control of our behaviour. That is, we have the impression that our conscious mind controls our behaviour. We consider alternatives, make plans, and then act. We get our bodies moving; we engage in behaviour.

Earlier in human history, philosophers attributed a life-giving animus, or spirit, to anything that seemed to move or grow independently. Because they believed that the movements of their own bodies were controlled by their minds or spirits, they inferred that the sun, moon, wind, tides and other moving entities were similarly animated. This primitive philosophy is called **animism** (from the Latin *animare*, ‘to quicken, enliven, endow with breath or soul’). Even gravity was explained in animistic terms: rocks fell to the ground because the spirits within them wanted to be reunited with Mother Earth.

Obviously, animism is now of historical interest only. No educated person believes that rocks fall because they

‘want to’. Rather, we believe that they fall because of the existence of natural forces inherent in physical matter, even if we do not understand what these forces are. But note that different interpretations can be placed on the same events. Surely, we are just as prone to subjective interpretations of natural phenomena, albeit more sophisticated ones, as our ancestors were. In fact, when we try to explain why people do what they do, we tend to attribute at least some of their behaviour to the action of a motivating spirit – namely, a will. In our daily lives, this explanation of behaviour may often suit our needs. However, on a scientific level, we need to base our explanations on phenomena that can be observed and measured objectively. We cannot objectively and directly observe ‘will’.

The best means we have to ensure objectivity is the scientific method, which is described in more detail in the next chapter. Psychology as a science must be based on the assumption that behaviour is strictly subject to physical laws, just as any other natural phenomenon is. The rules of scientific research impose discipline on humans whose natural inclinations might lead them to incorrect conclusions. It seemed natural for our ancestors to believe that rocks had spirits, just as it seems natural for people nowadays to believe that behaviour can be affected by a person’s will. In contrast, the idea that feelings, emotions, imagination and other private experiences are the products of physical laws of nature did not come easily; it evolved through many centuries.

Dualism: René Descartes

Although the history of Western philosophy properly begins with the Ancient Greeks, a French philosopher and mathematician, René Descartes (1596–1650), is regarded as the father of modern philosophy. He advocated a sober, impersonal investigation of natural phenomena using sensory experience and human reasoning. He assumed that the world was a purely mechanical entity that, having once been set in motion by God, ran its course without divine interference. Thus, to understand the world, one had only to understand how it was constructed. This stance challenged the established authority of the Church, which believed that the purpose of philosophy was to reconcile human experiences with the truth of God’s revelations.

To Descartes, animals were mechanical devices; their behaviour was controlled by environmental stimuli. His view of the human body was much the same: it was a machine. Thus, Descartes was able to describe some movements as automatic and involuntary. For example, the application of a hot object to a finger would cause an almost immediate withdrawal of the arm away from the

René Descartes (1596–1650).

source of stimulation. Reactions like this did not require participation of the mind; they occurred automatically. Descartes called these actions **reflexes** (from the Latin *reflectere*, ‘to bend back upon itself’). A stimulus registered by the senses produces a reaction that would be entirely physical and beyond voluntary control. There would be no intention or will to produce this physical reaction. Consider the well-known reflex of sensing the heat of a flame, as seen in Figure 1.4. The body recoils from flame in an involuntary way: we do not intentionally move away from the flame but our body reflexively puts in place a chain of muscle contractions which make us withdraw. The term ‘reflex’ is still in use today, but, of course, we explain the operation of a reflex differently, as you’ll see in Chapter 4.

What set humans apart from the rest of the world, according to Descartes, was their possession of a mind. This was a uniquely human attribute and was not subject to the laws of the universe. Thus, Descartes was a proponent of **dualism**, the belief that all reality can be divided into two distinct entities: mind and matter (this is often referred to as **Cartesian dualism**). He distinguished between ‘extended things’, or physical bodies, and ‘thinking things’, or minds. Physical bodies, he believed, do not think, and minds are not made of ordinary matter.

Although Descartes was not the first to propose dualism, his thinking differed from that of his predecessors in one important way: he was the first to suggest that a link exists between the human mind and its purely physical housing. Although later philosophers pointed out that this theoretical link actually contradicted his belief in

Figure 1.4 Descartes's diagram of a withdrawal reflex.

dualism, the proposal of an interaction between mind and matter, **interactionism**, was absolutely vital to the development of the science of psychology.

From the time of Plato onwards, philosophers had argued that the mind and the body were different entities. They also suggested that the mind could influence the body but the body could not influence the mind, a little like a puppet and puppeteer with the mind pulling the strings of the body. Not all philosophers adopted this view, however. To some, such as Spinoza (1632–1677), both mental events (thinking) and physical events (such as occupying space) were characteristic of one and the same thing, in the same way that an undulating line can be described as convex or concave – it cannot be described as exclusively one thing or another (this is called **double-aspect theory**).

Descartes hypothesised that this interaction between mind and body took place in the pineal body, a small organ situated on top of the brain stem, buried beneath the large cerebral hemispheres of the brain. When the mind decided to perform an action, it tilted the pineal body in a particular direction, causing fluid to flow from the brain into the proper set of nerves. This flow of fluid caused the appropriate muscles to inflate and move.

How did Descartes come up with this mechanical concept of the body's movements? Western Europe in the seventeenth century was the scene of great advances in the sciences. This was the century, for example, in which William Harvey discovered that blood circulated around

the body. It was not just the practical application of science that impressed Europeans, however, it was the beauty, imagination and fun of it as well. Craftsmen constructed many elaborate mechanical toys and devices during this period. The young Descartes was greatly impressed by the moving statues in the Royal Gardens (Jaynes, 1970) and these devices served as models for Descartes as he theorised about how the body worked. He conceived of the muscles as balloons. They became inflated when a fluid passed through the nerves that connected them to the brain and spinal cord, just as water flowed through pipes to activate the statues. This inflation was the basis of the muscular contraction that causes us to move.

This story illustrates one of the first examples of a technological device used to model and explain how the nervous system works. In science, a **model** is a relatively simple system that works on known principles and is able to do at least some of the things that a more complex system can do. For example, when scientists discovered that elements of the nervous system communicate by means of electrical impulses, researchers developed models of the brain based on telephone switchboards and, more recently, computers. Abstract models, which are completely mathematical in their properties, have also been developed. Clinical psychologists may interpret mental disorder according to a medical model which conceives of clinical mental disturbance as an illness.

Although Descartes's model of the human body was mechanical, it was controlled by the non-mechanical (in fact, non-physical) mind. Thus, humans were born with a special capability that made them greater than simply the sum of their physical parts. Their knowledge was more than merely a physical phenomenon.

Descartes's influence on the development of psychology was considerable. He proposed the revolutionary idea that the mind and the body were mutually interacting and suggested a method of studying 'the mind' which was based on reasoning and not metaphysical analysis. Descartes's notion of interactionism gave rise to two very influential but very different schools of thought in psychology at the end of the nineteenth and the beginning of the twentieth centuries: introspectionism and behaviourism. We consider these later in the chapter.

Empiricism: John Locke and David Hume

With the work of the English philosopher John Locke (1632–1704), the mechanisation of the whole world became complete. Locke did not exempt the mind from the mechanical laws of the material universe. Descartes's rationalism – pursuit of truth through reason – was replaced by **empiricism** – pursuit of truth through observation and experience (in Greek, *empeiria* means experience).

A prevalent belief in the seventeenth century was that ideas were innately present in an infant's mind. Locke rejected this belief. Instead, he proposed that all knowledge must come through experience: it is empirically derived. His model of the mind was a tablet of soft clay, a *tabula rasa*, smooth at birth and ready to accept the writings of experience imprinted upon it. Locke believed that our knowledge of complex experiences was nothing more than links between simple, primary sensations: simple ideas combined to form complex ones.

This notion was developed further by the Scottish philosopher David Hume (1711–76). In his book *A Treatise of Human Nature* (1739), Hume argued that the study of human nature could best be undertaken through experience and observation. Hume's conception of the mind was slightly different from that of Locke. Whereas Locke wrote of ideas, Hume wrote of perceptions which were composed of impressions and ideas. Impressions were what we would consider sensations – seeing print on a paper or hearing a loud bang; ideas were the less vivid recollection of such sense experiences. Impressions, according to Hume, were the most important perceptions because these were derived directly from observation. Any ideas based on content which was not derived empirically were not valuable and not trustworthy. Hume, therefore, espoused what is known as **positivism** – the school of thought which argues that all meaningful ideas can be reduced to observable material.

Perhaps Hume's greatest contribution to psychology was the **doctrine of the association of ideas**. In *An Inquiry Concerning Human Understanding* (1748), Hume argued that there were various types of connection or association between ideas. This was not itself a new idea. Aristotle had proposed the notion of an association of ideas: two stimuli if paired frequently enough would result in the presentation of one event stimulating thoughts of the other. Hume suggested three specific types of association: resemblance (when we look at someone's photograph, for example, this triggers off thoughts about that person), contiguity (thoughts of an object or event will trigger thoughts related to those objects and events), and cause and effect (the idea that actions have identifiable causes). These associations were the 'cement' that helped bind the universe, and all complex human experiences were based on simple ideas derived from impressions. The most important of these associations was cause and effect, and Hume developed this theme by describing behaviour in terms of custom and habit. According to Hume, if one performs an act which produces an effect which makes a repetition of that act likely, this is a habit or custom. For example, think of a simple behaviour such as switching on a light. Your knowledge that switching a light on will illuminate a room will result in your habitually pressing the switch if you need light.

These notions of habit and causality became very important in the twentieth century with the development of behaviourism and the work of the Swiss developmental psychologist Jean Piaget (1896–1980), described later.

Idealism: Bishop Berkeley

In contrast to the empiricists, the Irish bishop, philosopher and mathematician George Berkeley (1685–1753) believed that our knowledge of events in the world did not come simply from direct experience. Instead, Berkeley (who gave his name to the famous university in California) argued that this knowledge is the result of inferences based on the accumulation of past experiences derived through the senses. In other words, we must learn how to perceive. For example, our visual perception of depth involves several elementary sensations, such as observing the relative movements of objects as we move our head and the convergence of our eyes (turning inward towards each other or away) as we focus on near or distant objects. Although our knowledge of visual depth seems to be immediate and direct, it is actually a secondary, complex response constructed from a number of simple elements. Our perceptions of the world can also involve integrating the activity of different sense organs, such as when we see, hear, feel and smell the same object. The aspect of Berkeley's philosophy which argues that all ideas come from the senses (*esse est percipi*) is called **idealism**.

As you can see, the philosophers Locke, Hume and Berkeley were grappling with the workings of the human mind and the way in which people acquire knowledge. They were dealing with the concept of learning. Modern psychologists are still concerned with the issues that Berkeley raised. As philosophers, they were trying to fit a non-quantifiable variable – reason – into the equation.

Materialism: James Mill

With the work of the Scottish philosopher James Mill (1773–1836), the pendulum took its full swing from animism (physical matter animated by spirits) to materialism (mind composed entirely of matter). **Materialism** is the belief that reality can be known only through an understanding of the physical world, of which the mind is a part. Mill worked on the assumption that humans and animals were fundamentally the same. Both humans and animals were thoroughly physical in their make-up and were completely subject to the physical laws of the universe. He agreed in essence with Descartes's approach to understanding the human body but rejected the concept of an immaterial mind. Mind, to Mill, was as passive as the body. It responded to the environment in precisely the same way. The mind, no less than the body, was a machine.

In the nineteenth century, the philosophy of the past began to make way for the experimentation of the future. In the latter part of the century, a part of Germany gave birth to modern psychology as we know it. Its midwife was Wilhelm Wundt.

Modern psychology: from the Leipzig laboratory to the cognitive revolution

Wilhelm Wundt (1832–1920) was the first person to call himself a psychologist and he shared the conviction of other German scientists that all aspects of nature, including the human mind, could be studied scientifically, an approach summarised in his book *Principles of Physiological Psychology*, the first textbook in psychology.

Wundt's approach was experimental in nature and his and his colleagues' work was conducted at the Leipzig laboratory. Over one hundred studies were conducted in the first twenty years of the laboratory's life. Initially, these were studies of the psychological and psychophysiological aspects of vision (seeing), audition (hearing) and somatosensation (feeling and touching). Later work focused on reaction time and the process involved in perceiving and then responding to a stimulus. Wundt also explored the nature of attention and emotional feeling as well as word association.

The fact that Germany was the birthplace of psychology had as much to do with social, political and economic influences as with the abilities of its scientists and scholars. The German university system was well established, and professors were highly respected members of society. The academic tradition in Germany emphasised a scientific approach to a large number of subject areas, such as history, phonetics, archaeology, aesthetics and literature. Thus, in contrast to French and British scholars, who adopted the more traditional, philosophical approach to the study of the human mind, German scholars were open to the possibility that the human mind could be studied scientifically. Experimental physiology, one of the most important roots of **experimental psychology**, was well established there. Eventually, Wundt's influence began to extend to other parts of Europe (especially the UK) and to the USA.

Structuralism: Wilhelm Wundt

Wundt defined psychology as the 'science of immediate experience', and his approach was called **structuralism**, the first proper school of thought to emerge in the history of psychology. Its subject matter was the structure of the mind, built from the elements of consciousness, such as

ideas and sensations. These elements could be constructed into a table of elements similar to a chemical table of elements. Structuralism's raw material was supplied by trained observers who described their own experiences under well-controlled conditions. The observers were taught to engage in introspection (literally, 'looking within'), the use of which was governed by strict rules. Introspectionists observed stimuli and described their experiences. According to Boring (1953), observers participating in reaction time experiments had to produce approximately 10,000 introspective observations before their data were considered valid and they themselves considered to be qualified introspectionists.

Wundt's aims were threefold: to analyse the contents of conscious experience, to determine how the elements of consciousness are connected, and to devise a law which would explain such connections. Wundt and his associates, Edward Titchener (1867–1927) and Gustav Fechner (1801–87), made inferences about the nature of mental processes by seeing how changes in the stimuli caused changes in the verbal reports of their trained observers.

Wundt was particularly interested in the problem that had intrigued Berkeley: how did basic sensory information give rise to complex perceptions? His **doctrine of apperception** attempted to account for the fact that when we perceive, this perception is of a whole object and not separate elements of it. We see wholes, according to Wundt, because of the process of creative synthesis (or law of psy-

Wilhelm Wundt (1832–1920).

chic resultants): a process which combines or synthesises elements to form a whole. Again, this process is very similar to a process in chemistry in which individual chemical elements when combined will form a new, wholly different entity. The whole would not be equivalent to the sum of its parts. Much of Wundt's work, however, aimed to break down and analyse the contents of the mind rather than determine how they are combined.

Wundt was an ambitious and prolific scientist who wrote many books and trained many other scientists in his laboratory. However, his method did not survive the test of time; structuralism died out in the early twentieth century. The major problem with his approach was the difficulty encountered by observers in reporting the raw data of sensation, data unmodified by experience. Although introspectionism aimed to establish well-controlled experimental conditions which would lead to reliable introspective observations, there was often little agreement between observers about their introspections. The method has also been criticised for its reliance on retrospection; the recollection of an experience was frequently elicited some time after the experience itself had occurred and was, therefore, subject to error.

In addition, attention began to shift from study of the human mind to the study of human behaviour. Behaviourism provided a devastating and critical alternative to introspectionism. According to behaviourism's founding father, the American John B. Watson, introspectionism was akin to superstition, an argument considered in detail a little later on. Recently, psychologists have resumed the study of the human mind, but we now have better methods for studying it than were available to Wundt.

Although structuralism has been supplanted, Wundt's contribution must be acknowledged. He was responsible for establishing psychology as a recognised, experimental science that was separate from philosophy. He used methods which involved observation and experimentation and trained a great number of psychologists, many of whom established their own schools and continued the evolution of the new discipline.

Memory: Hermann Ebbinghaus

Most of the pioneers of psychology founded schools, groups of people having a common belief in a particular theory and methodology. In this context, the word school refers to a branch of a particular academic discipline, not a building or institution. Structuralism was a school of psychology. The exception to this trend was Hermann Ebbinghaus (1850–1909). In 1876, after receiving his Ph.D. in philosophy but still unattached to an academic institution, Ebbinghaus came across a second-hand copy of a book by Gustav Fechner describing a mathematical approach to the measurement of human sensation.

Intrigued by Fechner's research, Ebbinghaus decided to attempt to measure human memory: the processes of learning and forgetting.

Working alone, Ebbinghaus devised methods to measure memory and the speed with which forgetting occurred. He realised that he could not compare the learning and forgetting of two prose passages or two poems because some passages would undoubtedly be easier to learn than others. Therefore, he devised a relatively uniform set of materials – nonsense syllables, such as 'juz', 'bul' and 'gof'. He printed the syllables on cards and read through a set of them, with the rate of presentation controlled by the ticking of a watch. After reading the set, he paused a fixed amount of time, then read the cards again. He recorded the number of times he had to read the cards to be able to recite them without error. He measured forgetting by trying to recite the nonsense syllables on a later occasion – minutes, hours or days later. The number of syllables he remembered was an index of the percentage of memory that had been retained.

Ebbinghaus's approach to memory was entirely empirical; he devised no theory of why learning occurs and was interested only in gathering facts through careful, systematic observation. However, despite the lack of theory, his work made important contributions to the development of the science of psychology. He introduced the principle of eliminating **variable errors** by making observations repeatedly on different occasions (using different lists each time) and calculating the average of these observations. Variable errors include errors caused by random differences in the subject's mood or alertness or by uncontrollable changes in the environment. He constructed graphs of the rate at which the memorised lists of nonsense syllables were forgotten, which provided a way to measure mental contents across time. As you will see in Chapter 8, Ebbinghaus's research provided a model of systematic, rigorous experimental procedures that modern psychologists still emulate.

Functionalism: William James and James Angell

After structuralism, the next major trend in psychology was **functionalism**. This approach, which began in the USA, was in large part a protest against the structuralism of Wundt. Structuralists were interested in what they called the components of consciousness (ideas and sensations); functionalists were more interested in the process of conscious activity (perceiving and learning). Functionalism grew from the new perspective on nature provided by Charles Darwin and his followers. Proponents of functionalism stressed the biological significance (the purpose, or function) of natural processes,

William James (1842–1910).

including behaviours. The emphasis was on overt, observable behaviours, not on private mental events.

The most important psychologist to embrace functionalism was William James (1842–1910), brother of novelist Henry. As James said, ‘My thinking is first, last, and always for the sake of my doing.’ That is, thinking was not an end in itself; its function was to produce useful behaviours. Although James was a champion of experimental psychology, he did not appear to enjoy doing research, instead spending most of his time reading, thinking, teaching and writing during his tenure as professor of philosophy (later, professor of psychology) at Harvard University.

Unlike structuralism, functionalism was not supplanted; instead, its major tenets were absorbed by its successor, behaviourism. One of the last of the functionalists, James Angell (1869–1949), described its basic principles:

- Functional psychology is the study of mental operations and not mental structures. It is not enough to compile a catalogue of what the mind does; one must try to understand what the mind accomplishes by doing this.
- Mental processes are not studied as isolated and independent events but as part of the biological activity of the organism. These processes are aspects of the organ-

ism’s adaptation to the environment and are a product of its evolutionary history. For example, the fact that we are conscious implies that consciousness has adaptive value for our species.

- Functional psychology studies the relation between the environment and the response of the organism to the environment. There is no meaningful distinction between mind and body, they are part of the same entity.

Evolution and heritability: Charles Darwin and Francis Galton

Charles Darwin (1809–82) proposed the theory of evolution in his book *On the Origin of Species by Means of Natural Selection*, published in 1859. His work, more than that of any other person, revolutionised biology. The concept of natural selection showed how the consequences of an animal’s characteristics affect its ability to survive. Instead of simply identifying, describing and naming species, biologists began now to look at the adaptive significance of the ways in which species differed.

Darwin’s theory suggested that behaviours, like other biological characteristics, could best be explained by understanding their role in the adaptation of an organism (a human or other animal) to its environment. Thus, behaviour has a biological context. Darwin assembled evidence that behaviours, like body parts, could be inherited. In *The Expression of the Emotions in Man and Animals*, published in 1873, he proposed that the facial gestures that animals make in expressing emotions were descended from movements that previously had other functions. New areas of exploration were opened for psychologists by the ideas that an evolutionary continuity existed among the various species of animals and that behaviours, like parts of the body, had evolutionary histories. Darwin’s notion of natural selection has had great impact on the way in which we view the genetic determinants of behaviour (as Chapter 3 will show).

One of the first psychologists to study the influence of genetics on human behaviour was Sir Francis Galton (1822–1911), Darwin’s first cousin. Galton was a polymath who made many other contributions to the field of science: he constructed the first weather maps of the British Isles, discovered and named the weather phenomenon we know as anticyclone, invented the term ‘correlation’ (which describes the statistical relationships between two variables or factors), developed the technique of fingerprinting, founded the discipline of psychometrics, which applies statistical principles to the measurement of individual differences and the construction of psychological tests, and established the Anthropometric Laboratory in London in 1884, the birthplace of intelligence testing.

Galton was interested in discovering whether people's physical features correlated with each other and whether such correlations occurred for psychological features such as sensory capacity, reaction time, intellect and eminence. In fact, Galton did find that features such as height, arm length and weight were highly and positively correlated and argued from this that if one part of the body's dimensions were known then one could construct the rest of the body to scale.

Importantly, Galton was the first to provide statistical evidence for the heritability of psychological variables. In his study of eminent men, published in his book *Hereditary Genius* (Galton, 1869), Galton found that 31 per cent of illustrious men had eminent fathers and 48 per cent of these men had eminent sons. Of course, by today's standards, this study has several methodological shortcomings, not least of which is the collection of data from eminent men only (to make a valid comparison, you would also need to look at non-eminent men and their offspring). There is also the argument that eminence may not have been inherited but had been determined by the environment in which these men were raised (issues discussed in detail in Chapters 3 and 11). However, Galton remains an important figure in the history of psychology. His greatest contribution is the establishment of the study of individual differences as a scientific enterprise.

Psychodynamic theory: Sigmund Freud

While psychology was developing as a fledgling science, Sigmund Freud (1856–1939) was formulating a theory of human behaviour that would greatly affect psychology and psychiatry (not necessarily for the good) and radically influence intellectual thinking of all kinds. Freud began his career as a neurologist, so his work was originally firmly rooted in biology. He soon became interested in behavioural and emotional problems and began formulating his psychodynamic theory of personality, which would evolve over his long career. Although his approach was based on observation of patients and not on scientific experiments, he remained convinced that the biological basis of his theory would eventually be established.

Freud and his theory are discussed in detail in Chapter 14 (Personality) but he is mentioned here to mark his place in the history of psychology. His theory of the mind included structures, but his structuralism was quite different from Wundt's. He devised his concepts of ego, superego, id and other mental structures through talking with his patients, not through laboratory experiments. His hypothetical mental operations included many that were unconscious and hence not available to introspec-

tion. And unlike Wundt, Freud emphasised function; his mental structures served biological drives and instincts and reflected our animal nature.

For better or worse Freud's name is the one most closely allied to psychology in the mind of the public. In a recent study of the most eminent psychologists, as measured by citations in journals, introductory textbooks and nominations from self-selecting members of the American Psychological Society via an email survey, Hagbloom *et al.* (2002) found that Freud was the most widely cited author in the discipline, as you can see in Tables 1.6 a–c. In second place was Jean Piaget and in third, Hans J. Eysenck.

Behaviourism: Edward Thorndike and Ivan Pavlov

The next major trend in psychology, behaviourism, followed directly from functionalism. It went further in its rejection of the special nature of mental events, denying that unobservable and unverifiable mental events were properly the subject matter of psychology. Behaviourists believed that because psychology is the study of observable behaviours, mental events – which cannot be observed – are outside the realm of psychology. **Behaviourism** is thus the study of the relation between people's environments and their behaviour; what occurs within their heads is irrelevant.

One of the first behaviourists was Edward Thorndike (1874–1949), an American psychologist who studied the behaviour of animals. He noticed that some events, usually those that one would expect to be pleasant, seemed to 'stamp in' a response that had just occurred. Noxious events seemed to 'stamp out' the response, or make it less likely to recur. We now call these processes reinforcement and punishment, and they are described in more detail in Chapter 7 (Learning and behaviour). Thorndike defined the law of effect as follows (1905, p. 203):

Any act which in a given situation produces satisfaction becomes associated with that situation, so that when the situation recurs the act is more likely than before to recur also. Conversely, any act which in a given situation produces discomfort becomes disassociated from that situation, so that when the situation recurs the act is less likely than before to recur.

The **law of effect** is in the functionalist tradition. It observes that the consequences of a behaviour act back upon the organism, affecting the likelihood that the behaviour that just occurred will occur again. An organism does something, and the consequences of this action make that action more likely. This process is very similar to the principle of natural selection. Just as organisms that successfully adapt to their environments are more likely to survive and breed, behaviours that cause useful outcomes are more likely to recur.

Although Thorndike insisted that the subject matter of psychology was behaviour, his explanations contained mentalistic terms. For example, in his law of effect he spoke of 'satisfaction', which is certainly not a phenomenon that can be directly observed. Later behaviourists threw out terms like 'satisfaction' and 'discomfort' and

Ivan Pavlov (1849–1936) in his laboratory with some of his collaborators. His research revealed valuable, though unsought, information about the principles of learning.

Source: Bettman/CORBIS, reprinted by permission.

replaced them with more objective terms that reflected the behaviour of the organism rather than any feelings it might have.

Another major figure in the development of behaviourism was not a psychologist but a physiologist: Ivan Pavlov (1849–1936), a Russian who studied the physiology of digestion (for which he later received a Nobel Prize). In the course of studying the stimuli that produce salivation, he discovered that hungry dogs would salivate at the sight of the attendant who brought in their dishes of food. Pavlov found that a dog could be trained to salivate at completely arbitrary stimuli, such as the sound of a bell, if the stimulus was quickly followed by the delivery of a bit of food into the animal's mouth.

Pavlov's discovery had profound significance for psychology. He showed that through experience an animal could learn to make a response to a stimulus that had never caused this response before. This ability, in turn, might explain how organisms learn cause-and-effect relations in the environment. In contrast, Thorndike's law of effect suggested an explanation for the adaptability of an individual's behaviour to its particular environment. So, from Thorndike's and Pavlov's studies two important behavioural principles had been discovered.

Behaviourism: John B. Watson

Behaviourism as a formal school of psychology began with the publication of a book by John B. Watson (1878–1958), *Psychology from the Standpoint of a Behaviorist* (Watson,

1919). Watson was a charismatic professor of psychology at the Johns Hopkins University in the US, a popular teacher and writer and was a very convincing advocate of behaviourism. Even after leaving Johns Hopkins under mysterious circumstances and embarking on a highly successful career in advertising, he continued to lecture and write magazine articles about psychology.

According to Watson, psychology was a natural science whose domain was restricted to observable events: the behaviour of organisms. Watson's behaviourism can be best summed up by his definition published in an article entitled, 'Psychology as the behaviorist views it' (Watson, 1913):

Psychology as the behaviorist views it is a purely objective experimental branch of natural science. Its theoretical goal is the prediction and control of behavior. Introspectionism forms no essential part of its methods, nor is the scientific value of its data dependent upon the readiness with which they lend themselves to interpretation in terms of consciousness. The behaviorist, in his efforts to get a unitary scheme of animal response, recognises no dividing line between man and brute.

Watson believed that the elements of consciousness studied by structuralists were too subjective to lend themselves to scientific investigation. He defined psychology as the objective study of behaviour and the stimuli which produce such behaviour. The important feature of behaviourism was its reliance only on observable behaviour. Even thinking was reduced to a form of behaviour –

John B. Watson (1878–1958).

Source: Archives of the History of American Psychology.

talking to oneself. Watson described visually observable behaviour as ‘explicit behaviour’ and those behaviours which could not be directly observed but potentially observed as ‘implicit behaviour’. For example, we cannot see the body’s cells transmitting electrical signals but we can observe such behaviour by using the correct electrical recording equipment.

Another important feature, tied to observation, was that the brain had very little to do with what was directly observed. What was important to Watson was the concept of stimulus and response, an idea suggested by Descartes and explicitly described by Pavlov. Watson argued that, given the correct stimuli, the organism could learn to behave (give responses) in a specific way (in the same way that Pavlov’s dogs had ‘learned’ to associate the bell with the appearance of food). Watson, however, famously went further. In his book *Behaviorism* (1930), he argued:

Give me a dozen healthy infants, well-formed, and my own specified world to bring them up in and I’ll guarantee to take any one at random and train him to become any type of specialist I might select – doctor, lawyer, artist, merchant-chief and, yes, even beggar-man and thief, regardless of his talents, penchants, tendencies, abilities, vocations and race of his ancestors.

Many of Watson’s ideas, such as the notion that reflexes can be conditioned, have been incorporated into the mainstream of psychology, although the central tenet that all behaviour that is studied must be observable, has not. After Watson, a new form of behaviourism emerged which took Watson’s ideas and developed them further. This new form became known as **neobehaviourism** or **radical behaviourism**.

Radical behaviourism: Edward Tolman and Clark Leonard Hull

The period 1930–1960 saw a tremendous surge not only in the description of the ways in which organisms behaved but also in the explanations for why they behaved in the way they did. This surge was generated largely by the work of a group of American psychologists, Edward Tolman (1886–1959), Clark Leonard Hull (1884–1952) and B.F. Skinner (1904–1990). Each had a different view on how behaviour occurred but all used animal experiments and the procedures of learning experiments to support their theories. Hull, for example, proposed a highly detailed mathematical model of behaviour, based on his conditioning work with rats in his book *Principles of Behavior* (Hull, 1943), which sought

to explain almost all behaviour. The basic feature of Hull’s model was that all human (and any organism’s) behaviour evolves through interaction with the environment. However, this interaction occurs within a wider frame of reference – the biological adaptation of the organism to the environment. The variable intervening between environment and organism was drive – a bodily need arising from deprivation or desire or another motivational spur. Although one of the more widely cited psychologists of his day, Clark has not made a lasting impact on psychology largely because his extremely detailed mathematical analyses were based on few experiments, the results of which were generalised well beyond the scope of the experimental context.

Tolman suggested that it was important not only to observe the stimulus and response but to take into account intervening variables. To Tolman, these intervening variables were cognitions and demands, and Tolman’s theory became known as **purposive behaviourism**, so-called because all behaviour was goal-directed and had a purpose. Tolman’s work did not bequeath any major principles or laws, however, although interest in his work continues (Reid and Staddon, 1998). You will find out more about Hull’s and Tolman’s approaches in Chapter 7.

Radical behaviourism: Burrhus Frederic Skinner

The bequest of a major framework of thinking in psychology was left to B.F. Skinner (1904–1990), one of the most influential psychologists of the twentieth century whose entry into psychology’s history was serendipitous (he originally wanted to be a writer, and actually wrote novels using his research ideas). Skinner’s work gave birth to the technology of teaching machines (which have since been replaced by computers), the use of behaviour modification in instruction of the mentally retarded, and the use of behaviour therapy to treat mental disorders.

Skinner’s work focused on the idea of reinforcement and was based largely on observation of behaviour in pigeons. He found that a certain set of stimulus conditions (such as a box, hunger, food in sight) would elicit certain behaviours (strutting, random pecking). If the animal behaved in a certain way to obtain food then the food became the reinforcing stimulus or the reinforcer – a stimulus which increases the probability that behaviour will occur again. Using his observations of pigeons’ behaviour, Skinner found that the pigeons could be trained to behave in a specific way when responding to specific signals from their environment. For example, the pigeon would learn that it would receive food only if it pecked a food-dispensing lever a certain number of times; instead of randomly pecking at this lever it would then peck only the number of times necessary.

B.F. Skinner (1904–90).

This form of learning, instrumental or operant learning, was of three types. Positive reinforcement refers to pleasant reinforcers such as the attention or approval given to a child from a teacher. Punishment refers to a negative stimulus which is presented when a behaviour occurs (for example, a rat receiving an electric shock whenever it presses a lever). Negative reinforcement refers to a behaviour which reduces the likelihood of negative stimulation (for example, a rat pressing a lever to avoid electric shock).

Reinforcement could also occur according to scheduling. For example, fixed-interval reinforcement involved a reinforcer that was given only after a set time; fixed-ratio reinforcement involved a reinforcer that was given only after a predetermined number of responses. Examples of fixed-interval reinforcement include receiving a wage at the end of the week or a salary at the end of the month; an example of fixed-ratio reinforcement would be the delivery of payment after, say, a certain number of items had been produced in a factory or after a specific number of products had been sold. Chapter 7 takes up these ideas.

Unlike Tolman and Hull, however, Skinner did not propose any intervening variables. To him, the behaving person or pigeon or rat was an 'empty organism'. He argued that humans were machines which behaved in lawful and predictable ways and his system was almost entirely descriptive with little in the way of theory emerging from it. In addition to his scientific work, Skinner published a novel, *Walden Two*, in which he described the way in which radical behaviourism could operate (Skinner, 1948).

Psychologists, including modern behaviourists, have moved away from the strict behaviourism of Watson and Skinner; mental processes such as imagery and attention are again considered to be proper subject matter for scientific investigation. But Watson's emphasis on objectivity in psychological research remains. Even those modern psychologists who most vehemently protest against what they see as the narrowness of behaviourism use the same principles of objectivity to guide their research.

Genetic epistemology: Jean Piaget

While American approaches to psychology were dominated by the new behaviourism, a different approach to the study of cognitive function was being espoused in Europe. The Swiss psychologist Jean Piaget (1896–1980) became interested in the question of human knowledge and how we begin to acquire knowledge. He believed that answers to such questions could be obtained by empirical, scientific research and he would measure the development of the acquisition of knowledge in children by presenting them with intellectual tasks at various stages of their lives (in fact, Piaget had worked with Theophile Simon, the collaborator of the man who designed the first IQ test, Alfred Binet). Piaget termed his approach to psychology as **genetic epistemology**: the study of the origin of knowledge in child development.

Apart from Piaget's focus on the acquisition of knowledge in groups of individuals, another difference between his European approach and that of his American counterparts was the lack of interest in the applied nature of research. Questions regarding the possibility of improving or accelerating children's learning did not interest Piaget, nor did it interest other European researchers (Leahey, 2003). Although his work made little impact on psychology at the time, the subsequent circulation of his work – with translations of his books – led to a considerable interest in his research (Smith, 1996), so much so, that few psychologists have dominated the study of child development in the way that Piaget has. Piaget's contribution to our understanding of child cognition is assessed in Chapter 12.

Gestalt psychology: Max Wertheimer

The structuralism of Wilhelm Wundt was not the only German influence on the development of psychology. In 1911, a German psychologist, Max Wertheimer (1880–1943), bought a toy that presented a series of pictures in rapid succession. Each picture was slightly different from the one that preceded it, and the resulting impression was that of continuous motion, like a film. Wundt and his followers insisted that if we want to understand the nature of

human consciousness we must analyse it – divide it into its individual elements. But Wertheimer and his colleagues realised that the perception of a motion picture was not that of a series of individual still pictures. Instead, viewers saw continuity in time and space. They saw objects that retained their identity as they moved from place to place. Asking people to study these pictures one at a time and to describe what they saw (the structuralist approach) would never explain the phenomenon of the motion picture.

Wertheimer and his colleagues attempted to discover the organisation of cognitive processes, not their elements. They called their approach **Gestalt psychology**. *Gestalt* is a German word that roughly translates into ‘unified form’ or ‘overall shape’. Gestalt psychologists insisted that perceptions resulted from patterns of interactions among many elements – patterns that could exist across both space and time. For example, a simple melody consists of a pattern of different notes, played one at a time. If the melody is played in different keys, so that the individual notes are different, people can still recognise it. Clearly, they recognise the relations the notes have to each other, not just the notes themselves.

Although the Gestalt school of psychology no longer exists, its insistence that elements of an experience interact – that the whole is not simply the sum of its parts – has had a profound influence on the development of modern psychology. Gestalt psychology did not disappear because of some inherent fatal flaw in its philosophy or methodology. Instead, many of its approaches and ideas were incorporated into other areas of psychology. Gestalt psychology is discussed in more detail in Chapter 6.

Humanistic psychology

Humanistic psychology developed during the 1950s and 1960s as a reaction against both behaviourism and psychoanalysis. Although psychoanalysis certainly dealt with mental phenomena that could not be measured objectively, it saw people as products of their environment and of innate, unconscious forces. Humanistic psychologists insist that human nature goes beyond environmental influences, and that conscious processes, not unconscious ones, are what psychologists should study. In addition, they note that psychoanalysis seems preoccupied with mental disturbance, ignoring positive phenomena such as happiness, satisfaction, love and kindness. **Humanistic psychology** is an approach to the study of human behaviour that emphasises human experience, choice and creativity, self-realisation and positive growth. The father of humanistic psychology, Abraham Maslow (1908–1970), wrote: ‘What a man can be, he must be. He must be true to his own nature . . . [to a] desire to become more and more what one idiosyncratically is, to become everything that one is capable of becoming’ (1970, p. 46).

Humanistic psychologists emphasise the positive sides of human nature and the potential we all share for personal growth. In general, humanistic psychologists do not believe that we will understand human consciousness and behaviour through scientific research. Thus, the humanistic approach has not had a significant influence on psychology as a science. Its greatest impact has been on the development of methods of psychotherapy based on a positive and optimistic view of human potential.

The personality psychologists: Gordon Allport, Raymond Cattell, Hans Eysenck, Walter Mischel, Paul Costa and Robert McCrae

As the humanist movement was in full swing – or as swinging as it could manage – experimental psychologists had turned their attention to the scientific measurement of another important facet of behaviour: personality. This attention took the form of a search for universal **personality traits** – enduring personal characteristics which form a continuum along which we all fall. The earliest of these theorists was Gordon Allport (1897–1967) who, using dictionary terms as his starting point, suggested that personality comprised between 3 and 16 personality traits. Allport’s scheme formed the basis for the model devised by Raymond Cattell (1905–1998). He collected data from interviews and various questionnaires, concluding that 16 personality traits comprised the essence of personality.

A more parsimonious account, based on a statistical technique called factor analysis, was proposed by Hans J. Eysenck (1916–1997). In what was, until recently, one of the most widely accepted views of personality traits, Eysenck proposed that personality comprised three dimensions: neuroticism–stability, extraversion–introversion and psychoticism–normality, all of which had a biological basis. Each of us scores somewhere along all three dimensions. Meanwhile, influential American psychologists such as Walter Mischel (1930–) argued that traits did not exist and that, when we behave, we are reacting to changes in our environment or situation (this approach is called situationism): that we may respond in a consistent way lulls us into thinking that we possess something called ‘personality’, characterised by a number of traits. The debate continues, but the situationists seem to be fighting a losing battle. Substantial research supported Eysenck’s model but this was usurped in the 1980s by the Five Factor Model of Paul T. Costa and Robert R. McCrae. This, now the most widely accepted view of personality, argues that our personality comprises five traits which we possess to varying degrees: agreeableness, conscientiousness, extraversion, neuroticism and openness to experience. You’ll find more information on all of these approaches in Chapter 14.

The social psychologists

From the middle of the twentieth century there also appeared a phenomenal body of research into how we view and influence other individuals. Here, there are too many significant figures to mention but some of the most

prominent that contributed significant new data and models which helped us understand social behaviour include Leon Festinger, Albert Bandura, Stanley Milgram, Philip Zimbardo, Elliot Aronson, Robert Zajonc, Richard Nisbett and Edward Jones. All Americans or working in the US, these psychologists demonstrated how we could

hold two seemingly contradictory views (Festinger), how **deindividuation** could strip us of our humanity (Zimbardo), how observation of others makes us imitate them (Bandura), how we become obedient to authority (Milgram), how we interpret the causes of our own behaviour differently from how we interpret that of others (Nisbett, Jones), amongst other things. You'll find descriptions of their research and the impact this has had on our understanding of social behaviour in Chapters 15 and 16.

The cognitive revolution: beyond behaviourism

The emphasis on behaviourism in the first half of the twentieth century restricted the subject matter of psychology to observable behaviours. For many years, concepts such as consciousness were considered to be outside the domain of psychology. As one psychologist put it, 'psychology, having first bargained away its soul and then gone out of its mind, seems now . . . to have lost all consciousness' (Burt, 1962, p. 229).

In the decades that followed many psychologists protested against the restrictions of behaviourism and turned to the study of consciousness, feelings, memory, imagery and other private events (although behaviourism was still a potent force and continues to run through much of today's experimental psychology like marble).

Much of cognitive psychology uses an approach called **information processing** – information received through the senses is 'processed' by various systems in the brain. Some systems store the information in the form of memory, and other systems control behaviour. Some systems operate automatically and unconsciously, while others are conscious and require effort on the part of the individual. Because the information-processing approach was first devised to describe the operations of complex physical systems such as computers, the modern model of the human brain is, for most cognitive psychologists, the computer. As you will see in Chapter 7, another model (neural networks) is now being used as an alternative to the computer.

Although cognitive psychologists study mental structures and operations, they have not gone back to the introspective methods that structuralists such as Wundt employed. Instead, they use experimental methods, under controlled conditions, to test hypotheses and discover facts about how we think and remember. Cognitive psychologists such as Donald Broadbent, Stanley Schachter, Neal Miller, Don McClelland, Alan Baddeley, Ulric Neisser, Allan Paivio, Stephen Kosslyn, Endel Tulving, Elizabeth Loftus, Daniel Kahneman and Amos Tversky (the last two won the Nobel Prize for economics in 2002) discovered new and important data about how we learn to learn, remember and reason. You'll find their research in Chapters 8 and 11 but also throughout the book.

The biological revolution

Biology has always been closely tied to psychology and as psychology began to flourish, it was against a backdrop of some quite staggering discoveries in the physical science. For example, Descartes's hydraulic model of muscular movement was shown to be incorrect by Luigi Galvani (1737–98), an Italian physiologist who discovered that muscles could be made to contract by applying an electrical current directly to them or to the nerves that were attached to them. The muscles themselves contained the energy needed for them to contract. They did not have to be inflated by pressurised fluid. This discovery is the source of a modern-day technique for helping people recover from serious, paralysing illnesses and injury: the use of brain electrical activity to control objects such as a computer cursor or a prosthetic limb. There is a special Psychology in Action section on this technique in Chapter 4.

The brain and sensation: Johannes Müller

The work of the German physiologist Johannes Müller (1801–58) flags a definite transition from the somewhat sporadic, isolated instances of research into human physiology to the progressively more direct and precise exploration of the human body. Müller was a forceful advocate of applying experimental procedures to the study of physiology. He recommended that biologists should do more than observe and classify; they should remove or isolate animals' organs, test their responses to

chemicals, and manipulate other conditions in order to see how the organism worked. His most important contribution to what would become the science of

Johannes Müller (1801–58).

psychology was his **doctrine of specific nerve energies**. He noted that the basic message sent along all nerves was the same – an electrical impulse. And the impulse itself was the same, regardless of whether the message concerned was, for example, a visual perception or an auditory one. What, then, accounts for the brain's ability to distinguish different kinds of sensory information? That is, why do we see what our eyes detect, hear what our ears detect, and so on? After all, both the optic nerves and the auditory nerves send the same kind of message to the brain.

The answer is that the messages are sent over different channels. Because the optic nerves are attached to the eyes, the brain interprets impulses received from these nerves as visual sensations. You have probably already noticed that rubbing your eyes causes sensations of flashes of light. When you rub your eyes, the pressure against them stimulates visual receptors located inside. As a result of this stimulation, messages are sent through the optic nerves to the brain. The brain interprets these messages as sensations of light.

Müller's ideas have endured, forming the basis for investigations into the functions of the nervous system. For centuries, philosophers had identified thinking or consciousness as the distinguishing feature of the human mind and had concluded that the mind was located in the brain. Now the components of the nervous system were being identified and their means of operation were being explored.

Pierre Flourens (1794–1867), a French physiologist, provided experimental evidence for the implications of Müller's doctrine of specific nerve energies. He operated on animals, removing various parts of the nervous system. He found that the resulting effects depended on which parts were removed. He observed what the animal could no longer do and concluded that the missing capacity must have been the function of the part that he had removed. For example, if an animal could not move its leg after part of its brain was removed, then that region must normally control leg movements. This method of removal of part of the brain, called experimental ablation (from the Latin *ablatus*, 'carried away'), was soon adopted by neurologists, and it is still used by scientists today. Through experimental ablation, Flourens claimed to have discovered the regions of the brain that control heart rate and breathing, purposeful movements, and visual and auditory reflexes.

Brain damage and behaviour: Paul Broca and Carl Wernicke

One of the first people to apply the logic of Flourens's method to humans was Paul Broca (1824–80). In 1861, Broca, a French surgeon, reported the results of an

autopsy on the brain of a man who had suffered a stroke several years previously. The stroke (damage to the brain caused, in this case, by a blood clot) had caused the man to lose the ability to speak. The patient, whose real name was Leborgne, was called Tan because this was the only word he uttered. Broca discovered that the stroke had damaged part of the brain on the left side, as Figure 1.5 shows, although Marc Dax had reported similar findings earlier that century. Broca suggested that this region of the brain is a centre for speech – this part is now called Broca's area. Broca's work was followed, independently, by Carl Wernicke (1848–1905), who noted that damage to an adjacent part of the brain on the same side impaired his patient's speech comprehension and production. Chapter 10 has more on both of these language disorders and how psychologists still debate the areas which, if damaged, create problems in speech production and comprehension. Recent research, for example, suggests that the brain also needs to be injured outside Broca's area in order to see the deficit reported in his patient (Dronkers *et al.*, 2007).

Studying the effects of accidental brain damage on function has allowed neuroscientists to predict which regions of the brain may be involved in specific functions. One famous example of brain damage leading to speculation about the function of a brain region is that of Phineas Gage. Gage was a railroad construction supervisor who, in the mid-nineteenth century, had an accident at work. An iron rod shot through his face, through the front part of his brain and straight out of the top of his head. A reconstructed image of the trajectory of the rod through his skull can be seen in Figure 1.6a. Figure 1.6b is the only existing image of Gage (with the rod tastefully superimposed).

Figure 1.5 A photograph of Tan's brain. Note the egg-shaped cavity – this was thought to be responsible for his inability to speak fluently.

(a)

(b)

Figure 1.6 On a September afternoon in 1848, an unusual accident befell a young American railroad worker called Phineas Gage. An iron rod shot through his head as a result of an uncontrolled explosion at work. Almost 150 years later, Hannah Damasio and her colleagues at the University of Iowa took the medical reports of Gage's injury and plotted the course of the rod, using modern computer technology. (a) Shows one of the images of the rod's trajectory. (b) Shows a depiction of Gage himself.

Source: (a) From H. Damasio, T. Grabowski, R. Frank, A.M. Galaburda and A.R. Damasio, The return of Phineas Gage: Clues about the brain from a famous patient. *Science*, 1994, 264: 1102–05. Department of Neurology and Image Analysis Facility, University of Iowa. (b) From MIT:Bradford Macmillan, *An odd kind of fame*.

Whereas before the injury, Gage had been a hardworking and conscientious individual, after the injury he became boorish, unpleasant and unreliable. The part of the brain damaged seemed to be that responsible for inhibiting inappropriate behaviour. We now know that patients with damage to this part of the brain have difficulty in inhibiting such behaviour (there is more on this phenomenon in Chapter 13).

Localisation of function: Gustav Fritsch and Eduard Hitzig, Franz Gall and Johann Spurzheim

In 1870, the German physiologists Gustav Fritsch and Eduard Hitzig introduced the use of electrical stimulation as a tool for mapping the functions of the brain. For example, Fritsch and Hitzig discovered that applying a small electrical shock to different parts of the cerebral cortex caused movements of different parts of the body. In fact, the body appeared to be 'mapped' on the surface of the brain, so that the feet, hands, fingers and so on, had a part of the brain dedicated to them.

Originally, this work was conducted on dogs on Frau Hitzig's dressing table (because they had no available laboratory space). Such humble conditions gave rise to the first experiment in **localisation of function** in the brain – the goal of neuropsychology. No less elaborate, but ultimately doomed, was the attempt at localising function by Franz Gall (1758–1828) and Johann Spurzheim (1776–1832). Their anatomical personology – or as it is commonly known, phrenology – suggested that if we were very adept at a function the part of the brain responsible would be overactive. This overactivity caused an indentation in the skull. If a person was mathematically gifted, therefore, the part responsible for this would be active and cause a bump in the skull, which the experimenter could palpate. This hypothesis was beautifully testable and it was not long before the edifice came crashing down. It is, however, an attempt at localising function in the brain. Although Gall is best known for this, he also made more worthwhile contributions to neuroscience, such as identifying the importance of the left front part of the brain to speech.

Speed and magnitude of nerve impulses: Hermann von Helmholtz and Ernst Weber

A different and yet essentially physical approach to studying behaviour was also seen in the work of the German physicist and physiologist Hermann von Helmholtz (1821–94), who did much to demonstrate that mental phenomena could be explained by physiological means. This extremely productive scientist made contributions to both physics and physiology. He actively disassociated himself from natural philosophy, from which many assumptions about the nature of the mind had been derived. Müller, under whom Helmholtz had conducted his first research, believed that human organs were endowed with a vital immaterial force that coordinated physiological behaviour, a force that was not subject to experimental investigation. Helmholtz would allow no such assumptions about unproved (and unprovable) phenomena. He advocated a purely scientific approach, with conclusions based on objective investigation and precise measurement.

Hermann von Helmholtz (1821–94).

Until Helmholtz's time, scientists believed that the transmission of impulses through nerves was as fast as the speed of electricity in wires; under this assumption, transmission would be virtually instantaneous, considering the small distances that impulses have to travel within the human body. Helmholtz successfully measured the speed of the nerve impulse and found that it was only about 90 feet per second, which is considerably slower than the speed of electricity in wires. This finding suggested to later researchers that the nerve impulse is more complex than a simple electrical current passing through a wire, which is indeed true.

Helmholtz also attempted to measure the speed of a person's reaction to a physical stimulus, but he abandoned this attempt because there was too much variability from person to person. However, this variability interested scientists who followed him; they tried to explain the reason for individual differences in behaviour. Because both the velocity of nerve impulses and a person's reactions to stimuli could be measured, researchers theorised that mental events themselves could be the subject of scientific investigation. Possibly, if the proper techniques could be developed, one could investigate what went on within the human brain. Thus, Helmholtz's research was important in setting the stage for the science of psychology.

In Germany, a contemporary of von Helmholtz's, Ernst Weber (1795–1878), began work that led to the development of a method for measuring the magnitude of human sensations. Weber, an anatomist and physiologist, found that people's ability to tell the difference between two similar stimuli – such as the brightness of two lights, the heaviness of two objects, or the loudness of two tones – followed orderly laws. This regularity suggested to Weber and his followers that the study of perceptual phenomena could be as scientific as that of physics or biology. In Chapter 6 we consider the study of the relation between the physical characteristics of a stimulus and the perceptions they produce, a field called psychophysics, or the physics of the mind.

Cognitive neuroscience: the future of the biology of the 'mind'?

The cognitive revolution did not lead to a renewed interest in biology. But the extraordinary advances in neurobiology in the late twentieth century have revolutionised psychology. Neurobiologists (biologists who study the nervous system) and scientists and engineers in allied fields have developed ways to study the brain that were unthinkable just a few decades ago. We can study fine details of nerve cells, discover their interconnections, analyse the chemicals they use to communicate with each other, produce drugs that block the action of these chemicals or mimic their effects.

More importantly, using PET or (now, more commonly) fMRI, we can see the internal structure of a living human brain, and measure the activity of different processes of the brain – in regions as small as a few cubic millimetres – while people are thinking, feeling, perceiving, comprehending and moving (Martin, 2006; Raichle, 2008). One application of this technique can be seen in Figure 1.7 (a)–(b).

This combination of cognitive psychology and neuroscience – cognitive neuroscience – provides a different way of studying behaviour and describing its causes. Currently, the endeavours in cognitive neuroscience are, because of the nature of the techniques used, directed towards studying basic, yet essential, behaviour such as rudimentary reading, recognising emotion, remembering and speaking. But this is changing and studies are now using neuroimaging to study how people converse, make moral decisions, appreciate television programmes, react to a lover's face and voice and even understand magic tricks. You'll find a review of many of these studies in Chapter 4.

Conceptual and historical issues in psychology

As this chapter has shown you, understanding a discipline's past can help you better understand its present and its future. Understanding a discipline's past shows you the stages – usually chaotic, not linear or orderly – that psychology has gone through to reach the status it has attained today and the body of knowledge it has accrued. The shifts in approach and subject matter across its history will be reflected in its future shifts. But these shifts will be gradual. The danger in highlighting stages in history, as is done here, is that they are seen as discrete and self-contained. They are only discrete and self-contained because the prism of historical retrospection makes them so and we can reflect back, soberly, on some of the momentous conceptual and experimental changes that psychology underwent. We are currently amidst an extraordinary boom in neuroimaging work. In 50 years' time, all of this work may seem quaintly obsolete. We don't know.

Historical milestones are one thing. Conceptual issues are another. The trends and schools described here arose when researchers operated in a different world and context to that in which we operate today. Much – if not most – research conducted in universities is funded by government, and government has priorities. Will these priorities see a shift in the types of topics psychologists study in the future?

On a grander scale, conceptual issues can be virtually synonymous with philosophical issues. For example, the question 'Is the scientific method the best method for establishing truth?' is a philosophical, rather than a psychological question, because it doesn't have an absolute answer. When we have answers to questions, philosophy is dead. In the chapters that follow you should be able to see how the research they describe arose and in what context – how some of the work in social psychology emerged from real-life events, such as the apparent reluctance to assist a person crying for help, or a soldier saying he was only obeying orders, for example. Or how cross-cultural research on facial expression led to a theory of emotion. Or how research on race differences in IQ became controversial. Or how we classify and diagnose mental illness. Or how sociobiology, according to some views, reduces human beings to self-interested savages.

(a) Areas where normal readers show more activation than do dyslexic participants.

(b) Areas where dyslexic participants shown more activation than do normal readers.

Figure 1.7 Areas of activation in the human brain while it engages in language tasks. In this experiment, the reading performance and brain activation of dyslexic and normal readers are compared.

So far, you have seen how psychology is a discipline that comprises a number of different branches. This survey of the history of psychology reveals a number of methodological approaches to the study of behaviour. In

the next chapter you will see in more detail how psychologists study behaviour. You will also discover the dominant methodological approach to answering questions about psychology.

Chapter review

What is psychology?

- Psychology is the science of behaviour, and psychologists study a large variety of behaviours in humans and other animals.
- Psychology has many major branches:
 - Psychobiologists study the biological basis of behaviour.
 - Psychophysicists study people's physiological reactions, such as changes in heart rate and muscle tension.
 - Neuropsychologists study the relationship between central nervous system activity and structure and function.
 - Comparative psychologists study the evolution of behaviour by comparing the behavioural capacities of various species of animals.
 - Ethologists study the biological bases of behaviour through observation of animals in natural environments.
 - Sociobiologists attempt to interpret human and animal behaviour in terms of evolution and biological inheritance.
 - Behaviour geneticists study the degree of influence exerted by heredity and environment on behaviour.
 - Cognitive psychologists study complex human behaviours such as cognition, memory and attention.
 - Cognitive neuroscientists study the role of the human and animal brain in behaviour.
 - Developmental psychologists study the development of behaviour throughout the lifespan.
 - Social psychologists study the effects of people on the behaviour of other people.
 - Individual differences involves the study of the effects of specific characteristics or traits on behaviour.
 - Cross-cultural psychologists study the impact of culture on behaviour.
 - Forensic and criminological psychologists study the ways in which psychological knowledge can be applied in criminal and legal settings.
 - Clinical psychologists study the causes and treatment of mental disorders and problems of adjustment.
 - Health psychologists study the ways in which lifestyle and behaviour affect illness and health.
 - Educational psychologists assess the cognitive, social and emotional development of children in the school environment.
 - Consumer psychologists study what motivates people to consume and how consumers' perceptions are formed.

- Organisational or occupational psychologists study the behaviour of individuals and groups in the workplace.
- Ergonomists help to design machines and workplace environments that enhance work performance.

The development of psychology as a science

- Psychology has its modern roots in the thinking of the French philosopher and mathematician René Descartes who argued that the mind and the body were two separate entities which interacted (dualism).
- The mid-nineteenth century gave rise to materialism and empiricism. Materialism maintained that the mind was made of matter; thus all natural phenomena, including human behaviour, could be explained in terms of physical entities: the interaction of matter and energy. Empiricism emphasised that all knowledge was acquired by means of sensory experience; no knowledge was innate. The concept of empiricism was developed by the philosophers John Locke and David Hume.

Modern psychology

- The first laboratory of experimental psychology was established in Leipzig in 1879 by Wilhelm Wundt.
- Wundt and his colleagues' work gave rise to structuralism: the idea that the mind was made up of components which could be broken apart and studied. The method of studying these components was introspection – the observation and recall of experience.
- At about the same time, Ebbinghaus contributed important methods for objectively measuring learning and forgetting.
- Darwin's ground-breaking theory of evolution, or theory of natural selection, argued that traits necessary for survival would be inherited and that only those adaptively useful traits would survive.
- Francis Galton founded the scientific study of individual differences in human behaviour and suggested that certain psychological characteristics could be inherited.
- Functionalism, which grew out of Darwin's theory of evolution, was concerned with the processes of consciousness such as perceiving and learning. Its major advocates were William James and James Angell.
- Functionalism gave rise to behaviourism, founded by John Watson, which still dominates the way we do research. The

subject matter of behaviourism is observable behaviour; according to the behaviourists, mental events – because they were unobservable – should play no part in scientific psychology. Behaviourism developed a radical strain in the 1950s which viewed the organism's behaviour strictly in terms of stimulus and response.

- Humanistic psychology is concerned with the special nature of humanity and emphasises human experience, choice and creativity, and the potential for personal growth.
- The cognitive revolution arose from the belief that behaviourism's emphasis on observable behaviour missed some of the complexity of human cognition and behaviour. The cognitive

revolution saw a rekindling of interest in phenomena such as memory, thinking, creativity, imagination and so on, and human behaviour was interpreted in terms of information processing.

- The biological revolution in psychology manifested itself in the increased interest of psychologists in all fields – not just physiological psychology – in the role of biological factors in behaviour. This has given rise to cognitive neuroscience in which the disciplines of neuropsychology and cognitive psychology have combined and used neuroimaging methods to create a greater understanding of the role of the brain in thinking, feeling and perceiving, specifically to localise function in the brain.

Suggestions for further reading

The history of psychology

Crivellato, E. and Ribatti, D. (2007) Soul, mind, brain: Greek philosophy and the birth of neuroscience. *Brain Research Bulletin*, 71, 327–36.

Hock, R. (2009) *Forty studies that changed psychology* (6th edn). Harlow: Pearson Education.

Leahey, T.H. (2003) *A History of Psychology* (6th edn). Englewood Cliffs, NJ: Prentice Hall International.

Mandler, G. (2002) Origins of the cognitive (r)evolution. *Journal of History of the Behavioral Sciences*, 38, 4, 339–53.

Shepard, R.N. (2004) How a cognitive psychologist came to seek universal laws. *Psychonomic Bulletin and Review*, 11, 1, 1–23.

Several sources describe the history of psychology, including its philosophical and biological roots, and these are some very good introductions.

Concepts and controversies in psychology

Furnham, A. (1996) *All in the Mind*. London: Whurr Publishers.

Kassin, S., Briggs, K.H. and Tavis, C. (2008) *Current Directions in Introductory Psychology*. Boston: Allyn & Bacon.

Valentine, E.R. (1992) *Conceptual Issues in Psychology* (2nd edn). London: Routledge.

Excellent introductions to some of the controversial issues and the major concepts in psychology.

Influential psychologists

Cohen, D. (2004) *Psychologists on Psychology*. London: Hodder & Stoughton.

Fancher, R.E. (1996) *Pioneers of Psychology* (3rd edn). New York: W.W. Norton.

Kimble, G.A., Wertheimer, M. and White, C.L. (1991) *Portraits of Pioneers in Psychology*. Hillsdale, NJ: Lawrence Erlbaum Associates/American Psychological Association.

Cohen's book contains an excellent set of interviews with some of the leading psychologists of the time. The books by Kimble et al. and Fancher contain biographical sketches of the major scientists who have contributed to psychology and so provide a good potted introduction to the personalities (and themes, ideas and developments) in psychology.

Reflections on psychology's past and future

Fuller, R., Walsh, P.N. and McGinley, P. (1997) *A Century of Psychology*. London: Routledge.

Solso, R.L. (1997) *Mind and Brain Sciences in the 21st Century*. Cambridge, MA: MIT Press.

British Journal of Psychology, special issue, Supplement 1, April 2009.

The two books comprise a collection of chapters written by some of the last century's outstanding psychologists. Both are good books to read if you are interested in the leading scientists' assessment of psychology's past and their predictions of how psychology will develop in the future. The special issue of the British Journal of Psychology reprints some of the most influential research papers of the past 100 years, with commentaries.

Research methods in psychology

Explore the accompanying videos, simulations, and animations on MyPsychLab. This chapter includes activities on: Distinguishing independent and dependent variables • Personality testing • Ethics in Psychological Research • Descriptive statistics, finding the average • Check your understanding and prepare for your exams using the multiple choice, short answer and essay practice tests also available.

Clever Hans: A lesson in research methods

Because of his long-lasting fame at the turn of the century many people know about ‘Clever Hans’, the mind-reading horse. If people gave the owner a question for Hans, he would look directly at the horse and repeat the question in what seemed like a normal tone of voice. Hans would then lift his hoof and tap out the answer. Thus, if asked, ‘What is $2 + 2$ ’, Hans would tap the ground four times. After Hans had given the correct answer, the owner would reward the animal by patting it or give it food as a reward.

In 1904, several of the best-known scientists in Germany formed a ‘commission’ to study the animal. These distinguished scientists stated boldly that they could find no evidence that Hans was responding to external cues from his questioners and perhaps really could read minds. However, the psychologist on the commission, clearly not satisfied, told one of his graduate students to look into the matter.

The student put blinkers on Hans so the animal could not watch the people who were asking him the questions. The horse’s ability to respond correctly decreased significantly.

Clever Hans was, indeed, a ‘genius of a horse’ but was not a mind-reader. The animal was superb at reading ‘body language’ – cues that questioners almost always give to an animal. But these were so slight and so subtle that most people were completely unaware they were giving them. In this sense, the sceptics were right all along.

Source: Furnham, 1996, pp. 83–5.

WHAT YOU SHOULD BE ABLE TO DO AFTER READING CHAPTER 2

- Define and describe the scientific approach to studying psychological variables.
- Define concepts such as hypotheses, theories and variables.
- Have an awareness of the ethical principles adopted by psychologists.
- Describe the quantitative and qualitative approaches to psychology and be aware of the advantages and disadvantages of each.
- Have an awareness of how psychologists control variables.

QUESTIONS TO THINK ABOUT

- What is the scientific method and why is it so important to psychology?
- What are the goals of psychological research?
- Does following the steps of the scientific method guarantee that the results of a study will be important?
- Does the scientific method apply to all psychological research?
- How would you set up experiments to answer some of the questions you have about behaviour?
- How do the methods of psychology differ from those of other sciences? Do they?
- Why is obtaining informed consent from participants who take part in research important?
- Are some psychological subjects impossible to study? Why?
- What are the dangers in drawing conclusions from studies in which there is only one participant?

The process of discovery in psychology: the scientific method

The goal of psychological research is to discover, describe, explain and change the causes of behaviour. To do this, we need to describe behaviours and the events that are responsible for their occurrence in a language that is both precise enough to be understood by others and general enough to apply to a wide variety of situations. As you saw in Chapter 1, this language takes the form of explanations, which are general statements about the events that cause phenomena to occur. The nature of these general statements will become clear as we see how psychologists use the **scientific method**.

There are three major scientific approaches to research. **Naturalistic observations** – observations of people or animals in their natural environment – are the least formal and are constrained by the fewest rules. Naturalistic observations provide the foundations of the biological and social sciences. As Chapter 3 shows in detail, Charles Darwin's observation and classification of animals, plants and fossils during his voyage around the world provided him with the raw material for his theory of evolution. Jean Piaget collected much of his early data by observing his own children. **Correlational studies** are observational in nature, but they involve more formal measurement – of environmental events, of individuals' physical and social characteristics, and of their behaviour. Researchers examine the relations between these measurements in an attempt to discover the causes of the observed behaviours. **Experiments** go beyond mere measurement. A psychologist performing an experiment makes things happen and observes the results. As you will see, only an experiment can positively identify cause-and-effect relations.

The scientific method consists of a set of rules that dictates the general procedure a scientist must follow in their research. These rules are not arbitrary; they are based on logic. The following five steps summarise the rules of the scientific method that apply to experiments, the most rigorous form of scientific research. As we will see later, many of these rules also apply to observational studies. Some new terms introduced here without definition will be described in detail later in this chapter.

Stages in experimentation

- 1 *Identify the problem and formulate hypothetical cause-and-effect relations among variables.* This step involves identifying variables (particular behaviours and environmental and physiological events) and describing the relations among them in gen-

eral terms. Consider the hypothesis that positive mood increases creativity. This statement describes a relation between two variables – mood and creativity – and states that an increase in one causes an increase in the other.

- 2 *Design the experiment.* Experiments involve the manipulation of factors called independent variables and the observation of dependent variables (these are defined in detail later in the chapter). For example, if we wanted to test the hypothesis that positive mood (independent variable) increases creativity (dependent variable), each variable would have to be operationally defined. The independent variable must be controlled so that only it, and no other variable, is responsible for any changes in the dependent variable.
- 3 *Conduct the experiment.* The researcher must organise the material needed to perform the experiment, train the people who will conduct the research, recruit volunteers whose behaviour will be observed, assign each of these volunteers to a treatment group or a control group and arrange the setting for the experiment. The experiment is performed and the observations are recorded.
- 4 *Evaluate the hypothesis by examining the data from the study.* Do the results support the hypothesis, or do they suggest that it is wrong? This step often involves mathematical procedures used to determine whether the relationship between two variables is statistically significant, i.e. not due to chance.
- 5 *Communicate the results.* (See next section.)

Following these simple steps decreases the chances that we will be misled by our observations and come to incorrect conclusions from our research. The approach of formulating hypotheses and then setting up experiments to test them is sometimes known as **hypothetico-deductive**. As you saw in Chapter 1, and will see in Chapter 11, people have a tendency to accept some types of evidence even though the rules of logic indicate that they should not. The Cutting Edge box illustrates this, using a new study of the predictors of having the hepatitis B vaccine. This tendency usually serves us well in our daily lives, but it can lead us to draw the wrong conclusions when we try to understand the true causes of natural phenomena, including our own behaviour (the same tendency results in the making of common-sense mistakes when predicting the outcome of psychological research, as you saw in Chapter 1).

Communicating the results of scientific research

Once psychologists have learned something about the causes of a behaviour from an experiment or observational study, they must tell others about their findings. When a piece of research is complete, it is written up in

Cutting edge – Stories conquer statistics

Psychology, like all sciences, uses statistics to determine whether the results it finds are not due to chance. However, humans are less likely to believe statistics than they are convincing narratives: we find words more persuasive. There may be no evidence for a therapy working but a friend's positive experience of it may convince you to give it a go; there may be no statistical evidence that a multiple vaccination can cause autism, but parents will refuse to allow their children to become so vaccinated because of harrowing case studies allegedly demonstrating this link. Chapter 15 describes a few more of these errors in reasoning.

A study in *Health Psychology* has extended this phenomenon to the area of ill-health prevention (DeWit *et al.*, 2008). An online study examined the effects of narrative evidence and statistical evidence on men's perception of risk of contracting the hepatitis B virus and whether they would seek vaccination. All the participants were homosexual. As predicted, narrative evidence was more persuasive than statistical evidence in heightening awareness of the risk of contracting the illness and in predicting participants' intention to get vaccination.

the form of a journal paper and sent to an academic, peer-reviewed scientific journal. This means that the paper will be critically evaluated, usually anonymously, by two or three of the author's peers (the process is called 'peer review'). The editor and reviewer will be individuals with expertise in the author's field.

The scientific method insists that scientists report the details of their research so that other investigators can repeat, or replicate, the study. **Replication** is one of the great strengths of science; it ensures that erroneous results and incorrect conclusions are weeded out. When scientists publish a study, they know that if the findings are important enough, their colleagues will try to replicate it (perhaps with some variation) to be sure that the results were not just a statistical fluke, specific to the sample studied or the methods used, or the result of some unsuspected errors in the design or execution of the study.

The types of article that scientists will write fall broadly into four categories. First, there are empirical papers that report the conduct and results of an experiment. Most scientific journals publish papers of this kind (such as *Nature*, *Psychological Science*, *British Journal of Psychology*, etc.) and most follow a format. They will invariably comprise sections and these sections will include a title, an abstract, an introduction, the method, the results, a discussion, references and an appendix. There are deviations from this format: *Science* and the *Journal of Cognitive Neuroscience*, to name only two, do not adopt this structure (the study's methods are reported either at the end of the paper or on the journal's website). But, by and large, papers follow this structure:

- **Title (and affiliations).** The title describes the general thrust of the article. It is normally followed by the full names of all authors together with their affiliation (who they work for/on behalf of, e.g., 'Department of Psychology, Middlesex University, UK').
- **Abstract.** This is usually a 150–200 word paragraph that summarises ('abstracts' the information from) the article. It has a statement of intent, a brief description of the study and results and a general conclusion. Some abstracts have a different format and are sectioned in the same way as the paper: research suggests that this is a more informative way of summarising a paper.
- **Introduction.** This is the first of the four major sections of a paper. It reviews the literature pertaining to the subject of the paper and presents a set of hypotheses which the study aims to test.
- **Method.** This section describes what the experimenters did and who took part. Conventionally, this is divided into these subsections: participants, apparatus/materials and procedure. Under participants, all of the important information about the study's sample is included: age, sex, race, education and any other variable that the study is interested in. The apparatus/materials section includes details of any specialist technology or materials used. The procedure section describes what the experimenters did. Anyone reading this section should be able to conduct an identical experiment – facilities and time willing – on the basis of reading this section.
- **Results.** This section reports the results of the study. At this stage of your degree, reading the results section of a paper can seem like reading a foreign language because it is replete with impenetrable statistics.
- **Discussion.** The final major section, the discussion, discusses the results found and their implications for the field. It interprets findings in light of previously published data and suggests future avenues of enquiry.
- **References.** This section lists, usually in alphabetical order, all the studies cited in the text. Any study cited in the text should appear here and every item in the reference list should have been cited.

- **Appendix (optional).** Sometimes papers include appendices providing additional information such as word lists or questionnaires.

Secondly, in addition to journals that publish the results of experiments, there are also those that publish methodological papers reporting a new technique, questionnaire, procedure or new piece of equipment for use in psychological research. Thirdly, there are journals for theoretical papers that formulate a new theory arising from reviewed data. The journal *Psychological Review* is devoted to articles of this kind, for example. Finally, there are review papers that synthesise a number of articles on a given topic. *Psychological Bulletin* and *Current Direction in Psychological Science* publish papers exclusively of this

kind and are good journals for keeping abreast of general topics in psychology.

Most journals in psychology, however, tend to focus on the sub-areas of psychology. The *European Journal of Social Psychology*, *Memory and Cognition*, *Journal of Applied Psychology*, *Neuropsychologia*, *Child Development*, *Personality and Individual Differences*, *Health Psychology*, *Emotion*, and so on, are examples of this kind. Some journals publish even more specialised research (e.g. *Social Neuroscience*, *Laterality*).

Researchers also present their findings at conferences or professional conventions.

As a result of their research being disseminated, other psychologists can incorporate these findings in their own thinking and hypothesising.

Controversies in Psychological Science – Psychology and the media

The issue

The media are voracious beasts. Newspapers, television, radio and online sites all have space and air to fill, often with few resources. Psychology's asset, but also its Achilles heel, is that it studies a topic that most people think they know something about (human behaviour) and produces data that are fascinating and stimulate human interest. The BPS's Press Office has a media database of over 1,000 members, and receives around 350 queries a month. But how accurately is psychological and other research presented in the media and is this portrayal – skewed or otherwise – important?

The evidence

First, let's start with the source of the research. Simply because a paper is published in a science journal does not mean that its method or results are unassailable. At the extreme end, journals can publish data that turn out to be fraudulent. In 2005, the journal *Nature* found that 0.3 per cent of the 3,247 scientists who participated in their confidential study claimed to have published bogus data and 6 per cent admitted failing to publish data that contradicted their own theoretical positions. In the same year, *Science*, one of the two premier general science journals in the world, withdrew a paper by the Korean scientist Hwang Wo-suk because the stem cell lines he had created (and wrote about in *Science*) did not exist.

Another scandal broke in 2004 when the *Journal of Reproductive Medicine* published a physics-defying article on the effect of prayer on *in vitro* fertilisation which was generally agreed to be flawed and possibly fabricated. The author was later convicted of criminal fraud. In 2009, an anaesthesiologist was found to have made up most of the data in his 10-year publishing career, and, at the time of writing, editors

are being requested to withdraw 21 of his papers. This man researched the nature of pain management after operations – it was not a frivolous topic of little consequence. Even more seriously, flawed research claiming a link between the MMR vaccine and autism – and, more importantly, the enormously tendentious publicity this generated in 2002–3 – has caused completely avoidable harm to children, given the dramatic increase in measles and mumps following this hoo-hah.

Psychology is not immune. There continues to be debate over whether the British psychologist, Cyril Burt, invented his data concerning twins and intelligence. And, of course, there is the famous Sokal Hoax, in which a scientist submitted an utterly nonsensical anti-science article to a famously anti-objectivity social science journal and not only had it accepted but praised by the organ's clueless reviewers.

In experiments to examine whether the peer-review process works, researchers found that there is large variation in what reviewers judge to be quality research – reviewers can normally agree on the really bad studies, but there is more disagreement about the average-to-good ones. Science progresses by contradiction, and new articles develop ideas generated by previous publications or take into account variables that the previous studies had not. Although there are checks in place to weed out 'bad' research, it is common to see a lot of it published. This is why you should adopt an inquisitive but informed approach when reading research papers: do not be afraid to question an aspect of procedure or an analysis of logical thinking if you think it is wrong or misguided. You might be right.

While some of the stories you see reported or hear broadcast are well researched, balanced and informed it is generally the case that most are not. Journals are intended primarily for other scientists. Journals, however, are also consulted by medical or

Controversies in Psychological Science – *Continued*

science (or non-specialist) journalists interested in writing about innovative psychological breakthroughs. Conferences at which psychologists present the results of their studies are also extensively reported by specialist reporters in the media and some psychological societies have effective press offices which proactively publicise society conference papers.

However, never take any report you read in a newspaper or magazine or see or hear on the television or radio of a published study at face value. If you read the articles on the excellent website www.badsience.net, you will see why: journalists sometimes try to make a study more exciting than it is and make wild claims about the results that the researchers would never dream of doing. According to Goldacre (2008), ‘Science stories generally fall into one of three categories: the wacky stories, the “breakthrough” stories, and the scare stories. Each undermines and distorts science in its own idiosyncratic way’ (p. 208). Stories with headlines such as – and these are genuine – ‘Infidelity is genetic’, ‘Electricity allergy real’, ‘Scans that spot killer babies’ and ‘In future, all men will have big willies’ reflect a tenuous relationship with the data (if the data exist) they claim to report. Similarly, newspaper articles claiming to report the mathematical formula for (and, again, all of these are real) the perfect way to eat ice cream ($A \times Tp \times Tm / Pt \times At + V \times LT \times SP \times W / Tt = 3d20$, if you’re interested), the best sitcom, the best way to boil an egg, the best joke, the most depressing day of the year, are all bogus – they are not based on any real research or any real science. Most are commissioned by companies keen to harness the solid appeal of science to market their products.

The journalist Nick Davies, in his book *Flat Earth News*, describes the stories that boast none of the good features of journalism as ‘churnalism’: the writers parrot what is given to them by PR agencies or wire services, often unedited (Davies, 2008). In one survey, 80 per cent of British broadsheet news stories were ‘wholly, mainly or partially’ based on ‘material provided by news agencies and the PR industry’. This is not a trivial issue because most of us will have our first encounter with new studies, not from a studious acquaintance with Web of Knowledge or Science Direct, but from magazines, newspapers, television or radio. We rely on journalists – the conduit between us and the research – to present findings lucidly, accurately, interestingly and not to oversimplify the data or

misrepresent it. And the media has influence, through selecting what it exposes. After Kylie Minogue’s well-documented cancer, the *Medical Journal of Australia* reported a 40 per cent increase in mammogram bookings; in 2009, in the UK, stories reporting the terminal cancer of a female reality TV contestant appeared to coincide with an increase in cervical cancer checks. More self-servingly, the American Association for the Advancement of Science found that a mention of a researcher’s study in the *New York Times* increased the number of times his or her paper was referred to by other colleagues in their papers (this is an important indicator of impact in the science world). Television and radio exposure increased this still further.

One new field that gets both journalists and readers excited is neuroimaging. And the fact that you can illustrate a story involving the brain’s role in behaviour with a screen- and print-friendly brain scan makes the research even more appealing. But neuroimaging technology, and its data analysis, are complex and the studies using it very detailed in their method. Sometimes the details are sacrificed for a headline. Hence, stories screaming: ‘Scary or sensational? A machine that can look into the mind’ (genuine). Chapter 4 will take a further look at the role of brain scans and the way in which they make research more persuasive than a story with just words.

In rare circumstances, the authors (researchers and journalists) can collude. An excellent example of this was the so-called study reported in December 2005 – 2005 was clearly a good year for hoaxes – claiming that the success of Agatha Christie was attributable to her use of words and phrases that raised levels of chemicals in the brain (‘Agatha Christie grey cells mystery’ teased *The Sunday Times*). You would have thought that this study involved neuroimaging or analysis of readers’ brains. In fact, no. You would be hard pushed to find any brain research at all. The study – actually, an examination of the types of words used in Christie’s novels – was used to publicise a television documentary on Christie’s success. The only reference to brain activity in that programme came from a hypnotist and a self-help guru.

Conclusion

The important message of this story, and this section, is less complex than a Christie plot but as easy to understand as her prose: question everything.

Identifying the problem: getting an idea for research

According to Bausell (1993), psychologists undertake research for a wide variety of reasons – some sensible, some impracticable. Some of these include:

- changing distasteful professional practice;
- learning everything there is to know about a subject;
- discrediting a theory that is archaic or wrong;
- testing a theory to see if it is valid;
- lending credence to the experimenter’s own theory;

- furthering a career by producing a seminal study;
- furthering a career by obtaining a publication;
- obtaining a doctorate for professional gain;
- becoming famous;
- furthering scientific progress;
- discovering something of intellectual interest.

Which of these do you think makes the best, most realistic goal? Although scientists may undertake study for some or all of these reasons, it is unlikely that they will become famous through their scientific work. Very few scientists attract the fame (and pay) of members from more alluring professions. There are millionaires in psychology, but more in pop music.

Publishing a paper for personal gain is also a poor reason. Perhaps the two most important spurs to scientific research are the desires to further science and, more importantly, to discover something of intellectual interest. What do you need to become a good scientist? A great scientist certainly needs to be curious, hard working and dedicated – perhaps even obstinate and relentless. They need to be sceptical, open-minded and methodical. But above all, a successful scientist needs to have good ideas. Where do those ideas come from?

Constructing a hypothesis

A hypothesis is the starting point of any study. It is an idea, phrased as a general statement, that a scientist wishes to test through scientific research. In the original Greek, *hypothesis* means ‘suggestion’, and the word still conveys the same meaning. When scientists form a hypothesis, they are simply suggesting that a relation exists among various phenomena (like the one that might exist between increased positive mood and increased risk-taking). Thus, a **hypothesis** is a tentative statement about a cause-and-effect relation between two or more events. Productive and creative scientists formulate new hypotheses by thinking about the implications of studies that they have performed or that have been performed by others.

At other times, however, researchers may not know exactly what they expect to find. Such research endeavours are called ‘fishing expeditions’. In the same way that an angler may not know whether they will catch a trout or an old car seat, the researcher does not know whether they will find result X or result Y. An example of such research would be the measurement of people’s attitudes towards a particular subject such as animal experimentation or alternative medicine. In such cases, an experimenter would not be able to make an absolute prediction based on hypothetico-deductive reasoning (unless, for example, they compared attitudes among two groups such as vegans and meat-eaters, or users of conventional medicine and users of homoeopathic remedies).

Creating a theory

A **theory**, a set of statements designed to explain a set of phenomena, is an elaborate form of hypothesis. In fact, a theory can be a way of organising a system of related hypotheses to explain some larger aspect of nature. A good theory fuels the creation of new hypotheses. More accurately, a good scientist, contemplating a good theory, thinks of more good hypotheses to test. For example, Albert Einstein’s theory of relativity states that time, matter and energy are interdependent. Changes in any one will produce changes in the others. The hypotheses suggested by this theory revolutionised science; the field of nuclear physics rests largely on experiments arising from Einstein’s theory.

A good theory is one that generates testable hypotheses – hypotheses that can potentially be supported or proved wrong by scientific research. Some theories are so general or so abstract that they do not produce testable hypotheses and hence cannot be subjected to scientific rigour. The framework for most psychological research is larger in scope than a hypothesis but smaller in scope than a fully-fledged theory. For example, the frustration–aggression hypothesis in social psychology suggests that people (or other animals) tend to become aggressive when they do not achieve a goal that they have been accustomed to achieving. This hypothesis makes a prediction that might fit many different situations. Indeed, many experiments have been performed to test this hypothesis under different conditions.

Even though the frameworks that most psychologists construct fall short of constituting theories, they serve a similar function by stimulating researchers to think about old problems in new ways and by showing how findings that did not appear to be related to each other can be explained by a single concept. One recent theory of emotional experience, for example, suggests that increases or decreases in the left and right front part of the brain are associated with positive and negative emotions, reflecting a tendency to ‘withdraw’ or ‘approach’ a stimulus (Davidson and Sutton, 1995). Such a theory can be used to test a number of hypotheses such as, ‘depressed individuals will show less left frontal brain activity’ and research on frontal lobe activation and emotion has resulted in a modification of thinking on the relationship between the two (Peters and Harmon-Jones, 2009), as you’ll see in Chapter 13.

Quantitative research methods: designing an experiment

Although naturalistic observations enable a psychologist to classify behaviours into categories and provide hypothetical explanations for these behaviours, only an

experiment can determine whether these explanations are correct. This approach is known as **quantitative research** because behaviours are reduced to quantities or can at least be seen as quantifiable. Personality or visuospatial ability may be quantified by a score on a questionnaire, for example, or the ability to react correctly and quickly on a reaction time task may be quantified by the number of correct decisions and the speed of responding.

There are various types of experiment we can design. We could conduct an experiment in which we looked at the effect of sleep deprivation on mental arithmetic ability; one group might be deprived of sleep for 24 hours, another for 36 hours and another would be allowed to sleep normally. In a more elaborate study, we could use neuroimaging techniques to monitor changes in brain activation at each stage. In the neuroimaging study this would be the **control group** because it is unaffected by the features of the experiment that we are interested in looking at and can, therefore, be used as a comparison group. The others are called **experimental groups**. Because the individuals in one group are not the same people as the ones in another group, the design of the experiment is called **independent groups** or **between-groups**.

A slightly different experiment might involve people performing different levels of the same experiment. For example, we may be interested in finding out if people recognise real English words more quickly than they do pseudowords (words which follow the same rules of English but have no meaning) or non-words (words which do not follow the rules of English). This is called a lexical decision task. Here, every individual would respond to each type of word (but might be quicker responding to some types of word than others). Because each individual is exposed to the same condition of the experiment (each type of word), the design is called **repeated measures** or **within-groups**.

There are advantages to using both types of design: independent groups and repeated measures. For statistical reasons, it may be easier to obtain significant results by employing a repeated measures design because this approach eliminates the amount of variability that exists between data from different individuals. Because each participant acts as his or her control (that is, completes each condition in the experiment), there is less variability in the data (such as sex, age and personality differences or the ability to respond quickly to visual stimuli or the tendency to think better in the morning than in the afternoon, etc.).

Independent groups designs are advantageous when you do not want to expose the same individuals to the same conditions. For example, if we wanted to compare the effect of fat, carbohydrate and protein intake on people's ability to react quickly to visual stimuli (because

we hypothesised that certain foods made you drowsy), there would be disadvantages to having them all eat each different type of food (to begin with, if they were tested on different days, they may get better on the reaction time tasks because of practice; secondly, because different food is presented on each occasion, they may become suspicious). An independent groups design would help to eliminate these problems. Such designs are useful to medicine and the study of treatment for mental illness (as you will see in Chapter 18). A mentally ill group would take treatment A, another group treatment B, another group a placebo (we will come on to this later) and a final group would receive no treatment. If treatment A is successful, there should be a difference in outcome between this group and others in the study.

Imagine that you were a researcher who was interested in discovering whether people's cognitive ability declined with age. You take five groups of adults: 20–30-year-olds, 31–40-year-olds, 41–50-year-olds, 51–60-year-olds and the over-61-year-olds. You administer a series of tests which measures a range of cognitive abilities such as verbal and visuospatial ability. You find that whereas most of the over-61 group perform more poorly at most of the tests than do the other groups, they do better at some of the verbal tests such as vocabulary. What do you conclude from this study? If you conclude that verbal ability does not decline as rapidly as other abilities with age, you would be wrong. Can you think why? (The answer appears in Chapter 11.) Using the same example, what would be the theory and what would be the hypothesis in this experiment? What would be the independent and dependent variables?

Another approach to studying behaviour might be to conduct an experiment under laboratory or naturalistic conditions. In a laboratory experiment, the experimenter has control over most of the variables that they think will affect the outcome of the experiment. For example, we could design an experiment in which the effect of ambient noise on work performance was measured. We could expose individuals to specific noises at specific levels at specific times while they completed specific tasks and questionnaires assessing mood. Alternatively, we could set up a **field experiment** in which participants would be observed under fairly 'natural' conditions. For example, we might compare the effects of different office lighting conditions, or the weather, on individuals' mood and productivity.

The important feature of naturalistic observations is that the observer remains in the background and does not interfere with the people (or animals) being observed. In some cases, psychologists do interfere with a situation in a natural setting. For example, Chapters 15 and 16 describe some experiments designed to discover what factors determine whether bystanders come to the aid of people who have been hurt or who are in distress. An 'accident' is

staged, and the behaviour of passers-by is surreptitiously observed. Although studies such as these take place outside the laboratory – at job sites or on the street – they are experiments, not naturalistic observations. Such experiments might be called quasi-field studies.

Variables: what is studied and measured

Variables are things that have a particular value but which can vary. Scientists either measure or manipulate the values of variables. Manipulate literally means ‘to handle’ (from *manus*, ‘hand’).

Psychologists use the word ‘manipulate’ to refer to setting the value of a variable for experimental purposes. The results of this manipulation determine whether the hypothesis is true or false. Direct manipulation of an independent variable, for example, would involve placing individuals into different treatment groups, such as drug A, drug B, a placebo and no drug. Indirect manipulation would involve differentiating individuals with different personality types. For example, we might be interested in whether individuals low, medium or high in trait anxiety (the degree of anxiety they habitually feel) selectively attend to anxiety-related stimuli (such as pictures of snakes, spiders, blood and so on).

Or we might look at the effect of positive mood on risk-taking. We would assemble four groups of volunteers to serve as participants. We manipulate mood by having participants watch a comedy film (which would put participants in a positive mood), an unpleasant film (which would put participants in a negative mood) or a neutral film (which would not be expected to influence participants’ mood negatively or positively). We would have a fourth group which would watch no film (the control group). We would then examine the effect of this measure (mood) on risk-taking, such as the amount spent gambling at roulette (taking care, of course, to ensure that our ‘manipulation’ worked).

This experiment examines the effect of one variable on another. Here, the variable that we manipulate (mood) is called the **independent variable**. We could also have a second independent variable, such as the sex of the gambler (Do men or women gamble more? Would we have a good reason for hypothesising a sex difference?) The variable that we measure (risk-taking) is the **dependent variable**. An easy way to keep the names of these variables straight is to remember that a hypothesis describes how the value of a dependent variable depends on the value of an independent variable. Our hypothesis proposes that increased gambling depends on the individual’s level of mood. Suppose that you were interested in studying the effects of sleep deprivation on learning ability. Which of these two variables would be the independent

variable and which would be the dependent variable? How might you define these variables operationally? You can see the relationship between the two variables illustrated in Figure 2.1.

Sometimes, we want to understand the causes of behaviour in more than one specific situation. Thus, the variables that hypotheses deal with are expressed in general terms. Independent and dependent variables are categories into which various behaviours are classified. For example, we would probably label all of the following behaviours as ‘interpersonal aggression’: hitting, kicking, throwing something at someone. Presumably, these behaviours would have similar causes. A psychologist must know enough about a particular type of behaviour to be able to classify it correctly.

Although one of the first steps in psychological investigation involves naming and classifying behaviours, we must be careful to avoid committing the nominal fallacy or reification. The **nominal fallacy** refers to the erroneous belief that one has explained an event simply by naming it (*nomen* means ‘name’). Classifying a behaviour does not explain it; classifying only prepares us to examine and discover events that cause a behaviour. For example, suppose that we see a man frown and shout at other people without provocation, criticise their work when really it is acceptable, and generally act unpleasantly towards everyone around him. Someone says, ‘He’s really angry today.’ Does this statement explain his behaviour?

It does not; it only describes the behaviour. To say that he is angry suggests that an internal state is responsible for his behaviour – that anger is causing his behaviour. But all we have observed is his behaviour, not his internal state. Even if he is experiencing feelings of anger, these feelings still do not explain his behaviour. What we really need to know is what events made him act the way he did. Perhaps he has a painful toothache. Perhaps he had just learned that he was passed over for a promotion. Perhaps he had a terrible fight with his wife. Perhaps he had just read a book that advised him to be more assertive. Events like these are causes of both the behaviour and the feelings. Unless they are discovered, we cannot say that we have explained his behaviour. The

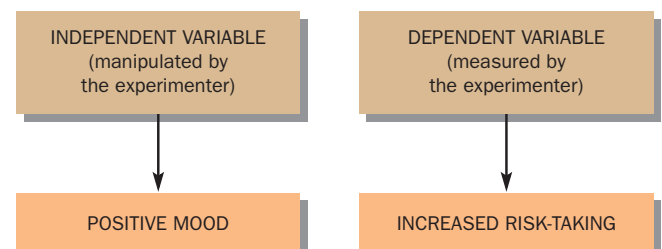

Figure 2.1 Independent and dependent variables described in the mood and risk-taking experiment.

task of a psychologist is to determine which of the many events that occurred before a particular behaviour caused that behaviour to happen.

Operational definitions

This translation of generalities into specific operations is called an **operational definition**: independent variables and dependent variables are defined in terms of the operations an experimenter performs to set their values or to measure them. In our proposed experiment, for example, the operational definition of the independent and dependent variables might be:

- Independent variable: participants' mood was induced by watching pleasant, neutral or unpleasant video films; a control group watched none of the films.
- Dependent variable: participants' risk-taking behaviour was measured by monitoring the amount of money spent betting on the outcome of a roulette wheel when the probability of winning was high and when it was low.

Providing an operational definition of variables is a hallmark of well-conducted research. If research is to be understood, evaluated and replicated by other people (step 5 of the scientific method described at the beginning of this chapter), the investigator must provide others with a thorough and adequate description of the procedures used to manipulate the independent variable and to measure the dependent variable. For example, a complete definition of the dependent variable (risk-taking) would have to include a detailed description of the type of gambling task and the probability of winning.

There are many ways to translate a general concept into a set of operations. We might decide to adopt a different measure of mood, such as having participants

complete a mental arithmetic task and inform them that they did well or badly (regardless of how they actually performed). This might also be expected to increase or decrease mood. We might choose a different measure of risk-taking such as asking participants to make decisions about a hypothetical risky treatment for a disease that they have (hypothetically) developed. Which operational definition of mood and risk-taking do you think is correct? Is there only one correct definition in this case? What these questions address is the issue of validity.

Validity

The **validity** of an operational definition refers to how appropriate it is – how accurately it represents the variable whose value has been manipulated or measured. You'll sometimes find the term 'ecological validity' being used: this refers to the degree to which the experimental context accurately presents that which the experimenter wants to reproduce. If you set up an experiment to monitor how much people laughed at a comedy, for example, and also measured their brain electrical activity and heart rate, which means attaching wires with electrodes to the head, fingers and chest, would this accurately represent the context in which a person would normally laugh at a comedy programme? The experience could be reasonably said to lack ecological validity.

Given enough time, the validity of an operational definition will emerge (or so we hope). If different investigators define the variable in slightly different ways but their experiments yield similar results, we become more confident that the research is leading to an understanding of the phenomena we are studying.

The issue of validity is illustrated, famously, by the Barnum effect. The Psychology in Action box tells you more.

Psychology in action – The Barnum effect

Research has shown that highly intelligent readers who are attracted to the boxed off sections of introductory psychology textbooks, have certain personalities. This personality evaluation is presented below – see how much or how little you disagree with it.

You are the type of person who has a tendency to be critical of yourself. You have a great need for other people to like and admire you but you pride yourself on being an independent thinker and do not accept others' statements without satisfactory proof. You have a great deal of unused capacity which you have not turned to your advantage. While you have some personality weaknesses, you are generally able to

compensate for them. You prefer a certain amount of change and variety and become dissatisfied when hemmed in by restrictions and limitations.

Does this description accurately reflect your own personality? It probably does. More than that, it probably applies to the majority of the population. These are universally valid statements which refer to nothing specific but to general feelings and beliefs that could apply to almost everyone. That most people believe that these vague personality descriptions accurately reflect their own personality is called the **Barnum effect** (Meehl, 1956). The phenomenon is named after Phineas T. Barnum, the great American circus showman, who declared

Psychology in action – Continued

The circus showman, P.T. Barnum, who gave his name to the Barnum effect.

Source: Popperfoto/Getty Images.

that there was a ‘sucker born every minute’ and believed that his entertainments provided ‘a little something for everybody’. The Barnum effect is seen clearly when individuals accept that ‘generalized, vague, bogus descriptions of themselves which have high base-rate occurrence in the general population’ are correct (Furnham and Schofield, 1987).

The phenomenon has a long history in psychology and a less honourable one among proponents of pseudoscience and pseudotherapy. Any clairvoyant or fortune-teller will make cunning use of the Barnum effect to dupe credulous punters. This is not surprising: people have been found to be more accepting of generalised feedback than actual, factual feedback (Merrens and Richards, 1970). A study of 68 personnel managers in the 1950s highlights the way in which we can accept the most vague statements about our personality as reflecting reality. Stagner (1958) administered personality tests to these managers and gave them 13 bogus statements that were assumed to represent actual feedback about their personality from the tests. The statements are listed in Table 2.1. See how many you agree with.

Table 2.1 The Barnum effect 1: personnel managers’ reactions to their ‘personality analysis’

	Judgements as to accuracy of item (% choosing)				
	Amazingly accurate	Rather good	About half and half	More wrong than right	Almost entirely wrong
You have a great need for other people to like and admire you	39	46	13	1	1
You have a tendency to be critical of yourself	46	36	15	3	0
You have a great deal of unused capacity which you have not turned to your advantage	37	36	18	1	4
While you have some personality weaknesses, you are generally able to compensate for them	34	55	9	0	0
Your sexual adjustment has presented problems for you	15	16	16	33	19
Disciplined and self-controlled outside, you tend to be worrisome and insecure inside	40	21	22	10	4
At times you have serious doubts as to whether you have made the right decision or done the right thing	27	31	19	18	4
You prefer a certain amount of change and variety and become dissatisfied when hemmed in by restrictions and limitations	63	28	7	1	1
You pride yourself as an independent thinker and do not accept others statements without satisfactory proof	49	31	12	4	4
You have found it unwise to be too frank in revealing yourself to others	31	37	22	6	4
At times you are extroverted, affable, sociable, while at other times you are introverted, wary and reserved	43	25	18	9	5
Some of your aspirations tend to be pretty unrealistic	12	16	22	43	7
Security is one of your major goals in life	40	31	15	9	5

Psychology in action – *Continued*

When asked to rate how strongly the participants agreed with these statements, almost all indicated that they believed them to some extent and one-third regarded their profile as a ‘good’ reflection of their character. For some statements such as, ‘You prefer a certain amount of change and variety . . .’, and ‘While you have some personality weaknesses . . .’, over 80 per cent of participants expressed agreement with them.

In an ingenious spin on the Barnum phenomenon, Furnham (1994) set up an experiment in which undergraduates gave samples of their hair to an experimenter. A week later the participants were given a ‘trichological analysis’ – 24 bland statements regarding their health based on the hair sample – that was totally bogus. Most students thought that these randomly applied statements were very accurate.

What does research on the Barnum effect tell us? First, it shows us that most individuals are inclined to accept bland feedback about themselves. Secondly, it shows us that the validity of a test involves more than intuitively ‘knowing’ that a test measures something. Most individuals – unless they knew about the Barnum effect – would have regarded the statements at the beginning of this section as true and might have accepted the statement that intelligent but sceptical readers are drawn to boxed-off areas of textbooks. This statement is, of course, nonsense. Thirdly, and perhaps most importantly, the Barnum effect shows us that we should always adopt a sceptical and questioning approach to statements made about human behaviour – even to this last statement.

Control of independent variables

If a scientist performs an experiment and finds that manipulating the value of the independent variable changes the dependent variable, the scientist can conclude that there is a cause-and-effect relation between the variables. That is, changes in the value of the independent variable cause changes in the value of the dependent variable.

In designing an experiment, the experimenter must manipulate the value of the independent variable and only the independent variable. For example, if we want to determine whether noise has an effect on people’s reading speed, we must choose our source of noise carefully. If we use the sound from a television set to supply the noise and find that it slows people’s reading speed, we cannot conclude that the effect was caused purely by noise. We might have selected an interesting programme, thus distracting the participants’ attention from the material they were reading. If we want to do this experiment properly, we should use noise that is neutral and not a source of interest by itself, for example, noise like the ‘sssh’ sound that is heard when an FM radio is tuned between stations.

In this example, we intended to test the effects of an independent variable (noise) on a dependent variable (reading speed). By using a television to provide the noise, we were inadvertently testing the effects of other variables besides noise on reading speed. We introduced unwanted variables in addition to the independent variable.

Schwartz (1999) cites a study showing that when respondents were asked to determine the causes of mass murder reported in newspapers, those doing so on notepaper headed ‘Institute of Personality’ cited more reasons related to personality whereas those doing so on notepaper headed ‘Institute of Social Science’ gave more

context-social related reasons for the crime. This example, and others in the review, shows that even small details in the conduct of research can influence respondents’ answers and thus affect validity.

Confounding and counterbalancing

One of the meanings of the word ‘confound’ is to fail to distinguish. If an experimenter inadvertently introduces one or more unwanted independent variables, they cannot distinguish the effects of any one of them on the dependent variable. That is, the effects of the variables will be confounded and this is called the **confounding of variables**. It is often difficult to be sure that independent variables are not confounded. We must be certain that when we manipulate the independent variable that variable only, and no other variable, is affected.

One method of addressing confounding variables is called **counterbalancing**, which means to ‘weigh evenly’. Imagine that an experimenter decided to investigate the effect of a memory-enhancing drug on people’s ability to remember concrete and abstract nouns. An experiment is designed in which three groups of people – one taking the drug, another taking a harmless pill and a control group which takes nothing – complete a word recognition experiment. For all groups, the concrete words are presented in the first part of the experiment and the abstract words are presented in the second half. To the experimenter’s surprise, although the drug group’s performance is better than the others’, all groups have more difficulty in remembering the abstract nouns. Does this finding mean that individuals find abstract nouns less memorable?

The answer is that, on the basis of the design of the experiment, we cannot know. Because the abstract words

always appeared in the second half of the experiment, it is possible that the groups simply felt more tired towards the end of the experiment and that their fatigue influenced their recognition scores; they may even have become more bored towards the end of the experiment. Perhaps, having been used to memorising concrete nouns, the shift to a different type of word interfered with the individuals' memory strategy. A solution would be to counterbalance the presentation of the types of word so that some individuals received the abstract nouns first followed by the concrete nouns whereas others received the concrete nouns first. If the original results were attributable to tiredness or fatigue then the same decrease in recall should be seen in the second half of the experiment. If individuals continue to recall abstract nouns less frequently than concrete nouns, then the result is not due to the effects of the confounding variables of tiredness and fatigue.

Having carefully designed a study, we must then decide how best to conduct it. This brings us to step 3 of the scientific method: performing the experiment. We must decide what participants will be used, what instructions will be given, and what equipment and materials will be used. We must ensure that the data collected will be accurate.

Reliability

If the procedure described by an operational definition gives consistent results under consistent conditions, the procedure is said to have high **reliability**. For example, measurements of people's height and weight are extremely reliable. Measurements of their academic aptitude (by means of standard, commercial tests) are also reliable, but less so.

Achieving reliability is usually much easier than achieving validity. Reliability is mostly a result of care and diligence on the part of researchers in the planning and execution of their studies. Alert, careful experimenters can control most of the extraneous factors that might affect the reliability of their measurements. Conditions throughout the experiment should always be as consistent as possible. For example, the same instructions should be given to each person who participates in the experiment, all mechanical devices should be in good repair, and all assistants hired by the experimenter should be well trained in performing their tasks. Noise and other sources of distraction should be kept to a minimum.

Another issue that affects reliability is the degree of subjectivity involved in making a measurement. In the experiment described above – the investigation of the effects of mood on creativity – our definition of mood was objective; even a non-expert could follow our procedure and obtain the same results. But researchers often attempt to study variables whose measurement is subjective, that is, it requires practical judgement and expertise.

For example, suppose that a psychologist wants to count the number of friendly interactions that a child makes with other children in a group. This measurement requires someone to watch the child and count the number of times a friendly interaction occurs. But it is difficult to be absolutely specific about what constitutes a friendly interaction and what does not. What if the child looks at another child and their gazes meet? One observer may say that the look conveyed interest in what the other child was doing and so should be scored as a friendly interaction. Another observer may disagree.

The solution in this case is, first, to try to specify as precisely as possible the criteria to be used for defining an interaction as friendly in order to make the measurement as objective as possible. Then, two or more people should watch the child's behaviour and score it independently, that is, neither person should be aware of the other person's ratings. If their ratings agree, we can say that the scoring system has high **interrater reliability**. If they disagree, interrater reliability is low, and there is no point in continuing the study. Instead, the rating system should be refined and the raters should be trained to apply it consistently. Any investigator who performs a study that requires some degree of skill and judgement in measuring the dependent variables must do what is necessary to produce high interrater reliability.

There are other ways in which a researcher can test the reliability of their data. For example, say that we wanted to examine whether an individual's responses on a personality questionnaire were reliable. One method of determining this might be to divide the questionnaire and compare the responses of the participant in each of the two sections of the questionnaire. If there is strong agreement between scores from each half, the questionnaire results are said to be reliable. This is called **split-half reliability** because the measure (the personality questionnaire) is split and responses to the two split parts compared.

But what if the questionnaire is too short for split-half reliability to be tested or the test measures many different factors (as an intelligence test does)? One way of testing reliability in such circumstances might be to administer the test at one session and then again at another session, some time apart. If the test is reliable, it should yield the same scores at the first as at the second session. This is called **test-retest reliability**. However, can you see a possible confound here? Imagine if you were to examine the test-retest reliability of an IQ test. The scores at the second session may be better because the participant has already undertaken the same test once. So, the test may be reliable but the data obtained from the test suggest that it is not. Can you think of a way of circumventing this problem? (Chapter 11, Intelligence and thinking, takes up this issue in more detail.)

Selecting participants

So far, we have dealt with what we, as researchers, would do – what hypothesis we would test, how we would design the experiment, and how we would obtain valid and reliable measurements. Now let us turn to the people who will participate in our experiment: our participants. How do we choose them? How do we assign them to the experimental or control group? These decisions must be carefully considered because, just as independent variables can be confounded, so can variables that are inherent in participants whose behaviour is being observed.

Consider the following example. A lecturer wants to determine which of two teaching methods works best. She teaches two courses in introductory psychology, one that meets at 9.30 a.m. and another that meets at 4 p.m. She uses one teaching method for the morning class and another for the afternoon class. At the end of the term she finds that the final examination scores were higher for her morning class. She concludes that from now on she will use that particular teaching method for all of her classes. However, there is a problem. Think about what this might be before you read the next sentence.

The two groups of participants for the experiment are not equivalent. People who sign up for a class that meets at 9.30 a.m. are likely to differ in some ways from those who sign up for a 4 p.m. class. Some people prefer to get up early whereas others prefer to sleep late. Perhaps the university sports department schedules some kinds of activity late in the afternoon, which means that students interested in participating in these activities will not be able to register for the 4 p.m. class. For many reasons, the students in the two classes will probably not be equivalent. Therefore, we cannot conclude that the differences in their final examination scores were caused solely by the differences in the teaching methods.

Of course, in the past ten years or so, researchers have also been exploiting the internet as a source of participants. It can be a quick and very effective way of recruiting large numbers of participants. It has advantages over paper-and-pencil (PP) versions of tests – the error rate is lower (electronic responses are more legible than written ones) and the response/take-up rate is higher. However, there is evidence that internet participants leave out more items on test inventories and choose the extreme ends of responding, selecting strongly agree/disagree more often than do PP participants.

All psychological experiments use samples – human or animal – and researchers usually know the type of sample they need. If they are testing the efficacy of a drug or the effectiveness of a type of rehabilitation following brain injury, for example, they include samples with specific characteristics. Most psychological researchers, however, recruit opportunity samples: people willing to give up their time and participate in research. But how representative are these opportunity samples? The Controversies in Psychological Science section takes up this topic.

Participants must be carefully assigned to the various groups used in an experiment. The usual way to assign them is by **random assignment**. One way to accomplish random assignment is to list the names of the available participants and then to toss a coin for each one to determine the participant's assignment to one of two groups. More typically, the assignment is made by computer or by consulting a list of random numbers. We can expect people to have different abilities, personality traits and other characteristics that may affect the outcome of the experiment, but if people are randomly assigned to the experimental conditions, these differences should – according to the principle of random sampling – be equally distributed across the groups.

Controversies in Psychological Science – How representative are samples in psychological research?

The issue

As a psychology student, you will inevitably be asked to participate in a psychology experiment. This may be part of your research methods or other course; or it may be an experiment run by your tutor or department. In fact, if you look at the method sections of scientific articles published in psychology, you will find that the majority of these reports recruit participants just like you: psychology students. This is a source of concern for some psychologists because the findings from such a group may not be representative of the behaviour of

other sections of the population. How representative, therefore, are examples in psychological research?

The evidence

In a study of recruits from undergraduate psychology classes who participate in psychology experiments, Quinones-Vidal *et al.* (2004) found that of all papers in the prestigious *Journal of Personality and Social Psychology* (a leader in its field) 92 per cent originated in the US and Canada and 99 per cent from Western countries.

Controversies in Psychological Science – Continued

Another study, which investigated the degree of over-representation of psychology students in psychology research published in the *British Journal of Social Psychology (BJSP)* and the *British Journal of Psychology (BJP)* in 1995 and 1996, found that of 107 studies 29 per cent used non-student adults and 15.9 per cent of the experiments were in a real-life environment (Banyard and Hunt, 2000). Twenty-eight per cent were based in a laboratory and 26.2 per cent were conducted in other parts of a university such as a lecture hall. Pressure to participate was evident in 58 per cent of the studies (students would take part to obtain course credit or because experiments were a course requirement).

Volunteers were used in 17.8 per cent of the studies. Over 70 per cent of papers in *BJSP* used self-report measures whereas over 50 per cent of *BJP* studies used laboratory-based measures. One-third of studies did not record how the sample was recruited and only 33 per cent of the 18,635 people who participated in the experiments were coded for their sex. Ethnicity was considered in only one study.

The study highlights some important points to remember when reading and explaining the findings of research (although this analysis was based on two journals published in two

years). The authors state that using students for research is acceptable but they query how representative this sample is.

The view is echoed in another study of ethnic representation among samples in applied psychology studies (Case and Smith, 2000). Case and Smith found that in 2,536 articles from 14 applied psychology journals taken in a 5-year period, almost 40 per cent indicated the ethnicity of the participant. In the articles that did include details of ethnicity, there was an over-representation of African Americans and an under-representation of Hispanic Americans (compared with the actual number of Hispanic people in the population).

Conclusion

‘Because psychological research must be relevant and appropriate for individuals from diverse ethnic backgrounds,’ the authors argue, ‘researchers must use samples that adequately represent diverse populations.’ They go on to argue that if we are to find out what works for whom, then we must include factors such as ethnicity in studies of psychological processes. When you read primary sources in psychology – journal articles – take some time to study the sample used and think of why the authors chose this sample.

Response bias... – An international perspective

Response bias – responding to a questionnaire in a way that is not genuine or honest but in an irrelevant way such as always responding ‘yes’ to a series of questions – is an important concept in research methods because it can skew results and tell researchers something which is not very meaningful. A Dutch study of six European countries has found that response bias varies by cultures.

Researchers used existing data from a multinational marketing survey to examine response bias in participants from Greece, Italy, Spain, France, Germany and the UK (Van Herk *et al.*, 2005). They found that unlike participants from north-western European countries, those from

Mediterranean countries showed an abnormally high tendency to agree than disagree with answers (acquiescence), and a greater likelihood to choose extreme response categories (e.g. selecting 1 or 5 on a 5-point scale). Greek participants, in particular, significantly exhibited these response biases. Spain and Italy scored higher on these two biases than did the UK, France and Germany. The British were the least acquiescent.

The authors suggest that such differences might reflect the different types of cultures in these countries: collectivistic versus individualistic. The more individualistic the societies were, the less acquiescent they seemed.

Researchers must remain alert to the problem of confounding subject variables even after they have designed an experiment and randomly assigned participants to the groups. Some problems will not emerge until the investigation is actually performed. Suppose that an experimenter was interested in learning whether anger decreases a person’s ability to concentrate. The experi-

menter acts rudely towards the participants in the experimental group, which presumably makes them angry, but treats the participants in the control group politely. After the rude or polite treatment, the participants watch a video screen that shows a constantly changing display of patterns of letters. Participants are instructed to press a button whenever a particular letter appears. This vigi-

lance test is designed to reveal how carefully participants are paying attention to the letters.

The design of this experiment is sound. Assuming that the participants in the experimental group are really angry and that our test is a valid measure of concentration, we should be able to make conclusions about the effects of anger on concentration. However, the experiment, as performed under real conditions, may not work out the way it was designed. Suppose that some of our 'angry' participants simply walk away. All experimenters are required to tell participants that they are free to leave at any time (and the section on ethics later in this chapter will tell you why); some angry participants might well do so. If they do, we will now be comparing the behaviour of two groups of participants of somewhat different character – a group of people who are willing to submit to the experimenter's rude behaviour and a group of randomly selected people, some of whom would have left had they been subjected to the rude treatment. Now the experimental group and control group are no longer equivalent. Figure 2.2 illustrates this.

The moral of this example is that an experimenter must continue to attend to the possibility of confounded variables even after the experiment is under way. The solution in this case? There probably is none. Because we cannot force participants to continue to participate, there is a strong possibility that some of them will leave. There is also the flip side to this problem, where participants will respond in an unnaturally positive way because this is what they believe the experimenter wants. For example, they may give answers on personality or other questionnaires that portrays them in the best light. This is called **social desirability**. As you will see in Chapters 15 and 16 (on social psychology), the relationship between

experimenter and participant is sometimes a complex one. Some psychological variables are, by their nature, difficult to investigate.

Participants' expectations

Participants in a psychology experiment are not simply passive participants whose behaviour is controlled solely by the independent variables manipulated by the experimenter. Participants know that they are being observed, and this knowledge is certain to affect their behaviour. This is sometimes known as the Hawthorne effect: the notion that the act of observation can change what it is you are observing. It derives from, ostensibly, a phenomenon that occurred in the Hawthorne Works of the Western Electric Company in Chicago in the 1920s and 1930s. The managers hypothesised that increasing the lighting conditions would increase productivity, which it did but this effect was short-lived. Productivity increases were seen when the lighting conditions changed, as if the workers were aware of the manipulation and worked harder (Adair, 1984). While the Hawthorne effect is not that well established (the name was given to the effect in a book published in 1953 and the original studies were never published; Chiesa and Hobbs, 2008), participants will behave as if an hypothesis is true if they find out the hypothesis. For example, Young *et al.* (2007) found that if people were given questionnaires on motion sickness to complete before they were exposed to virtual reality displays (which they were told might induce motion sickness), they reported more motion sickness than those who did not complete such questionnaires.

Because the study is being run by a psychologist, some participants are unlikely to take what they say at face value and will look for motives hidden behind an apparently simple task. Actually, most experiments are not deceptive at all; they are what they appear to be and 'deceptive' studies do not always succeed in fooling the participants. For example, suppose you are a participant in an experiment that was represented as being a learning study. On the table in front of you is an assortment of knives and pistols. The experimenter says, 'Oh, ignore them. Someone else left them here. They have nothing to do with this study.' Do you believe her? Probably not, and you will undoubtedly try to figure out how the presence of these weapons is supposed to affect your behaviour. You may suspect that the psychologist is trying to determine whether the presence of weapons will increase your hostility. With this suspicion in mind, you may (1) act naturally, so that you will not spoil the experiment; (2) act aggressively, to help the experimenter get the results you think she wants; or (3) act non-aggressively, to prove that you are immune to the effects of

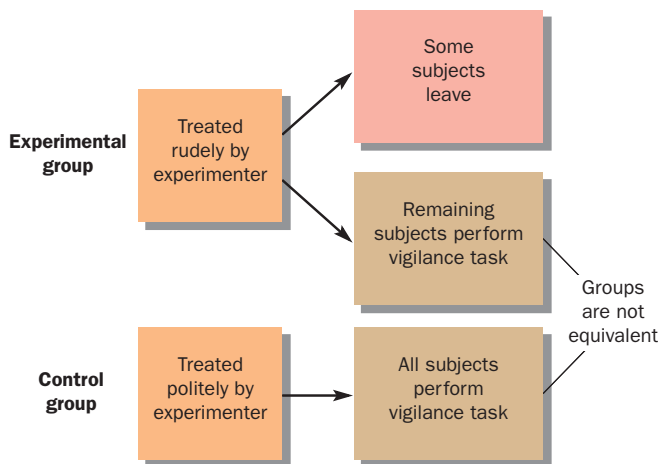

Figure 2.2 A possible problem with the anger and concentration experiment: loss of subjects from the experimental group.

objects associated with violence. The results of this study may not show the effects of the presence of weapons on aggression but, rather, show the relative numbers of people who select strategy 1, 2 or 3 in response to the knowledge that they are being observed.

Experimenters must always remember that their participants do not merely react to the independent variable in a simple-minded way. As Chapters 15 and 16 show, these considerations are especially important in social psychology experiments. In some of these studies, the experimenter or the experimenter's assistants act out roles designed to provide a particular kind of social situation to which the participants are exposed. Obviously, the participants' interpretation of these situations affects their behaviour.

Single-blind experiments

A special problem is posed by experiments in which participants' behaviour might be affected by their knowledge of the independent variable. Two methods of circumventing this problem are single- and double-blind experiments. For example, suppose that we want to study the effects of a stimulant drug, such as amphetamine, on a person's ability to perform a task that requires fine manual dexterity. We will administer the drug to one group of participants and leave another group untreated. We will count how many times each participant can thread a needle in a 10-minute period (our operational definition of fine manual dexterity). We will then see whether taking the drug had any effect on the number of needle threadings.

But there is a problem in our design. For us to conclude that a cause-and-effect relation exists, the treatment of the two groups must be identical except for the single variable that is being manipulated. In this case the mere administration of a drug may have effects on behaviour, independent of its pharmacological effects. The behaviour of participants who know that they have just taken amphetamine is very likely to be affected by this knowledge as well as by the drug circulating in their bloodstream. To solve this problem, we should give pills to the members of both groups. People in one group will receive amphetamine, and those in the other group will receive an inert pill – a **placebo**, from the Latin *placere*, 'to please'. A physician sometimes gives a placebo to anxious patients to placate them. Participants will not be told which pill they receive. By using this improved experimental procedure called a **single-blind study**, we can infer that any observed differences in needle-threading ability of the two groups were produced solely by the pharmacological effects of amphetamine. The placebo effect is a strong one – brain imaging studies have found that when people are given a placebo 'treatment' for pain, there is a reduction in the activation of brain areas involved in pain (Wager *et al.*, 2004).

Double-blind experiments

In a single-blind experiment, only the participants are kept ignorant of their assignment to a particular experimental group; the experimenter knows which treatment each participant receives. Now let us look at an example in which it is important to keep both the experimenter and the participants in the dark. Suppose we believe that if patients with mental disorders take a particular drug, they will be more willing to engage in conversation. The drug is given to some patients and a placebo is administered to others. We talk with all the patients afterwards and rate the quality of the conversation. But 'quality of conversation' is a difficult dependent variable to measure, and the rating is therefore likely to be subjective. The fact that the experimenters know which patients received the drug means that we may tend to give higher ratings to the quality of conversation with those patients. Of course, we would not intentionally cheat, but even honest people tend to perceive results in a way that favours their own preconceptions.

The solution to this problem is simple. Just as the patients should not know whether they are receiving a drug or a placebo, neither should the experimenter. That is, we should carry out a **double-blind study**. Someone else should administer the pill, or the experimenter should be given a set of identical-looking pills in coded containers so that both experimenter and patient are unaware of the nature of the contents. Now the ratings cannot be affected by any preconceived ideas the experimenter may have. The double-blind procedure does not apply only to experiments that use drugs as the independent variable. Suppose that the experiment just described attempted to evaluate the effects of a particular kind of psychotherapy, not a drug, on the willingness of a patient to talk. If the same person does both the psychotherapy and the rating, that person might tend to see the results in a light that is most favourable to their own expectations. In this case, then, one person should perform the psychotherapy and another person should evaluate the quality of conversation with the patients. The evaluator will not know whether a particular patient has just received psychotherapy or is a member of the control (untreated) group.

The expectations of experimenters can influence results in studies with laboratory animals as much as in studies with human participants. Rosenthal and Fode (1963) demonstrated the influence of expectations by having students train rats to learn the way through a maze. They told half the students that they had 'stupid' rats and the other half that they had 'smart' rats. In fact, there were no differences in the animals' abilities. However, an analysis of the results indicated that the 'smart' animals learned faster than the 'stupid' ones. The students' expectations clearly affected their rats' performances.

Presumably, the students who had ‘smart’ rats took better care of them, which affected the animals’ performances.

Correlational studies

To be certain that a cause-and-effect relation exists, we must perform an experiment in which we manipulate the independent variable and measure its effects on the dependent variable. But there are some variables, especially participant variables, that a psychologist cannot manipulate. For example, a person’s sex, genetic history, income, social class, family environment and personality are obviously not under the psychologist’s control. Nevertheless, these variables are important and interesting because they often affect people’s behaviour. Because they cannot be manipulated, they cannot be investigated in an experiment. A different method must, therefore, be used to study them: a correlational study.

The basic principle of a correlational study is simple: for each member of a group of people we measure two or more variables as they are found to exist, and we determine whether the variables are related by using a statistical procedure called correlation. Correlational studies are often done to investigate the effects of personality variables on behaviour. For example, we may ask whether shyness is related to daydreaming. Our hypothesis is that shy people tend to daydream more than people who are less shy. We decide how to assess a person’s shyness and the amount of daydreaming that they engage in each day, and we then take the measure of these two variables for a group of people. If shy people tend to daydream more (or less) than people who are not shy, we can conclude that the variables are related.

Imagine that we do find that shy people spend more time daydreaming. Such a finding tells us that the variables are related – we say they are correlated – but it does not permit us to make any conclusions about cause and effect. Shyness may have caused the daydreaming, or daydreaming may have caused the shyness, or perhaps some other variable that we did not measure caused both shyness and an increase in daydreaming. In other words, correlations do not necessarily indicate cause-and-effect relations.

A good illustration of this principle is provided by a correlational study that attempted to determine whether membership in the boy scouts would affect a person’s subsequent participation in community affairs (Chapin, 1938). The investigator compared a group of men who had once been boy scouts with a group of men who had not. He found that the men who had been boy scouts tended to join more community affairs groups later in life. The investigator concluded that the experience of being a boy scout increased a person’s tendency to join community organisations. However, this conclusion is not warranted. Can you see why? All we can say is that

people who join the boy scouts in their youth tend to join community organisations later in life. It could be that people who, for one reason or another, are ‘joiners’ tend to join the boy scouts when they are young and community organisations when they are older. To determine cause and effect, we would have to perform an experiment. For example, we would make some boys join the boy scouts and prevent others from doing so, and then see how many organisations they voluntarily joined later in life. Because we cannot interfere in people’s lives in such a way, we can never be certain that being a boy scout increases a person’s tendency to join community organisations later.

The news media often report the results of correlational studies. We are led to believe that because two variables are correlated, one event causes another. But this conclusion may not be true. For example, a news magazine reported a study in which small companies that make heavy use of computers were found to have productivity levels 2.5 times greater than companies that did not. Can we conclude that the heavy use of computers is the cause of the increased productivity? No, we cannot; correlation does not prove causation. Is it likely that the two types of small company (those that make heavy use of computers and those that do not) are identical in all other ways? Probably not. For example, companies that make heavy use of computers can afford to do so, and they can probably afford to make other investments that might increase productivity. In addition, these companies may also have managers who are up to date in other respects, and having modern ideas about other aspects of running a company may also improve productivity. The use of computers may indeed increase productivity, but the information presented does not permit us to come to this conclusion.

Can anything be done to reduce some of the uncertainty inherent in correlational studies? The answer is yes. When attempting to study the effects of a variable that cannot be altered (such as sex, age, socio-economic status or personality characteristics) we can use a procedure called **matching**. Rather than selecting participants randomly, we match the participants in each of the groups on all of the relevant variables except the one being studied. For instance, if we want to study the effects of shyness on daydreaming, we may gather two groups of participants, shy and non-shy. We select the participants in each group in such a way that the effects of other variables are minimised. We make sure that the average age, intelligence, income and personality characteristics (other than shyness) of the two groups are the same. If we find that, for example, the shy group is, on average, younger than the non-shy group, we will replace some of the people in the shy group with older shy people until the average age is the same.

If, after following this matching procedure, we find that shyness is still related to daydreaming, we can be more confident that the relation is one of cause and effect and that the differences between the two variables are not caused by a third variable. The limitation of the matching procedure is that we may not know all the variables that should be held constant. If, unknown to us, the two groups are not matched on an important variable, then the results will be misleading. In any case, even the matching procedure does not permit us to decide which variable is the cause and which is the effect; we still do not know whether shyness causes daydreaming or daydreaming causes shyness.

The strengths and limitations of correlational studies will become evident in subsequent chapters in this book. For example, almost all studies that attempt to discover the environmental factors that influence personality characteristics or the relation between these characteristics and people's behaviour are correlational.

Single-case studies

Not all investigations in psychology use groups of participants. **Single-case study research** explores the behaviour of individuals, and for some phenomena this method is very effective. Single-case study research can involve either experiments or correlational studies. Ebbinghaus's studies of memory, for example, were based on studies of individuals (usually, Ebbinghaus himself). Similarly, much of B.F. Skinner's work was based on small numbers of participants.

In a single-case study, psychologists can take advantage of events that have occurred outside their control and the most common of these are found in the field of neuropsychology. For example, a patient known as HJA was a businessman who had suffered a stroke and had consequently sustained damage to specific regions of his brain. HJA's behaviour after the damage was perceptually unusual. Although some aspects of his visual perception were preserved, he would have difficulty in recognising objects. For example, he would spend up to six hours making painstaking drawings of objects which he would be unable to name (Humphreys and Riddoch, 1987a, b). This is a disorder called **visual agnosia**, a specific deficit in the ability to perceive objects, described in more detail in Chapter 6. By conducting single-case studies of patients like HJA, psychologists can explore the behavioural consequences of unusual events or actions that the patient has suffered.

Single-case studies have contributed substantially to our knowledge of neuropsychology, the study of the relationship between the activity of the brain and its function, although this method has been criticised. For example, there is frequently no way of knowing for cer-

tain how an individual behaved before the accident; there is no control over the degree and type of injury; and there is the possibility that personal characteristics (such as medication use, sex, age, socio-economic status, IQ) could influence results (Shallice, 1988; Martin, 2006).

The single-participant research design (SPRD) does have advantages, however. One is that by continuously studying a participant over an extended period, we can be sure that the sample of behaviour that is measured is representative of the participant's typical behaviour. This also allows for easy replication although there are some studies which cannot be properly replicated – a learning intervention, for example, cannot be easily unlearned. The SPRD approach allows us to see the natural variability in the participant's behaviour – marked changes in behaviour that are not attributable to experimental manipulation. SPRDs also involve participants as their own controls, thereby reducing the individual difference that could account for differences between (and within) large groups.

Generalising from data

When we carry out an experiment or a correlational study, we probably assume that our participants are representative of the larger population. In fact, a representative group of participants is usually referred to as a **sample** of the larger population. If we study the behaviour of a group of 5-year-old children, we want to make conclusions about 5-year-olds in general. We want to be able to **generalise** our specific results to the population as a whole – to conclude that the results tell us something about human nature in general, not simply about our participants.

Many researchers recruit their participants from introductory courses in psychology because this is a convenient way of obtaining participants. The results of studies that use these students as participants can be generalised only to other groups of students who are similarly recruited. In the strictest sense, the results cannot be generalised to students in other courses, to adults in general, or even to all students enrolled in introductory psychology – after all, students who volunteer to serve as participants may be different from those who do not. Even if we used truly random samples of all age groups of adults in our area, we could not generalise the results to people who live in other geographical regions. If our ability to generalise is really so limited, is it worthwhile doing psychological research?

In reality we are not so strictly limited. Most psychologists assume that a relation among variables that is observed in one group of humans will also be seen in other groups as long as the sample of participants is not especially unusual. For example, we may expect data

obtained from prisoners to have less generality than data obtained from college students.

Application of psychological research

There is sometimes a distinction made in the sciences between applied and pure aspects of research. Pure research is research carried out for its own ends; the implications or consequences of such research are not known but it is designed simply to find out how something works or behaves (or does not). Applied research, on the other hand, is designed to have a practical application. Often in psychology (as in most other sciences), this dichotomy is false. Pure research can often have surprising practical applications: it depends on how creative the scientist is in finding such applications. Throughout this book, you will find examples of research that seems to fall into these categories. When you do, reflect on what you have read and try to see the point of having conducted that piece of research. The Psychology in Action sections in this book show how dry, academic, laboratory-based research can tell us much about how we behave ‘outside’ the laboratory. Should psychological research always have a practical outcome?

Qualitative analysis

The majority of research undertaken in psychology is empirical and quantitative. Another approach relies less on these types of data. Some researchers have argued that traditional quantitative techniques do not allow psychologists to explore the richness of human experience, feeling, thought and social interaction. They suggest that this richness is better measured by paying close attention to the ways in which people use words, express feelings and arguments and by allowing individuals to explore ideas in discussion. Themes and ideas can then be interpreted from transcripts of these discussions. This approach is called **qualitative analysis** and is concerned with ‘meanings, context and a holistic approach to material’ (Hayes, 1997). It is more popular in European research centres than in North America. The BPS’s Qualitative Methods Section was formed in 2006, for example, but a proposal for a new Division of Qualitative Inquiry was rejected by the American Psychological Association in 2008.

This approach is called phenomenological because the experience, reactions and feelings of the individual are considered to be of paramount importance. Originally, qualitative analysis emerged as a new paradigm in the 1970s called ethogenics which sought to provide a better method of investigation in psychology (Harré and Secord, 1972). The new approach placed great emphasis on

people’s use of language, especially the ways in which people accounted for their behaviour, thoughts and feelings: to understand real psychology meant analysing real talk (Foster and Parker, 1995) and this talk is, itself, ‘action’; we use words to convey some action (blame, sorrow, anger, etc.). The approach has been used to study the impact of a child’s serious illness on the family (Hopi *et al.*, 2005), how dietary regimes are viewed in people with type 2 diabetes (Peel *et al.*, 2005), and how doctor and patient interact with each other (McCabe *et al.*, 2002).

The emphasis in the qualitative approach is not on quantifying data (in many cases this is actively discouraged) but in exploring the quality of data in depth. Some qualitative analysts have insisted that this form of analysis should not involve any numbers or counting at all (Strauss and Corbin, 1990), although this strict criterion is not often adhered to. Many qualitative analyses draw attention to concepts involving quantity such as frequency of utterances. Another important distinction between qualitative and quantitative analysis is that the former views the researcher as being central to the analysis and the process of data collection: they may participate in or facilitate discussion and will analyse the data obtained from their research. The interpretation of the data is also undertaken by the researcher/interviewer.

The data for qualitative analysis usually come from group discussions or interviews and there are various methods for conducting qualitative analysis. Some of these are outlined below.

Structured and semi-structured interviews

Using the format of an interview to obtain information in psychology is not unusual. Many neuropsychological tests are administered by experimenters in an interview-type context. When such tests are administered, the researcher keeps to a strict ‘script’ in order to avoid influencing the performance of the respondent. In a sense, this is something like the format of a structured interview. The **structured interview** is conducted along predefined and predetermined lines with little scope for deviation from a script. The experimenter decides what they want to explore, with little variation between interviews. Many structured interviews may comprise an interviewer reading questions from a questionnaire and soliciting responses from an interviewee.

Sometimes, however, it may be interesting and informative to explore interviewees’ responses more deeply while keeping to some overall plan or structure. Semi-structured interviews provide such a possibility. The **semi-structured interview** allows the establishment of rapport with the interviewee by placing less emphasis on the order of questions, where the interviewer is free to

develop themes and issues raised by the interviewee and where open-ended questions are used. For example, whereas a structured interview might ask, 'Do you think that racism is caused by a, b, c or d?', a semi-structured interview might ask, 'What do you think are the causes of racism?' It is suggested that funnelling is a useful approach to semi-structured interviews: the interviewer elicits a general opinion and then probes more specific issues relating to this general view.

The semi-structured interview has proved to be useful to some qualitative analysts. Others, however, would argue that even a semi-structured format is too restrictive and that in order to elicit and understand genuine thoughts and feelings, you must allow discussion to occur freely (Hammersley, 2008). Such an approach is taken by discourse analysis.

Discourse analysis

Discourse analysis is a method which was developed in the mid-1980s to identify thoughts, feelings and themes from transcripts of data derived from conversations involving two or more individuals. Discourse analysis examines what people do with conversation and writing (Potter and Wetherell, 1995). Discourses themselves are linguistic repertoires (Potter and Wetherell, 1987) which vary according to context. The most detailed analysis of discourses would examine the use of sound and verbal devices in conversation as well as mechanisms of persuasion and argument (Edwards and Potter, 1992).

Discourse analysis places importance on the use of language and what people mean when they express themselves verbally (Billig, 1997). Such speech acts could be complicated and would require careful analysis in order to discover what was meant. Discourse analysis does not assume that attitudes are stable; in fact, it assumes that 'giving views' is relatively unstable and that a person can give one view to one person and a contrary view to another: context, therefore, is important to the interpretation of attitude. A teenage girl's attitudes towards social issues might be expressed differently to a parent and to a member of her peer group, for example (Billig, 1997). In Table 2.2, Billig outlines the typical discourse analysis which could be performed on these transcripts.

Transcripts should be read and reread; the analyst should begin to develop 'hunches' or intuitive understanding and they should, after rereading, create index categories of themes and major issues and of conversational details such as interruption or non-verbal agreement.

Conversation analysis

As the name suggests, **conversation analysis** involves the analysis of the content and use of conversation. The

Table 2.2 Suggested procedure for qualitative analysis

- Read background material about discursive psychology and topic of interest
- Decide on type of data to be studied
- Collect data
- Collect, listen to and transcribe tape-recordings
- Check the transcriptions against the tapes
- Read transcriptions
- Look for interesting features and develop 'intuitive hunches'
- Begin indexing themes and discursive features
- Write preliminary analysis, testing 'hunches' against data
- Draft and redraft analyses, making note of counter examples

assumption behind conversational analysis (CA) is that talk is action and that it is structurally organised. The focus is less on the content of the talk but on what people do with it – complaining, complementing, news-telling, turn-taking, and so on (Wilkinson and Kitzinger, 2008). Data are collected in 'naturalistic' environments – the researcher is not present and the participant is audio- or video-recorded. These data take the form of transcripts, complete with inbreaths, sound stretches, pauses and other example of oral punctuation. An example of how CA has been used to analyse how people use talk is seen in Table 2.3. This is a transcript of an exchange between two friends, Belle and Fanny, one of whom (Belle) has some bad news to break. Take a look at this exchange before reading on. Did you notice something unusual in the conversation? Although it was Belle who had bad news to break, it was Fanny who 'announced' the news. CA has revealed that we often do this – the recipient of bad news tends to be the one who raises the matter of bad news, whether it is a cancelled trip or a medical diagnosis (Drew, 1984; Maynard, 1992). In another example of the use of CA, Clayman and Heritage (2002) analysed 4,000 questions asked by journalists in US Presidential Conferences from 1950 to 2000, and found that the questions became less deferential and more combative over time.

Grounded theory

Grounded theory was one of the earliest attempts at qualitative analysis and involves establishing a set of strategies for the analysis of data and the construction of theory (Glaser and Strauss, 1967; Charmaz and Henwood, 2008). Individual cases, incidents or experiences are analysed and theories are derived from such analysis (Charmaz, 1990). Unlike discourse analysis, grounded theory actively attempts to develop theory from information obtained

Table 2.3 The format in which conversation is transcribed in conversation analysis. The first extract shows you a conversation between two friends, one of whom had bad news to break. The second is an exchange between a doctor and a patient which, again, involves the breaking of unwelcome news.

from transcripts of conversations. Theorising is made possible by painstaking line-by-line coding of transcripts, by memo-taking and by constructing categories (themes/patterns) from responses. The theory is therefore grounded in what the respondents have had to say. An example of the approach would be the exploration of the loss of self/the expression of self in patients who have suffered traumatic brain injury (Nochi, 1998).

Q methodology

One of the more complex of the qualitative techniques, Q methodology is also one of the most numerical and was first developed in the 1930s. It has been described as the systematic study of subjectivity and used to 'explore the subjective dimension of any issue towards which different points of view can be expressed' (Stenner *et al.*, 2008, p. 215). In this approach, data are collected in the form of Q-sorts: a collection of statements with which a participant agrees, disagrees or has no opinion about. A researcher might start with a clear question, such as 'What is your understanding of qualitative research?' and a number of items that represent this issue are devised (say around 100) and are given to students, qualitative practitioners and so on who sort them according to level of dis/agreement. A reduced number of around 60 will then be given to participants and each is rated on a 13-point scale for dis/agreement. The unique feature of Q methodology is that the person becomes the variable. Q methodology has been used in a number of contexts. One study found that the greater the disagreement about the causes of irritable bowel syndrome between the doctors and patients, the greater the patient's antagonism; the greater the agreement, the more positive the relationship (Stenner *et al.*, 2000).

Limitations of qualitative analysis

Qualitative analysis, although not widely used, has become a popular research tool in many areas of psychology where analysis can be used to explore issues such as attitudes to death, racism, the monarchy, sexual identity, chronic illness, work relationships and so on. Currently, qualitative analysis has had little impact outside these areas because of several perceived shortcomings. The most obvious, and difficult to reject, is that the process of qualitative analysis is subjective: the selection, analysis and interpretation of the material is made by the analyst. This introduces an element of bias into the study which could cloud an 'objective' analysis of the data. This argument is difficult to challenge effectively, although Hayes (1997) has suggested a 'half-way house' solution whereby a theory determined prior to the study may be used to guide later analysis. In this way,

the study has a pre-stated focus and direction but it also allows for unpredicted insights.

Hammersley (1992) has identified several examples of the perceived differences between qualitative and quantitative analysis. For example, it is assumed that the types of data analysed by the two methods are totally different; the environments in which studies take place are different; one focuses on meaning (qualitative), the other on behaviour; quantitative methods adopt natural science as a model whereas qualitative analysis rejects it; one is inductive, the other deductive; one seeks patterns, the other seeks laws and so on. Hayes (1997) has given an excellent account of how this dichotomy may be more imagined than real. For example, she argues that qualitative researchers do sometimes use measures of quantity and that quantitative methods are often applied in naturalistic settings. Qualitative analysts do use conversational analysis to study behaviour as well as meaning. Furthermore, the rejection of the natural science model assumes that all of the natural sciences adopt the same experimental approach. Of course, they do not. Hayes, therefore, argues that the dichotomy between the two types of research methods is not as great as it would appear. If you were to set up a study in which you wanted to explore people's attitudes to animal experimentation, say, which approach – qualitative or quantitative – would you think is best?

Ethics

Because psychologists must study living participants, they must obey ethical rules as well as scientific rules. Great care is needed in the treatment of human participants because we can hurt people in very subtle ways. The rules that govern psychologists' conduct during experiments have been set by governments, institutions or professional societies and all psychologists engaged in research must abide by them.

Research with human participants

In Europe, North America and elsewhere, research undertaken by hospitals and universities will have been vetted by an ethics committee, which decides on whether the proposed research meets the institution's ethical criteria regarding the welfare of human and animal participants in scientific research. Various professional societies such as the British Psychological Society (2006) and American Psychological Association (2002) issue guidelines for the treatment of humans and animals participating in research. In some countries, data may also fall within the remit of a data protection Act which, in its most general

form, allows an individual access to any information held electronically about them and, in research, allows the participant control over the use of such material.

The BPS lists a number of recommendations which its members should follow (British Psychological Society, 2006). These recommendations fall into the general categories of consent, deception, debriefing, withdrawal, confidentiality and protection of participants.

In general terms, a psychologist must treat participants with respect and must have taken all conceivable and practicable precautions to ensure that participants are not harmed. Threats to health, well-being, values and dignity should be eliminated.

Informed consent

An important part of any procedure designed to ensure the proper treatment of participants is informed consent. When possible, a psychologist should always inform the participant of the nature of the experiment and, having been told the detail of this research, the participant – if willing – will consent to take part. This represents **informed consent**. Of course, it is not always possible to secure informed consent because divulging all aspects of the experiment will influence the decisions, thoughts, feelings and behaviours of the participant. This is considered in more detail in the section on deception.

Usually, the potential participant reads a written statement prepared by the researcher. This discloses aspects of the research that might affect a person's willingness to participate in the study. The informed consent statement constitutes a contract between participant and researcher and is normally signed by both of them. Examples of these appear in Figure 2.3.

If participants are children, informed consent should be obtained from parents or guardians. The issue of child participation in research is an interesting one because, as you will see in Chapter 12, a child begins to grasp concepts and understand abstract ideas at certain periods in its development. This is the principal reason why parents or guardians consent to their children's participation on their behalf. A study from the University of Texas suggests that this is sensible because children often do not understand the purpose of an experiment or may not understand what confidentiality of a person's data means (Hurley and Underwood, 2002). Although the children understand some aspects better than others, they may continue to extend their trust to the experimenter.

As with healthy, normally developing child participants, if a child or an adult participant is mentally ill, is unable to communicate or is mentally retarded, then a parent, healthcare worker or guardian should be informed and consent obtained from disinterested independent advisers.

Attitudes of Mental Illness Study Informed Consent Form

Please read the following information carefully and before you sign this form please ask questions you may have about the 'attitudes to mental illness' study and your participation in it.

In this study you will be asked to rate your agreement/disagreement with a series of statements about mental illness, along a 7-point scale with 1 representing strong agreement and 7 representing strong disagreement. For example, if you strongly agreed with the statement 'I think that all mental illness is biological in origin', you would circle '1'. The study will take approximately 30 minutes to complete.

I fully understand the nature of the 'attitudes to mental illness study', that my participation is voluntary and that at any time I can terminate my participation without penalty. I am also aware that all my personal details and any information gathered about me will be kept confidential and will not be used for any purpose that is unrelated to the study. I understand that my data may be used to conduct analysis that may later be used for publication but that I will not be personally identifiable from these data

Signed _____ Date _____ (participant)

Figure 2.3 (a) An example of a consent form used in research.

If a researcher is undertaking observational research then the privacy and psychological well-being of the participant must be accounted for. Unless consent to being observed is obtained, participants should normally be observed only under conditions where they would expect to be observed by strangers.

Deception

Psychologists are advised never to withhold information or mislead participants if an individual is likely to be uneasy when eventually told the purpose of the experiment. Sometimes, however, withholding information or using misleading information is necessary for good scientific reasons. When this occurs, it must be undertaken after obtaining the sound advice and approval of an ethics committee and colleagues.

Debriefing

When participants take part in an experiment, the experimenter is obliged to disclose to the participant the real

HIGHFLYER UNIVERSITY DEPARTMENT OF PSYCHOLOGY Psychology of Learning Experiment

I confirm that I give my full and informed consent to participate in the above experiment. I understand that the information I provide will remain anonymous and disguised so that I may not be identified. I therefore give my permission for the results of this study to be published.

- (a) I understand that as part of this study I will be required to learn the works of Shakespeare.
- (b) I have been informed that the general aim of the study is to investigate learning strategies.
- (c) I have been informed that my general participation in this study will not involve unexpected discomforts or risks.
- (d) I have been informed that there are no disguised procedures in this experiment. The instructions can be taken at face value.
- (e) I understand that the experimenter will answer any questions that I have regarding the study once I have participated.
- (f) I understand that I am free to withdraw from the study at any time without penalty.

Concerns about the study may be directed to the Chair of the Ethics Committee, School of Psychology, HighFlyer University

Experimenter _____ Date _____

Participant _____ Date _____

Figure 2.3 (b) A second example, suggested by R.J. Sternberg (1988a).

and actual nature of the experiment and to answer any questions that the participant may ask about the experiment. This is called **debriefing**.

Withdrawal

If a participant feels that they have been unfairly misled or improperly treated, the participant has the absolute right to withdraw from the experiment. In fact, it should be made clear to all participants from the outset of the experiment that they are free to withdraw at any time, for whatever reason. The participant has the right to withdraw consent following the experiment or debriefing and request that their data be discarded or destroyed, or both.

Confidentiality

Laws of the land notwithstanding, information and data provided by the participant in research are confidential. If data are published then those of individuals should not be identifiable, unless consent has been obtained.

Protection of participants

Tied to the recommendations concerning consent and deception are those governing the protection of the partici-

pant, which are very similar. Psychologists have a primary responsibility to their participants to avoid harm (physical or mental) and if harm is identified, to remove it.

Controversies in Psychological Science – Can research with animals help us to understand human behaviour?

The issue

Although most psychologists study the behaviour of humans, some study the behaviour of other animals. When we use another species of animal for our own purposes, we should be sure that what we are doing is both humane and worthwhile. Evidence suggests that whereas students regard the use of animals in medical testing as being warranted, they are less likely to agree that animals should be used in psychological experiments (Furnham and Heyes, 1993). Can animal research in psychology, therefore, be humane and worthwhile?

The evidence

Humane treatment is a matter of procedure. We know how to maintain laboratory animals in good health in comfortable, sanitary conditions. For experiments that involve surgery, we know how to administer anaesthetics and analgesics so that animals do not suffer. Most industrially developed societies have strict regulations about the care of animals and require approval of the procedures that will be used in the experiments in which they participate. There is no excuse for mistreating animals in our care. In fact, the vast majority of laboratory animals are treated humanely because government departments ensure it.

Whether an experiment is worthwhile is more difficult to say. We use animals for many purposes. We eat their meat and their eggs and drink their milk; we turn their hides into leather; we extract insulin and other hormones from their organs to treat people with diseases; we train them to do useful work on farms or to entertain us. These are all forms of exploitation. Even having a pet is a form of exploitation: it is we – not they – who decide that they will live in our homes. The fact is, we have been using other animals throughout the history of our species.

Pet-owning causes much more suffering among animals than scientific research does. As Miller (1983) notes, pet owners are not required to receive permission to house their pets from boards of experts that include veterinarians, nor are they subject to periodic inspections to ensure that their homes are clean and sanitary, that their pets have enough space to exercise, and that their diets are appropriate. Scientific researchers are. Miller also notes that 50 times more

dogs and cats are killed by humane societies each year because they have been abandoned by their former owners than are used in scientific research.

The use of animals in research and teaching is a special target of animal rights activists. Nicholl and Russell (1990) examined 21 books written by activists and calculated the number of pages devoted to concern for different uses of animals. Next, they compared the relative concern the authors showed for these uses to the numbers of animals involved in each of these categories. The authors showed relatively little concern for animals used for food, hunting or furs or for those killed in pounds. However, although only 0.3 per cent of the animals were used for research and education, 63.3 per cent of the pages were devoted to this use. In terms of pages per million animals used, the authors showed 665 times more concern for research and education than for food and 231 times more than for hunting. Even the use of animals for furs (which consumes two-thirds as many animals as research and education) attracted 41.9 times less attention per animal.

Conclusion

Our species is beset by medical, mental and behavioural problems, many of which can be solved only through research involving animals. In fact, research with laboratory animals has produced important discoveries about the possible causes or potential treatments of neurological and mental disorders, including Parkinson's disease, schizophrenia, manic-depressive illness, anxiety disorders, obsessive-compulsive disorders, anorexia nervosa, obesity and drug addictions. Although much progress has been made, these problems are still with us and cause much human suffering. Unless we continue our research with laboratory animals, these problems will not be solved. Some people have suggested that instead of using laboratory animals in our research, we could use tissue cultures or computer simulations. Unfortunately, tissue cultures or computer simulations are not substitutes for living organisms. We have no way to study behavioural problems such as addictions in tissue cultures, nor can we program a computer to simulate the workings of an animal's nervous system. If we could, we would already have all the answers.

Chapter review

The scientific method in psychology

- The scientific method allows us to determine the causes of natural phenomena.
- There are three basic forms of scientific research: naturalistic observations, experiments and correlational studies.
- Hypotheses are statements or predictions made on the basis of naturalistic observations, previous experiments or from formal theories.
- Psychologists might conduct experiments in which groups are independent of each other, the individuals in one group are not the same as those in the other (independent groups design); or experiments in which the same individuals take part in all conditions of the experiment (repeated measures design).
- An independent variable is an event, factor or action that is manipulated by the experimenter; the dependent variable is the quantity measured in an experiment (and is hypothesised to be influenced by the independent variable). To perform an experiment, a scientist alters the value of the independent variable and measures changes in the dependent variable.
- A psychologist must specify the particular operations that they will perform to manipulate the independent variable and to measure the dependent variable.
- Operational definitions are a necessary part of the procedure by which a hypothesis is tested; they can also eliminate confusion by giving concrete form to the hypothesis, making its meaning absolutely clear to other scientists.
- Validity is the degree to which an operational definition produces a particular value of an independent variable or measures the value of a dependent variable.
- Reliability refers to the consistency and precision of an operational definition.
- Researchers achieve high reliability by carefully controlling the conditions of their studies and by ensuring that procedures are followed correctly. Measurement involving subjectivity requires researchers to seek high interrater reliability.
- When designing an experiment, experimenters ensure that they control extraneous variables that may confound their results. If an extra variable is inadvertently manipulated and if this extra variable has an effect on the dependent variable, then the results of the experiment will be invalid. Confounding of subject variables can be caused by improperly assigning participants to groups or by treatments that cause some participants to leave the experiment.
- Most participants in psychological research try to guess what the experimenter is trying to accomplish, and their conclusions can affect their behaviour. If knowledge of the experimental condition could alter the participants' behaviour, the experiment should be conducted with a single-blind procedure (where the

participant is unaware of the condition they are in). If that knowledge might also alter the experimenter's assessment of the participants' behaviour, a double-blind procedure should be used (where the participant and experimenter are unaware of the condition that the participant is in).

- Correlational studies involve assessing relations among variables that the researcher cannot readily manipulate, such as personality characteristics, age and sex. The investigator attempts to hold these variables constant by matching members in each of the groups on all relevant variables except for the one being studied. Correlational studies cannot determine which variable is the cause and which is the effect.
- Single-subject research consists of the detailed observation of individual participants under different conditions. Case studies involve careful observations of the behaviour of specific people, such as those with psychological or neurological disorders.
- Researchers are seldom interested only in the particular participants they study; they want to be able to generalise their results to a larger population. The confidence that researchers can have in their generalisations depends on the nature of the variables being studied and on the composition of the sample group of participants.
- Qualitative analysis involves the examination of individuals' expression of ideas, thoughts and feelings and is usually based on transcripts of discussion between individuals or between the experimenter and an individual/individuals.

Ethics

- Because psychologists study living organisms, they must follow ethical principles in the treatment of their participants. Professional societies run by and for psychologists develop ethical guidelines that require informed consent, confidentiality and a post-experiment debriefing.
- Participants may withdraw their consent to participate at any time before or during an experiment without any penalty. If deception is necessary, the experimenter must be certain that the participants will not be harmed psychologically or physically and that their dignity will be maintained.
- Committees review all psychological research before giving their consent for it to be carried out to ensure that these guidelines are met.
- Research that involves the use of laboratory animals is also guided by ethical principles. It is incumbent on all scientists using these animals to see that they are housed comfortably and treated humanely, and laws have been enacted to ensure that they are. Such research has already produced many benefits to humankind and promises to continue to do so.

Suggestions for further reading

Research methods: general reading

There are many books about research methods, design and analysis available. Some of them you probably would not want to read – they aren't the most riveting reads – but they serve a purpose in explaining how to do things. The best of research methods books, however, manage to engage you in the process of finding out how people behave. Some of these include the following:

Bausell, R.B. (1993) *Conducting Meaningful Experiments: 40 steps to becoming a scientist*. London: Sage.

Bausell's short book is a very well-written, straightforward account of what you need to know and to do in order to become a scientist. It is laid out in the form of principles (40 of them) which the author describes, explains and illustrates.

Foster, J.J. and Parker, I. (1995) *Carrying Out Investigations in Psychology*. Leicester: BPS Books.

Another text which approaches research methods from the psychologist's perspective and considers aspects of design not considered in more quantitative texts.

Robson, C. (2002) *Real World Research* (2nd edn). Oxford: Blackwell.

Robson's excellent, well-written book delivers a comprehensive account of how to conduct 'difficult' research (i.e. out of the laboratory).

Solso, R.L., Johnson, H.H. and Beal, M.K. (1998) *Experimental Psychology* (6th edn). Harlow: Longman.

Solso et al.'s text provides a lot of very useful information about tracking down materials and writing up research as well as analysing some real, published research section by section.

Critical thinking

Gabennesch, H. (2006) Critical thinking: What is it good for? *Skeptical Inquirer*, 30, 2, 36–41.

Martin, G. N. (2009) *Research and Study Update for Psychology* (3rd edn). Harlow: Pearson Education.

Matthies, B. (2005) The psychologist, the philosopher, and the librarian: The information-literacy version of CRITIC. *Skeptical Inquirer*, May/June, 49–52.

Meltzoff, J. (1998) *Critical Thinking about Research: Psychology and related fields*. Washington, DC: American Psychological Association.

Meltzoff's is an extraordinary book because instead of analysing real research articles for quality, the author has composed several fictitious ones to highlight flaws in the ways in which studies are conducted, analysed and reported. The first half of the book is an excellent introduction to research methods; the second half consists of the research articles with a critical analysis of each. Superb for helping you develop critical thinking skills. The papers by Matthies and Gabennesch give some sound advice on critical thinking, as does the Martin title.

Qualitative research

Smith, J.A. (2008) *Qualitative Psychology* (2nd edn). London: Sage.

Willig, C. and Stainton-Rogers, W. (2008) *The Sage Handbook of Qualitative Research in Psychology*. London: Sage.

Two relatively accessible texts on qualitative analysis.

Ethical issues in psychological testing

Francis, R.D. (2009) *Ethics for psychologists*. Oxford: Wiley-Blackwell

Gale, A. (1995) Ethical issues in psychological research. In A.M. Coleman (ed.), *Psychological Research Methods and Statistics*. London: Longman.

Hurley, J.C. and Underwood, M.K. (2002) Children's understanding of their research rights before and after debriefing: Informed assent, confidentiality and stopping participation. *Child Development*, 73, 132–43.

Lindsay, G. (1996) Psychology as an ethical discipline and profession. *European Psychologist*, 1, 2, 79–88.

Wilhelm, K. (2006) Do animals have feelings? *Scientific American Mind*, 17, 1, 24–9.

Gale's succinct chapter is a good introduction to ethics and psychological research. Lindsay's article considers the ethical basis for the development of 'ethical codes' in psychology (such as those adopted by the British, American and European psychologists' associations). Hurley and Underwood's paper considers the implications of child development for obtaining ethical consent and for testing with children.

Evolution, genetics and behaviour

Science finds the secret of a hot kiss

If you always thought you had a special chemistry with your loved one, you may finally have been proved right.

Researchers have found that a passionate kiss unleashes a complex surge into the brain which makes a lover feel excited, happy or relaxed.

There is also speculation that this hormone release may be triggered directly by an exchange of sexually stimulating pheromones in the saliva.

[The] research looked at the impact of kissing on levels of two hormones, oxytocin and cortisol, in 15 male–female couples before and after holding hands and before and after kissing.

This chapter includes activities on: Chromosomes • Dominant and recessive traits • Twin studies and adoption studies of heritability • The inheritance of Huntington's disease and Phenylketonuria • Check your understanding and prepare for your exams using the multiple choice, short answer and essay practice tests also available.

WHAT YOU SHOULD BE ABLE TO DO AFTER READING CHAPTER 3

- Describe Darwin's theory of evolution.
- Outline the principles of genetic inheritance.
- Evaluate the contribution of genetics to psychology.
- Describe and evaluate sociobiology and evolutionary psychology's contribution to our understanding of behaviour.
- Discuss some of the reasons why we are sexually attracted to certain body types.
- Describe the psychological and evolutionary significance of altruism.

QUESTIONS TO THINK ABOUT

- What do you think is meant by the term 'evolution of behaviour'?
- When did the modern human being evolve?
- What are the implications of the theory of evolution for psychology?
- How do you think the process of evolution could explain modern behaviour such as romantic attraction, jealousy, language and marriage?
- Are we attracted to certain body types? If so, why?
- Why do you think that we have become more intelligent and sophisticated than our ancestors?
- What do you understand by the terms 'genetics' and 'heredity'?
- Does culture or genetics have the greater influence on behaviour? Is the question an important one to ask?
- Are there any behaviours that can be unaffected by genetics?
- Why can we be altruistic and are we more altruistic to certain people than others?

The development of evolutionary theory

From my early youth I have had the strongest desire to understand and explain whatever I observed, that is, to group all facts under some general laws. . . . Therefore, my success as a man of science, whatever this may have amounted to, has been determined, as far as I can judge, by complex and diversified mental qualities and conditions. Of these, the most important have been – the love of science – unbounded patience in long reflecting over any subject – industry in observing and collecting facts – and a fair share of invention and common sense. With such moderate abilities as I possess, it is truly surprising that I should have influenced to a considerable extent the belief of scientific men on some important points.

Source: Darwin, 1887, pp. 67–71.

These fairly humble words were written by a man who has influenced the course of scientific thought more than any other individual since Copernicus (who, in 1543, proposed that the sun, not the earth, was at the centre of the universe). Charles Darwin argued that, over time, organisms originate and become adapted to their environments by biological means. This concept is referred to as **biological evolution** – changes that take place in the genetic and physical characteristics of a population or group of organisms over time – and it stands as the primary explanation of the origin of life (Dawkins, 1986). The bicentenary of Darwin's birth was marked in 2009, together with the 150th anniversary of the publication of one of the most important books published in the past 300 years – *On the Origin of Species by Means of Natural Selection*. In this book, Darwin distilled his theory of evolution.

There is evidence of life on earth a billion years after the formation of the earth 4.5 billion years ago (Eiler, 2007) and the human race has existed, in various forms, for over 10 million years. This time-span has seen a tremendous change in our physical appearance, our biology and our behaviour. Our brains have developed, our societies have become more sophisticated, our intelligence has increased, our ability to communicate has improved, we have developed language systems. These processes illustrate the ways in which we have evolved and evolutionary theory seeks to explain why we have evolved in the way that we have. Why do birds have wings, giraffes have long necks, humans have bigger brains than other higher primates? How do changes in organic structure

occur and how does this happen? The answers to questions such as these have important implications for the topics discussed in other chapters in this book: intelligence, personality, social interaction, the use of language, the perception and expression of emotion, sex, hunger, mental disorder and so on.

Although it has its roots in biology, Darwin's work transcends biology and has influenced all the natural sciences, especially psychology (Dewsbury, 2009). In fact, Darwin himself had some aspirations for the young science. He wrote in 1859.

In the distant future, I see open fields for more important researches. Psychology will be based on a new foundation, that of the necessary acquirement of each mental power and capacity by gradation. Much light will be thrown on the origin of man and his history.

Since the 1970s, some psychologists have become increasingly aware of the various ways in which biology can influence behaviour. As you will see later in the chapter, many behavioural differences among organisms, both within and across species, correspond to genetic and other biological differences. Understanding these differences and their evolution allows psychologists to understand behaviour in terms of its possible origins and **adaptive significance** – its effectiveness in aiding the organism to adapt to changing environmental conditions.

For example, gregariousness is the tendency to form groups or to be sociable; people tend to form social units. We live in families, have circles of friends, and join groups, such as churches, clubs or professional or recreational societies and political organisations. To understand the adaptive significance of gregariousness, we need to consider two questions. First, what events and conditions in a person's lifetime might contribute to an individual's gregariousness – what function does gregariousness serve in helping people adapt to the changing circumstances of life? Secondly, what events and conditions in the evolution of our species favoured gregariousness – what functions has gregariousness served in the history of humankind? These are important questions because a complete understanding of gregariousness, like any behaviour, requires that we understand both the past and present conditions that influence it.

In other words, psychologists might research how past environmental conditions favoured gregariousness over a more solitary existence as a means of organising human culture and how the immediate environment influenced day-to-day sociability. They are interested in understanding both **ultimate causes** (from the Latin *ultimatus*, 'to come to an end') of behaviour – events and conditions that, over successive generations, have slowly shaped the

behaviour of our species – and **proximate causes** (from the Latin *proximus*, ‘near’), namely immediate environmental variables that affect behaviour.

By understanding how adaptive behaviour developed through the long-term process of evolution, psychologists are able to gain a more thorough understanding of our ability to adjust to changes in our immediate environment. To understand the present, we must understand the past – the history of the individual and the history of our species. We behave as we do because we are members of the human species – an ultimate cause – and because we have learned to act in special ways – a proximate cause. Both biology and environment contribute to our personal development.

Relatively recently, a field of psychology has emerged, **evolutionary psychology** (Tooby and Cosmides, 1989; Buss, 1995), which attempts to describe and explain how an organism’s evolutionary history contributes to the behaviour patterns and cognitive strategies it uses for reproduction and survival during its lifetime. Evolutionary psychology’s contribution to our understanding of human behaviour is assessed later in the chapter. First, however, we describe Darwin’s theory of evolution. An understanding of this complex theory will help shed light on how behaviour has been interpreted, by some psychologists, in terms of evolution.

In the beginning: the voyage of the *Beagle*

The story of how Charles Darwin developed his theory illustrates the mix of hard work, intellect and good fortune that often makes scientific discovery possible. In fact, Darwin’s work is an excellent example of how observation and experimentation can lead to scientific breakthroughs.

After receiving a degree in theology from the University of Cambridge, England, in 1831, Darwin met a Captain Robert FitzRoy who was looking for someone to serve as an unpaid naturalist and travelling companion during a five-year voyage on board HMS *Beagle*. The *Beagle*’s mission was to explore and survey the coast of South America and to make longitudinal measurements worldwide.

During the voyage, Darwin observed the flora and fauna of South America, Australia, South Africa and the islands of the Pacific, South Atlantic and Indian Oceans. He collected creatures and objects of every sort: marine animals, reptiles, amphibians, land mammals, birds, insects, plants, rocks, minerals, fossils and seashells. These specimens, which were sent back to England at various stages of the trip, were later examined by naturalists from all over Europe.

Darwin did not form his theory of evolution while at sea. Although he was impressed by the tremendous amount of diversity among seemingly related animals, he believed in creationism, the view that all living things were designed by God and are non-evolving (Gould, 1985).

Charles Darwin (1809–82).

The Origin of Species

Upon his return home to England in 1836, Darwin continued to marvel at the many ways animals and plants adapt to their environments. He sifted through his collections, often discussing his findings and ideas with other scientists. He carefully reviewed the work of earlier naturalists who had developed their own theories on evolution. Darwin was not the first person to propose a theory of evolution, but he was the first to amass considerable evidence in its favour. He became interested in artificial selection, a procedure in which particular animals are mated to produce offspring that possess desirable characteristics. For example, if a farmer wished to develop cattle that yielded the largest steaks, then they would examine the available breeding stock and permit only the ‘beefiest’ ones to reproduce. If this process is repeated over many generations of animals, the cattle should become beefier. In other words, in artificial selection, people select which animals will breed and which will not based on specific, desirable characteristics of the animals.

As he pondered on whether there might be a natural process corresponding to the role that humans play in artificial selection, Darwin’s views on evolution began slowly to change. He believed that ‘selection was the keystone of man’s success in making useful races of animals and plants. But how selection could be applied to organisms living in a state of nature remained for some time a mystery to me’ (Darwin, 1887, p. 53).

A year-and-a-half later, on reading Malthus’s *Population*, Darwin proposed that because the ‘struggle for existence’ continued in plants and animals, then

favourable variations would be preserved and unfavourable ones would die out. The result of such 'selection' would be the development of new species (Darwin, 1887).

This proposal contains the idea of natural selection: within any given population, some members of a species will produce more offspring than will others. Any animal that possesses a characteristic that helps it to survive or adapt to changes in its environment is likely to live longer and to produce more offspring than are animals that do not have this characteristic.

Darwin was well aware of the significance of his discovery but did not publish his theory until 20 years later, taking great pains to develop a clear, coherent and accurate case for his theory.

Darwin might have been even slower in publishing his theory had it not been for an intriguing coincidence. In 1858, he received a manuscript from the Welshman, Alfred Russell Wallace, another naturalist, outlining a theory of natural selection identical to his own. Darwin's colleagues suggested that he and Wallace make a joint presentation of their separate works before a learned society – the Linnean Society – so that each might lay equal claim to the theory of natural selection. This was done, and a year later Darwin published his 'abstract', which we know today as *The Origin of Species*. The book sold out on its first day of publication and has been selling steadily ever since. And although theories of evolution had existed before Darwin, he was the first to offer a systematic explanation for how evolution worked.

Natural selection and evolution

Two concepts are central to Darwin's theory of evolution: adaptation and natural selection. **Adaptation** refers to the ability of generations of species to adapt effectively to changes in the environment. **Natural selection** refers to the process whereby some variations in species will be transferred from one generation to the next but others will not. The Oxford zoologist, Richard Dawkins, has likened the process of natural selection to a sieve because it leaves out what is unimportant (Dawkins, 1996).

Darwin's theory has four basic premises:

- 1 The world's animal and plant communities are dynamic, not static: they change over time with new forms originating and others becoming extinct.
- 2 The evolutionary process is gradual and continuous. New species arise through slow and steady environmental changes that gradually 'perfect' each species to its surroundings. When sudden and dramatic changes occur in the environment, a species' ability to adapt is usually challenged. Some species adapt and live; others become extinct.
- 3 All organisms are descended from an original and common ancestor. Over time, the process of natural selection has created different species, each specifically adapted to its ecological niche.
- 4 Natural selection not only causes changes within populations during changing environmental conditions but also acts to maintain the status quo under relatively constant environmental conditions.

According to Jacob (1977), natural selection results from two characteristics of life. First, reproduction produces offspring that are slightly different from their parents. Secondly, interaction with a changing environment requires that living things adapt behaviourally to its vagaries, otherwise they will risk injury, illness or death. The interaction of these factors causes differential reproduction, and, ultimately, evolution. Evolution, in this sense, is a process that is strongly influenced by behavioural adaptations to changing environments (Buss *et al.*, 1998).

Natural selection

The essence of Malthus's essay, which Darwin was reading when the idea of natural selection first occurred to him, was that the earth's food supply grows more slowly than populations of living things. The resulting scarcity of food produces competition among animals, with the less fit individuals losing the struggle for life. For example, wolves who are agile are better able to capture prey than are slower packmates. Fast wolves will therefore tend to outlive and out-reproduce slower wolves. If a wolf's tendency to run fast is a genetically controlled trait, it will be passed on to its offspring. These offspring will be more likely to catch prey and will therefore live longer and have more opportunities to reproduce.

The ability of an individual to produce offspring defines that individual's reproductive success – the number of viable offspring it produces relative to the number of viable offspring produced by other members of the same species. Contrary to popular interpretation, 'survival of the fittest' does not always mean survival of the most physically fit or of the strongest. The evolutionary 'bottom line' is not physical strength but reproductive success. Physical strength is only one factor that might contribute to such success. In humans, for example, good looks, charm and intelligence play an important role in an individual's ability to attract a mate and reproduce. What is more, natural selection is not 'intentional'. Giraffes did not grow long necks in order to eat leaves from trees, but those with longer necks who were able to reach the leaves successfully reproduced while the others died out.

Two aspects of natural selection – variation and competition – are the critical factors that determine whether any particular animal and its offspring will enjoy reproductive success.

Variation

Variation includes differences among members of a species, such as physical characteristics (size, strength or physiology) and behavioural characteristics (intelligence or sociability). What factors are responsible for these sorts of variation?

First, an individual organism's genetic make-up – or its **genotype** – differs from that of all other individuals (except in the case of identical twins). As a result of these genetic differences, an individual organism's physical characteristics and behaviour, or its **phenotype**, also differs from that of every other individual.

Every individual's phenotype is produced by the interaction of its genotype with the environment. In essence, the genotype determines how much the environment can influence an organism's development and behaviour. For instance, identical twins have exactly the same genotype. If they are separated at birth and one twin has a better diet than the other, their phenotypes will be different: the better-fed twin is likely to be taller and stronger. However, regardless of diet, neither twin will ever become extremely tall or very muscular if they do not possess the genes for tallness and muscularity. Likewise, neither twin will realise their full potential for tallness and muscularity if they do not eat a nourishing diet. In this example, both the genotype (the genes related to tallness and muscularity) and a favourable environment (a well-balanced, nourishing diet) must be present for either twin to reach their full growth potential.

Phenotypes and the genotypes responsible for them may or may not be selected, depending on the particular advantage they confer. Consider, for example, the thirteen species of finch that Darwin discovered in the Galapagos Islands, located off the west coast of South America. A striking physical difference among these birds is beak size. Some finches have a small, thin beak phenotype and others have a large, thick beak phenotype. Birds having small, thin beaks feed on small seeds covered by weak shells, and birds having large, thick beaks feed on large seeds covered by tough shells.

In a study that investigated the relationship between rainfall, food supply and finch population on one island, Grant (1986) discovered that the amount of rainfall and the size of the food supply directly affected the mortality of finches having certain kinds of beak. During droughts, small seeds became scarce. As a result, the finches having small, thin beaks died at a higher rate than finches having bigger, thicker beaks. During the next few years, the number of finches having bigger, thicker beaks increased – just as the principle of natural selection would predict. During times of plentiful rain, small seeds became abundant, and the number of finches having small, thin beaks became more plentiful in subsequent years.

Grant's study makes two important points. First, although evolution occurs over the long run, natural selection can produce important changes in the short run – in the space of only a few years. Secondly, phenotypic variation, in this case differences in beak size, can produce important selective advantages that affect survival. Imagine if all the finches had small, thin beaks: during the drought, most, if not all, of these finches might have died. None would be left to reproduce and these finches would have become extinct on this island. Fortunately, there was phenotypic variation in beak size among the finches, and because phenotypic variation is caused by genetic variation (different genotypes give rise to different phenotypes), some finches – those having large, thick beaks – had an advantage. Their food supply (the larger seeds) was relatively unaffected by the drought, enabling them to out-survive and out-reproduce the finches with small, thin beaks.

On the basis of this evidence, one might reasonably assume that all finches should have developed large, thick beaks. However, when rain is plentiful and small seeds are abundant, birds with small, thin beaks find it easier to feed. Under these environmental conditions, these birds have a phenotypic (and genotypic) advantage.

Competition

The second aspect of natural selection is **competition**. Individuals of a given species share a similar environment. Because of this, competition within a species for food, mates and territory is inevitable. Every fish captured and eaten by one bald eagle is a fish that cannot be captured and eaten by another bald eagle. If one bald eagle finds a suitable mate, then there is one fewer potential mates for other bald eagles and so on.

Competition also occurs between species when members of different species vie for similar ecological resources, such as food and territory. For example, yellow-headed blackbirds and red-winged blackbirds eat the same foods and occupy the same types of breeding territory; thus, they compete for these resources. Such competition does not involve competition for mates (yellow-headed blackbirds do not court red-winged blackbirds and vice versa). However, although these species do not compete for mates, their competition for other resources indirectly influences reproductive success because the ability to find and court a suitable mate depends on the ability to stake out and defend a territory having an adequate food supply. The probability of a yellow-headed blackbird finding a mate and successfully rearing a family depends not only on its success in competing against other yellow-headed blackbirds, but also on its success in competing against red-winged blackbirds.

Natural selection works because the members of any species have different phenotypes. Because these phenotypes

are caused by different genotypes, successful individuals will pass on their genes to the next generation. Over time, competition for food and other resources will allow only the best-adapted phenotypes (and their corresponding genotypes) to survive, thereby producing evolutionary change. This is what the theory would predict.

Knowledge and acceptance of evolution

How widespread do you think the acceptance of the theory of evolution is? In the United States, it is law that science and religion are taught separately and that banning the teaching of evolution is unconstitutional (Scott and Matzke, 2007). In 2007, the Council of Europe's Parliamentary Assembly passed a resolution recommending that member states do not teach creationism as if it were the equivalent of science. One survey of over a thousand students at a large American university, however, found that 25 per cent reported that their biology teacher had taught them creationism and 20 per cent were taught neither biology nor creationism (Moore, 2007). Creationism – the rejection of the theory of evolution in favour of the belief that the world was originated by a Creator – has gained some momentum in the US, although recent legal rulings suggest that evolution is fighting back. Creationism's new incarnation is Intelligent Design but, to all intents and purposes, the terms are synonymous. The fierce and often acrimonious debate that exists between scientists and intelligent design advocates – see Dawkins's excoriating *The God Delusion* – could probably make a Controversies in Psychological Science section in itself.

Since 1985, American adults at various time intervals have been asked if the following statement is true or false: 'Human beings, as we know them, developed from earlier species of animals'. In 2002, US data were compared with those from 9 European countries, with 32 countries in 2005 and with a survey of Japanese respondents in 2001 (Miller *et al.*, 2006). Figure 3.1 illustrates agreement/disagreement with the statement by nation.

Miller *et al.* found that over 20 years the percentage of Americans agreeing with the statement fell from 45 per cent to 40 per cent. Those who completely rejected the statement also fell from 48 per cent to 39 per cent. Those who were unsure jumped from 7 per cent in 1985 to 21 per cent in 2005. In later surveys, respondents were given the option of responding in a different way. They were asked whether the statement was definitely true, probably true, probably false, definitely false or don't know. A third of Americans considered the statement to be false and only 14 per cent regarded it as definitely true. European and Japanese respondents were more likely to accept the statement as true. In fact, the only country which was more sceptical than the US was Turkey. Eighty per cent of Iceland, Denmark, Sweden and France agreed; 78 per cent of the

Figure 3.1 This graph shows 34 nations' degree of agreement with the statement 'Human beings, as we know them, developed from earlier species of animals'. The survey was undertaken in 2005.

Source: Miller, J.D., Scott, E. & Okamoto, S. (2006) Public acceptance of evolution. *Science*, 313, 765–6. Reprinted with permission from AAAS.

Japanese did. In European countries, the percentage absolutely disagreeing ranged from 7 per cent (Denmark, France, United Kingdom) to 15 per cent (The Netherlands).

Those who strongly believed in God, who prayed often and held pro-life beliefs were the most rejecting of the statement. All of these were more common in the US. Miller *et al.* explains the geographic disparity by suggesting that biblical fundamentalism – Genesis is to be read literally – is greater in the US, whereas in Europe Genesis is regarded as being more of a metaphor. A third of US

respondents also agreed that half of the genes of mice and humans are identical and 38 per cent believed that we have half in common with chimps (as you'll see later, the percentage we share is a lot higher). Even if respondents disagreed with evolution, you might expect them to have a reasonable knowledge of the building blocks of life. Fewer than half of Americans surveyed were able to provide a passable definition of DNA.

Human evolution

Reconstruction of human evolution is a difficult job, something akin to assembling a giant jigsaw puzzle whose pieces have been scattered throughout the world. Some of the pieces may have been lost for ever; others have become damaged beyond recognition; and those few that are found force continual reinterpretation of how the other pieces might fit the puzzle. Another way in which we can date our remains is via carbon dating. Animals breathe a form of (naturally occurring) radioactive carbon called C14. When an animal dies, this carbon decays but at a constant rate. By examining the content of the carbon in the fossil or surrounding material, therefore, we can estimate the date of its existence. One problem here is that the amount of carbon found can be influenced by the amount in the air at the time.

We can also analyse the changes in DNA between similar fossils – the less the change in DNA, the closer the two fossils are in time. But the best we can do is make an educated guess about the evolution and lifestyles of our ancestors.

Many biologists and natural historians of Darwin's time believed that natural selection applied to all animals, including humans. Others insisted that although natural selection applied to other animals, it did not apply to humans. However, through study of the fossil record and recent developments in genetic research, we now know that our species is related genetically to other mammals. The gorilla and the chimpanzee are our closest living relatives, and together we appear to have descended from a common ancestor. You may have heard it said that we share 99 per cent of our genes with chimps. In fact, what we share is DNA involved in the production of proteins. Ninety-nine per cent of our DNA in this regard is identical (King and Wilson, 1975). Why, then, are we not exactly hirsute, whooping, tyre-swinging, banana-eaters? The reason is that 98 per cent of the human genome is not involved in the production of proteins. The remainder is involved in the timing of production and how much is produced (these are called regulatory genes – there is a more detailed description of genetics later in the chapter). It is this percentage which causes the great difference between the species (Demuth *et al.*, 2006; Cohen, 2007). Humans also have multiple copies of genes that chimps

do not (Pennisi, 2006). Therefore, while we have proteins in common, it is the way in which these proteins are organised which determines the differences between us.

Our dependence on information from fossil remains and other archaeological artefacts is problematic. As Byrne (1995) has colourfully pointed out, much of what we conclude about our ancestors' behaviour from archaeological findings is speculative; some is sensible speculation but it is speculation nonetheless. There is no way of empirically or conclusively demonstrating that artefacts were used in the way in which we suggest or that they indicate a specific way of living or behaving. In this sense, **paleoanthropology** – the study of human behaviour using information from fossil remains – is more like detective work than scientific work. 'The reality', Byrne argues, 'is that we will never know with confidence the answers to many of the most important questions we would like to ask about what happened in the past five million years' (1995, p. 6).

With this caveat in mind, the general pattern of evolution is thought to occur something like this. Our evolution from a common ancestor appears to have begun in Africa about 2 to 4 million years ago (Clark, 1993).

The earliest humans have been labelled *Homo habilis* (literally 'handy man'). *Homo habilis* was small (only about 1.3 m tall and about 40 kg in weight), but was bipedal (able to walk upright on two feet). Compared with its predecessor – a species called *Australopithecus* ('apes from the South') – *Homo habilis* had a larger brain and more powerful hands. The strong hands were well suited to making simple stone tools; hence the name 'handy man'. A natural selection interpretation of such adaptively significant traits would argue that these early humans adapted to the environment in terms of creating shelter against the elements, catching and preparing food, and making weapons for self-defence.

Homo habilis was succeeded, about 400,000 years later, by *Homo erectus* ('upright man'). *Homo erectus* had a much larger brain and stood more erect than *Homo habilis* and had a more complex lifestyle. *Homo erectus* was the first of our ancestors to establish regular base camps, which probably served as centres for social activities, including the preparation and eating of food. We cannot be absolutely sure that these interpretations are the correct ones, however. *Homo erectus* created more efficient and stronger tools than did *Homo habilis*, successfully hunted big game, and discovered and used fire. Fire enabled these early humans to cook food, remain warm in cold weather and protect themselves from predators. *Homo erectus*'s use of fire, coupled with its apparent social nature and its ability to hunt and/or scavenge big game, permitted it to explore and settle new environments, including Europe, Asia, America and other parts of Africa (Spoor *et al.*, 2007).

The earliest known *Homo sapiens* ('intelligent man') appears to have arisen about 500,000 years ago. The best known of the early *Homo sapiens*, *Homo sapiens neanderthalensis* (so-called Neanderthals, named after the German valley in which the fossils were discovered), lived throughout Europe and Central Asia between approximately 300,000 and 35,000 years ago. Neanderthals constructed small huts from bones and animal skins and sometimes burned bones as fuel. They were skilled big game hunters, tool makers and clothiers, and they had cultural rituals for burying their dead. In one Neanderthal burial site unearthed in France, a small boy was found positioned on his left side with a small pillow of flints under his head and an axe positioned by his right hand. Similar Neanderthal burial sites have been discovered, suggesting that these humans possessed cultural traditions not previously found in the prehistoric record.

Informed speculation suggests that Neanderthals and modern humans (*Homo sapiens sapiens*) overlapped each other, although the origin of *Homo sapiens sapiens* is unclear. It seems to have arisen between 200,000 and 100,000 years ago. The Neanderthals became extinct around 25,000 years ago, with last evidence of their existence found in Gibraltar (Finlayson *et al.*, 2006). What is

clear, though, is that the *Homo sapiens sapiens* line has survived to flourish in all parts of the world, despite the presence of hostile climate, terrain and predators. Figure 3.2 charts the suspected development of *Homo sapiens sapiens*. Some theorists have suggested that the variety of species is greater nearer the equator (Hillebrand, 2004) and that tropical environments create a museum and a cradle for species to flourish (McKenna and Farrell, 2006).

Natural selection and human evolution

The apparent success of the human species in adapting to a variety of ecological niches stems from the fact that natural selection has favoured two important human characteristics: **bipedalism**, the ability to move about the environment on two feet, and **encephalisation**, increased brain size. The ability to walk upright, which appears to have evolved in our early hominid ancestors over 4 million years ago (Boaz, 1993; Ruff *et al.*, 1997), may have arisen from the need to stand on branches to reach food on other branches above (Thorpe *et al.*, 2007). Bipedalism allowed not only greater mobility, but also freed the hands for grabbing, holding and throwing objects. The ability to grasp

Figure 3.2 Major milestones in human evolution. The ability to walk upright freed the hands for tool use and other manipulative skills. Increased brain size accompanied increased intelligence. These two adaptations combined probably contributed significantly to all other major adaptations in human evolution.

Source: Adapted from Lewin, R., *Human Evolution: An illustrated introduction*. Cambridge, MA: Blackwell Scientific Publications, Inc., 1984.

objects, in combination with an expanding capacity for learning and remembering new skills provided by a larger brain, led to advances in tool making, food gathering, hunting and escaping predators (Eccles, 1989).

Early hominids had a brain volume of 650 cm³ (and they were about 155cm tall). Current humans have a brain size of 1,500 cm³ and are, on average, 175 cm tall. It used to be thought that there was a relationship between body size and brain volume. However, the relationship is between relative size and brain volume and Figure 3.3 (a)–(c) shows the differences in brain and body size between various species. The increase in our brain relative to our size is called **positive brain allometry**. This began around 2 million years ago and has increased, more or less, since – from 450 cm³ (*Homo habilis*) to

1,000 cm³ (*Homo erectus*) to 1,350 cm³ 100,000 years ago (*Homo sapiens*). The increase may be attributable to better diet, better defence and, therefore, better survival. Children began to live longer, thus enabling the brain to be more fully developed when they conceived.

As the brain became larger, more of its volume – especially the front part which is the most recently evolved – appeared to become devoted to thinking, reasoning, decision-making and other complex cognitive, ‘higher’ functions. We will return to the role of this part of the brain in thinking in Chapter 11.

Another important ability that emerged from encephalisation was planning: the ability to anticipate future events and to consider the effects of these events on an individual or group of individuals. Such planning might have involved the organisation of hunts, the institution of social customs and events (such as weddings and funerals), and the planting and harvesting of crops. Over time, the interaction between bipedalism and encephalisation allowed humans to exploit new environments and establish well-organised communities.

Advances in tool making and hunting, combined with the use of fire for cooking, protection and warmth, were adaptive: they helped humans to live longer. The increased lifespan of humans may have aided the gradual accumulation of wisdom as the older members of early

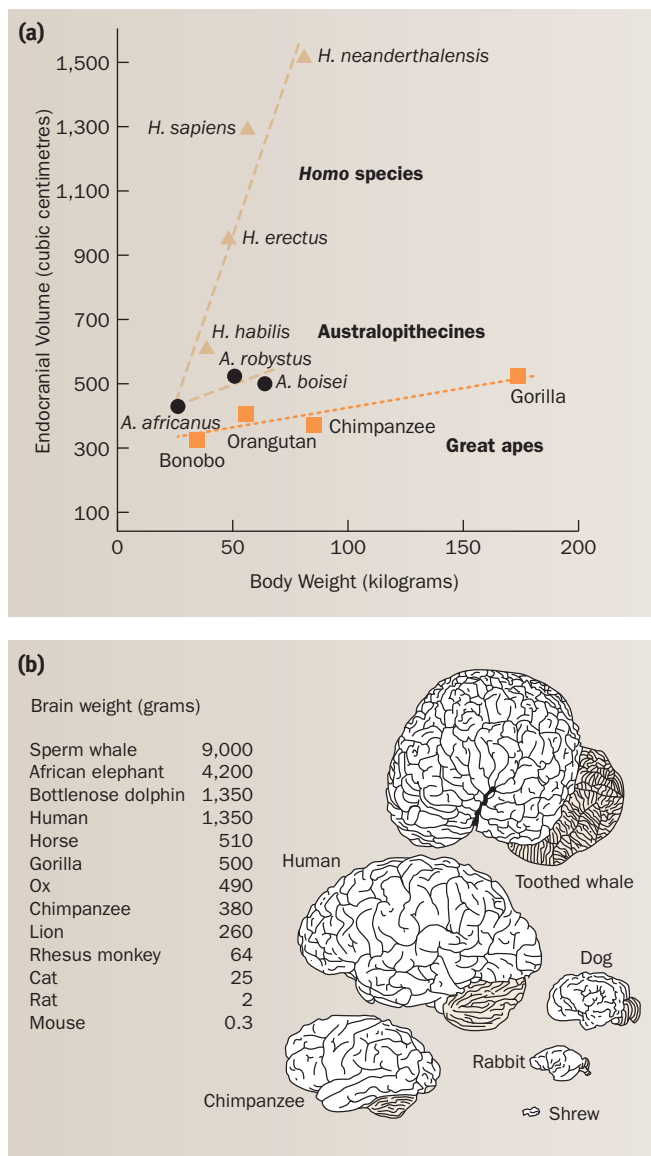

Figure 3.3 These three figures show the relationship between brain size and body weight in our human ancestors and non-human primates (a); the weight of various species brains (b); and the relationship between body weight and brain size in a variety of different species (c).

Source: Dicke, U. and Roth, G. (2008). Intelligence evolved. *Scientific American Mind*.

human communities began to share their knowledge with younger members through language. Although the fossil record cannot tell us when language first developed, we assume that those who were able to communicate with others through language had a distinct advantage over those who could not.

Language originated and subsequently evolved because of its immensely adaptive significance (Pinker, 1994). As Skinner (1986) noted, language not only provided a simple means of warning others of danger, but also provided a means of communicating important information to others, such as the location of a good hunting spot or instructions on how to craft a tool. Perhaps the most important advantage conferred by language was its ability to reinforce the already strong social tendencies of early humans. Language is the foundation upon which all human cultures are built and you'll discover more about this in Chapter 10.

As the evolution of cultures continued, humans gained an increasing ability to control and modify their environment. The same intellectual resourcefulness that permitted early humans to discover and use fire and to invent useful tools prompted the agricultural revolution of 10,000 years ago, the Industrial Revolution of 200 years ago, and the technological revolution that began only 50 years ago with the invention of the transistor, the integrated circuit and the computer. **Cultural evolution**, or the adaptive changes of cultures in response to changes in the environment over time, is possible only because humans have been genetically endowed with a capacity for learning and language. As cultural anthropologist Marvin Harris (1991) has noted, our capacity for learning has evolved because (1) it leads to 'a more flexible and rapid method of achieving reproductive success', and (2) it allows entire groups of people to 'adjust or take advantage of novel opportunities in a single generation without having to wait for the appearance and spread of genetic mutations' (p. 27). For example, advances in medicine have allowed us to control life-threatening diseases such as polio, smallpox, malaria, tetanus, typhoid fever and diphtheria. It would take hundreds of thousands of years, maybe even millions, to evolve immunities to these diseases.

Curiously, however, evolution may have led to a genetic advantage in some which has made them more resistant to the human immunodeficiency virus or HIV. This is a fatal virus which attacks the immune system and leads to the illness autoimmune deficiency syndrome (AIDS). Today, 20 per cent of Southern Africans are infected with the virus. It was first reported around 50 years ago in Africa and, around 30 years later, cases appeared in the US and Europe. One theory for the appearance of the virus in humans may be that it invaded our system via ingestion. Monkeys contract a similar form called simian immune deficiency virus, but they appear resistant to it. This form of the virus was thought to be transferred to humans via

food – so-called bushmeat (from monkeys). Some humans, however, may also be resistant. Those who can trace their ancestry to northern Europe at the time of the plague might be beneficiaries of ancestors who were resistant to the bacterium that caused the plague (Galvani and Slatko, 2003). Both the plague and AIDS attack white blood cells. Around 10 per cent of the ancestors of these northern Europeans appear to have a copy of the gene which protected against the plague; 5 per cent of southern Europeans do, but no Africans do.

Heredity and genetics

Darwin's work unveiled the process of natural selection and created new frontiers for exploration and experimentation. One of the most important of these frontiers is **genetics**, the study of 'the structure and function of genes and the way in which genes are passed from one generation to the next' (Russell, 1992, p. 2). Genetics, then, also involves the study of how the genetic make-up of an organism influences its physical and behavioural characteristics. Related to genetics are the principles of **heredity**, the sum of the traits and tendencies inherited from a person's parents and other biological ancestors. Although Darwin had built a strong case for natural selection, he could not explain a key tenet of his theory – inheritance.

The Brit, Francis Crick, and the American, John Watson, who cracked the DNA code and were rewarded with a Nobel Prize in 1962, jointly with Marcus Williams.

Source: A. Barrington Brown/Science Photo Library Ltd.

He knew that individual differences occurred within a given species and that those differences were subject to natural selection. But he did not know how adaptations were passed from parent to offspring.

Six years after *The Origin of Species* was published, Gregor Mendel, an Austrian monk who conducted experimental cross-breeding studies with pea plants, uncovered the basic principles of heredity. Mendel demonstrated conclusively how height, flower colour, seed shape and other traits of pea plants could be transmitted from one generation to the next. His work has since been applied to studying heredity in thousands of plants and animals.

The basic principles of genetics

Genes are segments of genetic material called **DNA** (deoxyribonucleic acid) – strands of sugar and phosphate that are connected by nucleotide molecules of adenine, thymine, guanine and cytosine. Each pairs up with another, but guanine always pairs with cytosine and adenine with thymine. These pairs form steps in a spiral staircase called a double helix. That is, the DNA is configured like a twisted ladder: the sugar and phosphate form the sides and the four nucleotides form the rungs. You can see this in Figure 3.4.

The particular sequence of these nucleotide molecules directs the synthesis of protein molecules that regulate the biological and physical development of the body and its organs. Some protein molecules regulate cell development and others regulate the chemical interactions that occur within cells. Three billion pairs of these proteins form our genetic code (Plomin, 2008).

Protein synthesis

Genes can only influence our development and behaviour through protein synthesis. Proteins are strings of amino acids arranged in a chain. Each sequence of nucleotides (adenine, thymine, guanine and cytosine) specifies a particular amino acid. In a sense, genes are ‘recipes’ consisting of different nucleotide sequences. In this case, the recipe is for combining the proteins necessary to create and develop physiological structures and for behaviour – how those structures might function in response to environmental stimulation.

Strictly speaking, however, there are no genes for behaviour, only for the physical structures and physiological processes that are related to behaviour. For example, when we refer to a gene for schizophrenia (a mental disorder characterised by irrational thinking, delusions, hallucinations and perceptual distortions), we are really referring to a gene that contains instructions for synthesising particular proteins, which, in turn, are responsible for the development of specific physiological processes that are sensitive to certain stressful environmental conditions (we may even

Figure 3.4 The structure and composition of DNA. DNA resembles a twisted ladder whose sides are composed of molecules of sugar and phosphate and whose rungs are made of combinations of four nucleotide bases: adenine (A), thymine (T), guanine (G) and cytosine (C). Genes are segments of DNA that direct the synthesis of proteins and enzymes according to the particular sequences of nucleotide bases that they contain. In essence, genes serve as ‘recipes’ for the synthesis of these proteins and enzymes, which regulate the cellular and other physiological processes of the body, including those responsible for behaviour.

Source: Based on Watson, J.D., *Molecular Biology of the Gene*. Menlo Park, CA: Benjamin, 1976.

be wrong in specifying just one gene – there may be more than one). The influence of genetics on mental disorders is discussed in more detail in Chapter 18.

Genes also direct the synthesis of **enzymes**, proteins which govern the processes that occur within every cell in the body, and thus control each cell’s structure and func-

tion. As we will see later, a faulty gene may contain instructions for synthesis of faulty enzymes, which produces serious physiological and behavioural problems.

Chromosomes and meiosis

Genes are located on **chromosomes**, the rod-like structures made of DNA found in the nucleus of every cell. In essence, genes are particular regions of chromosomes that contain the recipes for particular proteins. Each set of chromosomes contains a different sequence of genes. We inherit 23 individual chromosomes from each of our parents, giving us 23 pairs – 46 individual chromosomes – in most cells of the body. One pair of chromosomes, the **sex chromosomes**, contains the instructions for the development of male or female sex characteristics – those characteristics that distinguish males from females.

Sexual reproduction involves the union of a sperm, which carries genetic instructions from the male, with an ovum (egg), which carries genetic instructions from the female. Sperms and ova differ from the other bodily cells in at least two important ways. First, new bodily cells are created by simple division of existing cells. Secondly, all 23 pairs of chromosomes divide in two, making copies of themselves. The copies pull apart, and the cell splits into two cells, each having a complete set of 23 pairs of chromosomes. Sperms and ova are formed by a special form of cell division called **meiosis**. The 23 pairs of chromosomes break apart into two groups, with one member of each pair joining one of the groups. The cell splits into two cells, each of which contains 23 individual chromosomes. The assignment of the members of each pair of chromosomes to a particular group is a random process; thus, a single individual can produce 223 (8,388,608) different ova or sperms.

Although brothers and sisters may resemble each other, they are not exact copies. Because the union of a particular sperm with an ovum is apparently random, a couple can produce $8,388,608 \times 8,388,608$, or 70,368,774,177,664 different children. Only identical twins are genetically identical. Identical twins occur when a fertilised ovum divides, giving rise to two identical individuals. Fraternal twins are no more similar than any two siblings. They occur when a woman produces two ova, both of which are fertilised (by different sperms).

Sex is determined by the twenty-third pair of chromosomes: the sex chromosomes. There are two different kinds of sex chromosomes, X chromosomes and Y chromosomes. Females have a pair of X chromosomes (XX); males have one of each type (XY). Because women's cells contain only X chromosomes, each of their ova contains a single X chromosome (along with 22 other single chromosomes). Because men's cells contain both an X chromosome and a Y chromosome, half of the sperm they produce contain an X chromosome and half contain a Y chromosome. Thus, the sex of a couple's offspring

depends on which type of sperm fertilises the ovum. A Y-bearing sperm produces a boy, and an X-bearing sperm produces a girl. Figure 3.5(a) illustrates this process; Figure 3.5(b) shows the human chromosomes.

Figure 3.5 (a) Determination of sex: the sex of human offspring depends on whether the sperm that fertilises the ovum carries an X or a Y chromosome.

(b) Human chromosomes: the presence of a Y chromosome indicates that this sample came from a male. A sample from a female would include two X chromosomes.

Source: CNRI/Science Photo Library Ltd.

Dominant and recessive alleles

Each pair of chromosomes contains pairs of genes: one gene in each pair is contributed by each parent. Individual genes in each pair can be identical or different. Alternative forms of genes are called **alleles** (from the Greek *allos*, ‘other’). Consider eye colour, for example. The pigment found in the iris of the eye is produced by a particular gene. If parents each contribute the same allele for eye colour to their child, the gene combination is called homozygous (from the Greek *homo*, ‘same’, and *zygon*, ‘yolk’). However, if the parents contribute different alleles, the gene combination is said to be heterozygous (from the Greek *hetero*, ‘different’). Heterozygous gene combinations produce phenotypes controlled by the **dominant allele** – the allele that has a more powerful influence on the expression of the trait. The allele for brown eyes is dominant. When a child inherits the allele for brown eye colour from one parent and the allele for blue eye colour from the other parent, the child will have brown eyes. Brown eye colour is said to be a dominant trait. The blue eye colour controlled by the **recessive allele** – the allele that has a weaker effect on the expression of a trait – is not expressed. Only if both of a child’s alleles for eye colour are of the blue type will the child have blue eyes. Thus, having blue eyes is said to be a recessive trait. Inheritance of two alleles for brown eyes will, of course, result in brown eyes. You can see this in Figure 3.6.

Other eye colours, such as hazel or black, are produced by the effects of other genes, which influence the dominant brown allele to code for more (black) or less (hazel) pigment in the iris.

It is important to remember that the genetic contributions to our personal development and behaviour are extremely complex. One reason for this complexity is that protein synthesis is often under polygenic control, that is, it is influenced by many pairs of genes, not just a single pair. The inheritance of behaviour is even more complicated, because different environments influence the expression of polygenic traits. Consider, for example, the ability to run. Running speed for any individual is the joint product of genetic factors that produce proteins for muscle, bone, blood, oxygen metabolism and motor coordination (to name but a few) and environmental factors such as exercise patterns, age, nutrition, accidents and so on.

Genetic diversity

No two individuals, except identical twins, are genetically identical. Such genetic diversity is a characteristic of all species that reproduce sexually. Some organisms, however, reproduce asexually, such as yeast and fungi. Nurseries often reproduce plants and trees through grafting, which is an asexual process. But when we examine

the world around us, we find that the overwhelming majority of species reproduce sexually. Why?

One answer is that sexual reproduction increases a species’ ability to adapt to environmental changes. Sexual reproduction leads to genetic diversity, and genetically diverse species have a better chance of adapting to a changing environment. When the environment changes, some members of a genetically diverse species may have genes that enable them to survive in the new environment. These genes manufacture proteins that give rise to physical structures, physiological processes, and, ultimately, adaptively significant behaviour that can withstand particular changes in the environment.

This reasoning explains why so many insects, such as cockroaches, have survived our species’ best efforts to exterminate them. The lifespan of insects is very short, so that even in a short period of time, many generations are born and die. When we attempt to alter their environment, as we do when we apply an insecticide to their habitat, we may kill many of them. However, some survive because they had the right combination of genes (and hence, the necessary physiological processes and behaviour patterns) to resist the toxic effects of the poison. The survivors then reproduce. Our reaction is to attempt to develop a new poison to which this generation of insects is not resistant. The result is a sort of evolutionary ‘arms race’ in which both insects and humans produce newer and more powerful adaptations in response to each other (Dawkins, 1986).

Influences of sex on heredity

An individual’s sex plays a crucial role in influencing the expression of certain traits. A good example is haemophilia, an increased tendency to bleed seriously from even minor injuries. The blood of people who do not have haemophilia will begin to clot in the first few minutes after they sustain a cut. In contrast, the blood of people who have haemophilia may not do so for 30 minutes or even several hours. Haemophilia is caused by a recessive gene on the X chromosome that fails to produce a protein necessary for normal blood clotting. Because females have two X chromosomes, they can carry an allele for haemophilia but still have normal blood clotting if the other allele is normal. Males, however, have only a single X chromosome, which they receive from their mothers. If the gene for blood clotting carried on this chromosome is faulty, they develop haemophilia.

The gene for haemophilia is an example of a **sex-linked gene**, so named because this gene resides only on the sex chromosomes. There are also sex-related genes that express themselves in both sexes, although the phenotype appears more frequently in one sex than in the other. These genes are called **sex-influenced genes**. For example, pattern baldness (thin hair across the top of the head)

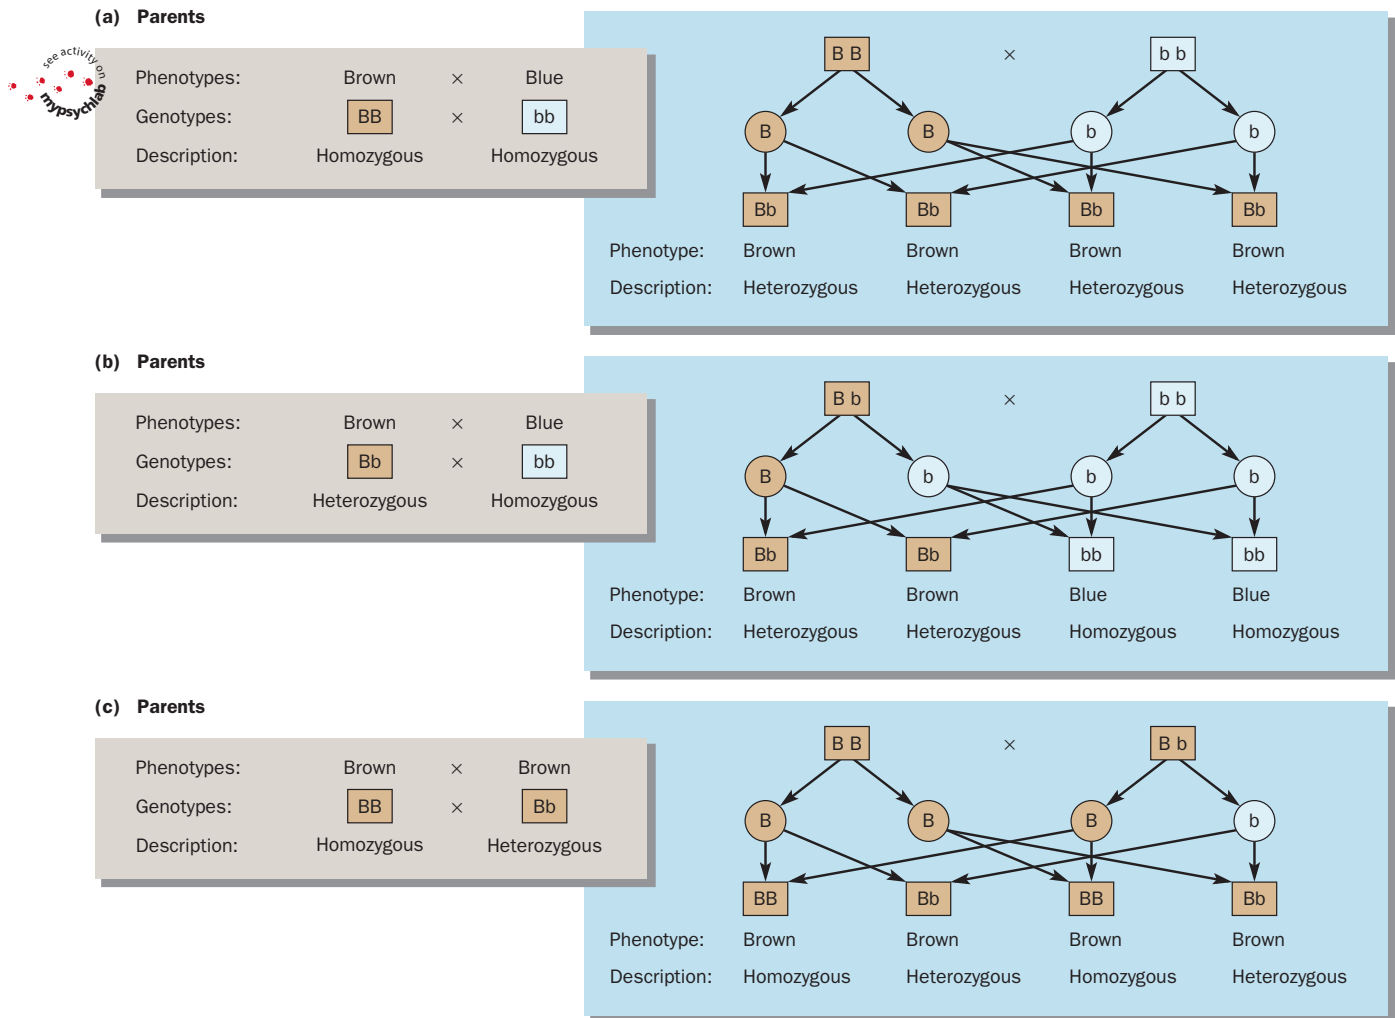

Figure 3.6 Patterns of inheritance for eye colour. **(a)** If one parent is homozygous for the dominant eye colour (BB), and the other parent is homozygous for the recessive eye colour (bb), then all their children will be heterozygous for eye colour (Bb) and will have brown eyes. **(b)** If one parent is heterozygous (Bb), and the other parent is homozygous recessive (bb), then their children will have a 50 per cent chance of being heterozygous (brown eyes) and a 50 per cent chance of being homozygous recessive (blue eyes). **(c)** If one parent is homozygous dominant (BB), and the other parent is heterozygous (Bb), then their children will have a 50 per cent chance of being homozygous for the dominant eye colour (BB) and will have brown eyes, and a 50 per cent chance of being heterozygous (Bb) for the trait and will have brown eyes.

Source: Based on Klug, W.S. and Cummings, M.R., *Concepts of Genetics* (2nd edn). Glenview, IL: Scott, Foresman, 1986. © 1986 Scott, Foresman & Co. Reprinted by permission of Addison Wesley Educational Publishers, Inc.

develops in men if they inherit either or both alleles for baldness, but this trait is not seen in women, even when they inherit both alleles. The expression of pattern baldness is influenced by an individual's sex hormones, which are different for men and women. The effects of these hormones on expression of pattern baldness explains why it is much more common among men than women.

Sex-related chromosomes may be responsible for social cognition in humans (Skuse *et al.*, 1997). Skuse and his colleagues examined a group of females aged between 6 and 25 years who had Turner's syndrome. **Turner's syn-**

drome is a genetic disorder in which all or part of one X chromosome in females is absent. These individuals are within the normal range of intelligence but they do have problems with social adjustment. In 70 per cent of Turner's individuals, the remaining X chromosome is maternal in origin (Xm); in the rest it is paternal (Xp). Skuse and his group examined whether there were any differences between those individuals with an X chromosome that was maternal or paternal in origin.

The researchers found that those with the maternally derived chromosome were less well adjusted than the 45,

Xp individuals. The 45, Xm individuals were also less skilled in verbal ability and in reasoning, two functions which are essential to social cognition. The authors of the study suggest that these results indicate a genetic locus for social cognition. They also suggest that because the social cognition chromosome is derived from the father, this might explain why certain 46, XY males (whose X chromosome is derived from the mother) are more susceptible to developmental disorders such as autism (a disorder of social communication, language and emotion) than are 46, XX females. Developmental disorders such as autism are described in more detail in Chapter 12.

Mutations and chromosomal aberrations

Changes in genetic material are caused by **mutations** or **chromosomal aberrations**. Mutations are accidental alterations in the DNA code within a single gene. Mutations are

the original source of genetic diversity. Although most mutations have harmful effects, some may produce characteristics that are beneficial in certain environments. Mutations can be either spontaneous, occurring naturally, or the result of human-made factors such as high-energy radiation.

Haemophilia provides one of the most famous examples of mutation. Although haemophilia has appeared many times in human history, no other case of haemophilia has had as far-reaching effects as the spontaneous mutation that was passed among the royal families of nineteenth-century Europe. Through genealogical analysis, researchers have discovered that this particular mutant gene arose with Queen Victoria (1819–1901). She was the first in her family line to bear affected children – two female carriers and an afflicted son. The tradition that dictates that nobility marry only other nobility caused the mutant gene to spread rapidly throughout the royal families, as you can see from Figure 3.7.

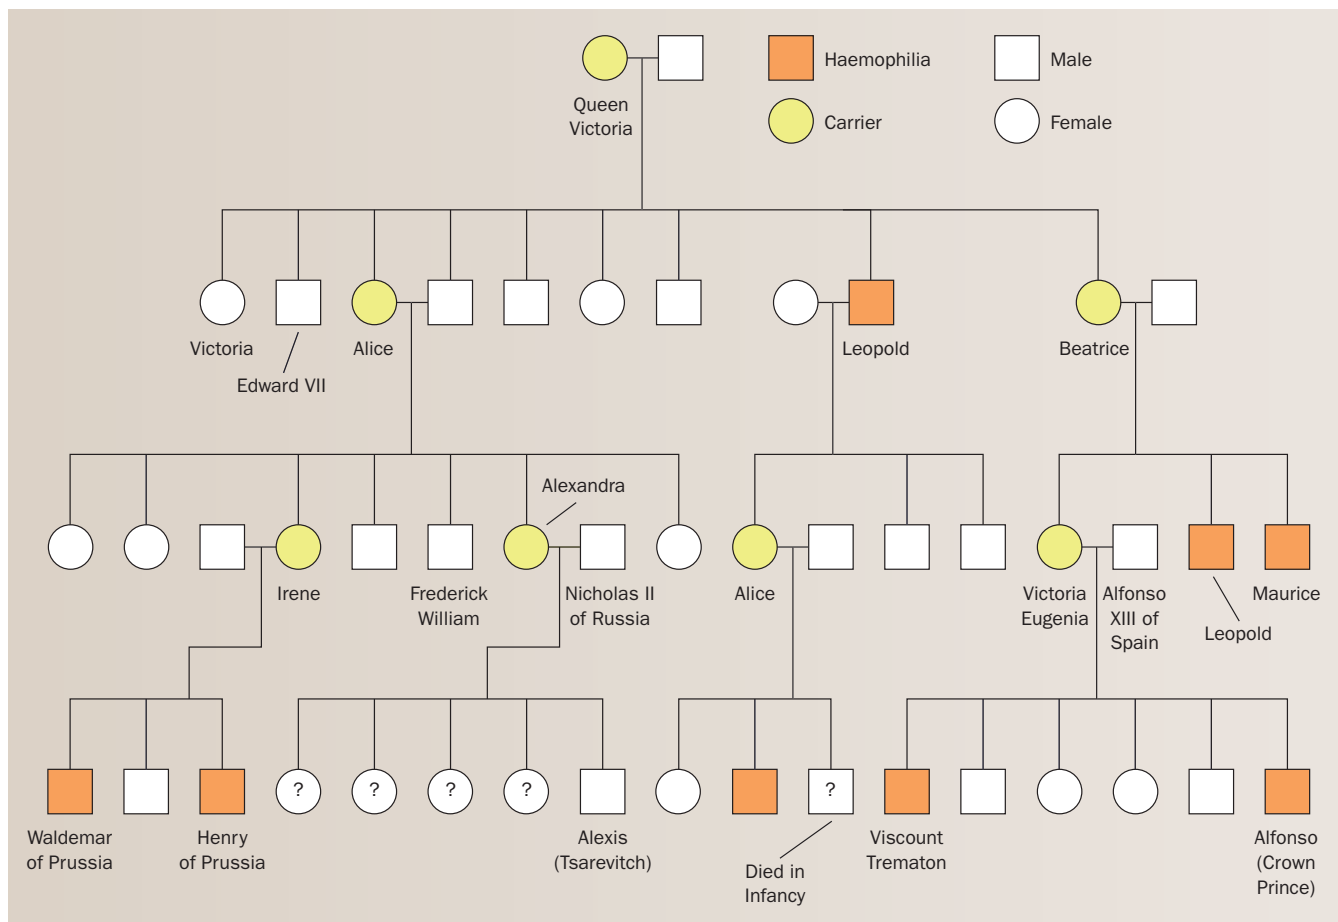

Figure 3.7 Genealogical analysis of the inheritance of haemophilia among European royal families. The gene for this disorder most likely originated with Queen Victoria of England. She was the first woman in the English royal family to bear an afflicted son or a carrier daughter. Circles represent females; squares represent males; a question mark indicates that carrier/affected status is unknown for that individual.

Source: Adapted from Winchester, A.M., *Genetics: A survey of the principles of heredity*. Boston: Houghton-Mifflin, 1972.

The second type of genetic change, chromosomal aberration, involves either changes in parts of chromosomes or a change in the total number of chromosomes. An example of a disorder caused by a chromosomal aberration – in this case, a partial deletion of the genetic material in chromosome 5 – is the **cri-du-chat syndrome**. Infants who have this syndrome have gastrointestinal and cardiac problems, are severely mentally retarded, and make crying sounds resembling a cat's meowing (hence its name, 'cry of the cat'). In general, the syndrome's severity appears to be directly related to the amount of genetic material that is missing. Psychologists and developmental disability specialists have discovered that early special education training permits many individuals having this syndrome to learn self-care and communication skills. This fact highlights an important point about genetics and behaviour: even behaviour that has a genetic basis can often be modified through training or experience, a notion called **epigenetics**.

Epigenetics

External events like trauma, drug abuse, lack of affection can affect the functioning of DNA. When these happen, the DNA does not alter, but is coated with molecules. These molecules alter the expression of the gene in two ways – either by preventing protein being constructed or by accelerating it. As you have seen, protein is essential to maintain the body and the brain. In the body, there is selective gene expression – each cell in the body may have the same gene but different cells use different types of gene. It does this via a molecule called ribonucleic acid (RNA), an intermediate molecule which is used by proteins attached to DNA to convert into other proteins. This is why a cell from the lung, for example, is different from one from the brain or the heart.

A gene can be silenced; molecules can be prevented from accessing it and this is what epigenetic mechanisms do. They either facilitate or block access to the genes in cells. This, consequently, affects gene expression. In one experiment, the stress response of rats whose mothers had licked or groomed them consistently for up to 10 days after birth was compared with those who had not. The first group showed less anxiety and stress. The gene that allows the release of a hormone called corticosterone was examined in these pups and those who had not been licked had fewer corticosterone receptors in their brain (Meaney, 2004). One proposed mechanism for this is that the hormone interacts with a structure in the brain called the hypothalamus to prevent it from overreacting to stressful events.

A chromosome unravelled

Source: Science Photo Library Ltd: Jacopin

Another protein, brain-derived neurotrophic factor (BDNF), which is important for the growth, integrity and functioning of cells, is lower in women with depression and it has been suggested that distressing events or experiences can alter the DNA that encodes this protein. In one experiment, 'bully' mice and smaller, normal mice were placed in a cage together for 5 minutes and then separated by a mesh for 10 days (Berton *et al.*, 2006). As you might predict, the smaller mice showed the typical stress reaction – they would become submissive and anxious. However, when their brains were examined for levels of BDNF, these were lower in the bullied mice. More importantly, the molecule known to affect the expression of this protein was found in one region of the mice's brains. This molecule had shut off the BDNF protein. A course of antidepressants raised the levels of BDNF.

Similar to these genes are 'knockout genes', which work in a similar way. The animal is exposed to radiation which damages a gene. This inserts nucleotides in the gene which prevent it from expressing itself, hence, the gene has been 'knocked out'. When the gene which encodes for spatial learning had been knocked out in rats, their ability to learn to swim to a platform that was not visible underneath a pool of water was impaired (Nakazawa, 2003).

Genetic disorders

Many genes decrease an organism's viability – its ability to survive. These 'killer genes' are actually quite common. On average, each of us has two to four of them. Fortunately, these lethal genes are usually recessive, and there are so many different types that most couples do not carry the same ones. When a child inherits the domi-

nant healthy gene from one parent and the recessive lethal gene from the other, the destructive effects of the lethal gene are not expressed.

A few lethal **genetic disorders** are caused by a dominant gene, however. Different dominant lethal genes express themselves at different times in the lifespan. A foetus may die and be spontaneously aborted before a woman even realises that she is pregnant; a baby may be stillborn, or the lethal genes may not be expressed until adulthood.

There are many human genetic disorders. Those described below are some of the more common ones that impair mental functioning and behaviour and so are of special interest to psychologists.

Down syndrome

Down syndrome is caused by a chromosomal aberration consisting of an extra twenty-first chromosome (Simonoff *et al.*, 1996). People having Down syndrome are generally short, have broad skulls and round faces, and show impaired physical, psychomotor and cognitive development. It occurs in around 1 in 1,000 births (DeGrouchy and Turleau, 1990) and about 15 per cent of children born with this condition die before their first birthday, usually from heart and respiratory complications. The frequency of Down syndrome increases with the age of the mother: about 40 per cent of all Down syndrome children are born to women over 40 years old. To a lesser extent, the age of the father also increases the chances of Down syndrome. Although people having Down syndrome are mentally retarded, special educational training permits many of them to hold jobs involving simple tasks. Despite the fact that Down syndrome is caused by a chromosomal aberration, it is not a hereditary disorder.

Huntington's disease

Huntington's disease is a disorder of movement involving involuntary dance-like (choreiform), jerky movement. It does not emerge until the afflicted person is between 30 and 40 years old and is caused by a dominant lethal gene on the arm of chromosome 4 that results in degeneration in certain parts of the brain. Before the onset of this disease, an individual may be healthy in every respect. After onset, however, the individual experiences slow but progressive mental and physical deterioration, including loss of coordination and motor ability. Death generally occurs 5–15 years after onset. Because the age of onset for Huntington's disease is long after sexual maturity, this

lethal gene can be passed from parent to child before the parent even knows that he or she has the gene. The disease is rare (the prevalence is 2–7 individuals per 1,000) but because it is autosomal dominant, the child of a parent with Huntington's disease has a 50 per cent chance of developing the disease. If the gene is present in the carrier, it will be expressed. There are genetic tests which help identify those individuals who carry the gene but this may present a horrible dilemma: if a person takes the test and is found not to carry the gene, then all well and good. If, however, the person is identified as a carrier, then this person will develop the disease and die from it because there is currently no cure. The Psychology in Action section describes some of the psychological consequences of this disclosure.

Phenylketonuria

Individuals with **phenylketonuria** (PKU) are homozygous for a recessive gene on chromosome 12 responsible for synthesis of a faulty enzyme (called phenylalanine hydroxylase – around 500 mutations of the enzyme's gene have been identified; see Widaman, 2009). This renders them unable to break down phenylalanine, an amino acid found in many foods. As a result, blood levels of phenylalanine increase, causing severe brain damage and mental retardation. Greater than 10 mg phenylalanine can be dangerous; a diet low in phenylalanine three weeks after birth can reduce this to between 3 and 10 mg. PKU is one of the many diseases for which infants are routinely tested before they leave the hospital. It occurs in 1 in 10,000–15,000 infants and those diagnosed as having PKU are placed on a low-phenylalanine diet shortly after birth.

The disorder was originally reported by a Norwegian dentist who noticed that his two retarded children had a peculiar odour. This odour aggravated his asthma so badly that he could not stay in the same room with them (Plomin, 1997). Folling, the physician who examined the children, found excess amounts of phenylpyruvic acid in their urine because of disturbed phenylalanine metabolism. If diet is unrestricted, intellectual ability plummets and mental retardation can occur by the age of 2 (the child's IQ would be around 50 or less, compared with the average 100). This decline is irreversible if there is no change in diet, which highlights the importance of altering diet quickly. Children who have been placed on a low phenylalanine diet for 20 years achieve normal development but if the diet is discontinued there is a drop in IQ performance (Koch *et al.*, 2002). When the diet is restarted, the points are

regained. It is estimated that for every mg of phenylalanine above 6.6, there is a 4.7 point loss in IQ (Koch *et al.*, 2003).

The mechanism for the illness is unclear but two candidates are the deficiency of a brain chemical called dopamine (described in the next chapter) or the slowing of myelination, the process whereby parts of a nerve cell are coated (this coating makes cells communicate more effectively) (Widaman, 2009).

Fragile X

Fragile X is the most important cause of mental retardation after Down syndrome and is the most common inherited cause of mental retardation (Simonoff *et al.*, 1996). It affects twice as many boys as girls (Kahkonen *et al.*, 1987) and is so called because the X chromosome is fragile and easily broken. Children with fragile X tend to have large foreheads, prominent jaws and brow, and protruding ears.

Psychology in action – The psychological consequences of genetic counselling

Genetic testing of susceptibility to disease has brought with it many remarkable psychological benefits, certainty and relief following a negative outcome being two of the more obvious. Positive outcomes appear to present an entirely different picture and one which may not be beneficial. Many anecdotal sources suggest that knowing the positive outcome of a genetic test for disease is associated with a decline in self-esteem and psychological well-being. There may also be health impairments that are unrelated to the disease.

Couples having a family history of genetic disorders often seek genetic counselling, the process of determining the likelihood that a couple may produce a child having a genetic disorder. Individuals who suspect that they may have a genetic disorder may also seek such counselling. In women who might be carriers of the breast cancer gene (*BRCA1/2*), they do so for the sake of their children (d'Agincourt-Canning, 2006). Similar reasons, plus a feeling of responsibility to their families, are behind reasons for genetic testing for colon cancer and Huntington's disease (Warner *et al.*, 2006; Etchary, 2006).

In instances where the woman is already pregnant, the foetus can be tested for genetic disorders. In fact, such testing is often recommended for pregnant women over 35 years of age or for those whose family pedigrees reveal a genetic problem. The most common prenatal detection method is amniocentesis, which involves removal and examination of foetal cells found in the amniotic fluid surrounding the foetus, usually during the sixteenth week of pregnancy. The chromosomes in the foetal cells are examined for incomplete, missing or extra chromosomes. In addition, amniocentesis allows parents to know the sex of their unborn child, which may be relevant in the case of sex-linked disorders.

The first step in genetic counselling is generally a pedigree analysis of the family or families involved. This analysis identifies any family history of genetic disorders and provides an estimate of the likelihood that a genetic disorder is present. If

a family history of genetic disorders is discovered, the genetic counsellor discusses the probability of the couple having a child who has a disorder. In the case of an individual, the counsellor may recommend screening for the disorder.

A group of researchers from the Netherlands (Tibben *et al.*, 1997) examined levels of psychological distress in carriers and non-carriers of Huntington's disease at four testing points: before knowing the results, one week after, six months after and three years after. They found that although helplessness increased in carriers and decreased in non-carriers at one week, the difference disappeared after six months. Those carriers with children reported greater distress than those without, and the partners of non-carriers were less distressed than those of carriers at three years. A study from the USA suggests a similar response but one which may be mediated by people's approaches to coping with the illness (Codori *et al.*, 1997). Codori *et al.* examined levels of hopelessness and depressive symptoms in patients tested positive for Huntington's disease and those tested negative. They found that those who were least well adjusted were likely to have been positively diagnosed, were married with no children and were closer to their estimated age of onset.

Men and women can differ in how they respond to the results of genetic testing (Marteau *et al.*, 1997). Women carrying the cystic fibrosis gene mutation, for example, have been found to be more likely than men to be more relieved when told they were non-carriers but were also more likely to be less relieved than men when informed that they were carriers.

These studies highlight a number of important questions in the area of genetic testing: which individual differences are risk factors for the anxiety and distress experienced following a positive test? Does the degree of distress change depending on the type of disease diagnosed? What are the long-term consequences of knowing the results of genetic testing? Studies such as those above present a fairly coherent beginning to finding answers to such questions.

Heredity and behaviour genetics

Each of us is born into a different environment and each of us possesses a unique combination of genetic instructions. As a result, we differ from one another. Consider your fellow undergraduates, for example. They come in different sizes and shapes, they vary in personality and intelligence, and they possess unequal artistic and athletic abilities. To what extent are these sorts of differences attributable to heredity or to the environment? If all your classmates had been reared in identical environments, any differences between them would necessarily be due to genetics. Conversely, if all your classmates had come from the same fertilised egg but were subsequently raised in different environments, any differences in their personal characteristics would necessarily be due only to the environment.

Heritability is a statistical term that refers to the amount of variability in a trait in a given population that is due to genetic differences among the individuals in that population. Heritability is sometimes confused with inheritance, the tendency of a given trait to be passed from parent to individual offspring. But heritability does not apply to individuals, it pertains only to the variation of a trait in a specific population. The more that a trait in a given population is influenced by genetic factors, the greater its heritability. The scientific study of heritability – of the effects of genetic influences on behaviour – is called **behaviour genetics**. As noted by one of this field's most prolific researchers, Robert Plomin, behaviour genetics is intimately involved with providing an explanation of why people differ (Plomin, 2008). As we will see below, behaviour geneticists attempt to account for the roles that both heredity and the environment play in individual differences in a wide variety of physical and mental abilities. The contribution of behaviour genetics to our understanding of the determinants of intelligence and personality are considered in more detail in Chapters 11 and 14.

Studying genetic influences

Although farmers and animal breeders had experimented with artificial selection for thousands of years, only within the past 150 years has the relation between heredity and behaviour been formally studied in the laboratory. Mendel's careful analysis of genetic influences on specific characteristics gave us the first good clue that traits were actually heritable. As you saw in Chapter 1, Galton (1869) stimulated further interest in this field with his studies showing that intelligence tends to run in families: if parents are intelligent then, in general, so are their children. The search for genetic bases of behaviour has been active ever since. In fact, the search to understand the relative contributions of heredity and environment to human behaviour is among the most heavily researched areas in psychology.

Artificial selection in animals

Any heritable trait can be selected in a breeding programme. The heritability of many traits in animals, such as aggression, docility, preference for alcohol, running speed, and mating behaviours, can be studied by means of artificial selection.

Consider, for example, Tryon's (1940) study of maze learning in rats. Tryon wished to determine whether genetic variables influenced learning. He began his study with a large sample of genetically diverse rats. He trained them to learn a maze and recorded the number of errors each rat made in the process. He then selected two groups of rats – those that learned the fastest (bright) and those that learned the slowest (dull). He mated 'bright' rats with other 'bright' rats and 'dull' rats with other 'dull' rats. To ensure that the rats were not somehow learning the maze from their mothers, he 'adopted out' some of the pups: some of the bright pups were reared by dull mothers and some of the dull pups were reared by bright mothers. He found that parenting made little difference in his results, so this factor can be discounted.

Tryon continued this sequence of having rats learn the maze and selectively breeding the best with the best (bright) and the worst with the worst (dull) over many generations. Soon, the maze performance of each group was completely different. He concluded that maze learning in rats could be manipulated through artificial selection.

Later studies showed that Tryon's results were limited by the standard laboratory cage environment in which rats lived when they were not running the maze. For example, Cooper and Zubek (1958) demonstrated that differences in maze ability were virtually eliminated when bright and dull strains of rats were reared in either enriched environments designed to stimulate learning (cages containing geometric objects, such as tunnels, ramps and blocks) or impoverished environments designed to inhibit learning (cages containing only food and water dishes).

However, Cooper and Zubek's rats that were reared in the standard laboratory cage performed similarly to Tryon's rats: the bright rats outperformed the dull rats. Thus, changing the environmental conditions in which the rats lived had an important result – reducing the effects of genetic differences between the bright and dull rats. This finding makes good sense when you consider the fact that genes are not expressed in the absence of an environment.

Tryon's research demonstrated that over successive generations a trait can be made to become more or less likely in a given population, but we do not know precisely why. We do not know whether genes related to learning or genes related to other traits were selected. Tryon's rats may have been neither especially bright nor especially dull. Perhaps each of these strains differed in its capacity to be motivated by the food reward that awaited it at the end of the maze.

Can gene manipulation ever occur in humans? Recent experiments involving the cloning of sheep illustrate the power of molecular genetics in radically altering nature’s forms. Gene mapping may help us to understand how specific DNA sequences can influence physiological processes that affect behaviour, emotion, remembering and thinking and play a crucial role in identifying specific genes involved in psychological disorders (Plomin and DeFries, 1998). Some of these issues are discussed in the chapters on memory, intelligence and mental disorders (Chapters 8, 11 and 18).

Twin studies

There are two barriers to studying the effects of heredity on behavioural traits in humans. First, ethical considerations prevent psychologists and geneticists from manipulating people’s genetic history or restricting the type of environment in which they are reared. For example, we cannot artificially breed people to learn the extent to which shyness, extraversion or any other personality characteristics are inherited or deprive the offspring of intelligent people of a good education to see if their intelligence will be affected. Secondly, in most cases, the enormous variability in human environments effectively masks any correlation that might exist between genetics and trait expression.

Psychologists have been able to circumvent these barriers by taking advantage of an important quirk of nature – multiple births. Recall that identical twins, also called **monozygotic (MZ) twins**, arise from a single fertilised ovum, called a zygote, that splits into two genetically identical cells. **Fraternal or dizygotic (DZ) twins** develop from the separate fertilisation of two ova. DZ twins are no more alike genetically than any two siblings. Because MZ twins are genetically identical, they should be more similar to one another in terms of their psychological characteristics (such as personality or intelligence) than either DZ twins or non-twin siblings (see Figure 3.8).

Concordance research examines the degree of similarity in traits expressed between twins. Twins are concordant for a trait if both of them express it or if neither does, and they are discordant if only one expresses it. If concordance rates (which can range from 0 to 100 per cent) of any given trait are substantially higher for MZ twins than for DZ twins, heredity is likely involved in the expression of that trait. Table 3.1 compares concordance values between MZ and DZ twins for several traits.

When we observe a trait exhibiting a high concordance for MZ twins but a low one for DZ twins, we can conclude that the trait may be strongly affected by genetics. This is especially true for a trait such as blood type, which has a heritability of 100 per cent. If the concordance rates are similar, the effect of heredity is low. For

Figure 3.8 Monozygotic twins.

Source: Corbis: Outline.

example, consider the characteristic of religious beliefs. In this case, a high concordance value (that is, both twins having similar beliefs) probably reflects the fact that they acquired their beliefs from their parents. In fact, the concordance rate for religious beliefs of DZ twins is generally just as high as that of MZ twins (Loehlin and Nichols, 1976). Thus, religious beliefs are not inherited.

Twin studies have been used to study a wide range of psychological phenomena. This research has shown that genetic factors affect cognitive abilities such as language ability, mathematical ability and vocabulary skills; personality traits such as extraversion (the tendency to be outgoing) and emotional stability; personality development; psychological disorders such as schizophrenia and mental retardation; and attitudes (Plomin *et al.*, 1994b; Bouchard and Propping, 1993).

Table 3.1 Comparison of concordance rates between monozygotic (MZ) and dizygotic (DZ) twins for various traits

Trait	Concordance %	
	MZ	DZ
Blood types	100	66
Eye colour	99	28
Mental retardation	97	37
Measles	95	87
Idiopathic epilepsy	72	15
Schizophrenia	69	10
Diabetes	65	18
Identical allergy	59	5
Tuberculosis	57	23

Controversies in Psychological Science – Are attitudes genetically inherited?

The issue

Although social psychologists have explored why people hold the attitudes that they do, little research has considered the role of genetics in how these attitudes are formed. The general view is that our attitudes are shaped by our learning and by our experience. However, there are studies of dizygotic and monozygotic twins which suggest that pairs of identical twins hold more similar views on subjects such as religion, crime, punishment and so on than do pairs of dizygotic twins (Eaves *et al.*, 1989).

The evidence

In a study of the attitudes of 195 pairs of monozygotic twins and 141 pairs of dizygotic twins, Olson and his colleagues asked participants for their views on 30 diverse topics such as crossword puzzles, the death penalty for murder, sweets, immigration, loud music, making racial discrimination illegal, exercising and so on (Olson *et al.*, 2001). Participants also rated themselves according to 20 personality traits, were asked how athletic, strong and physically attractive they thought they were and whether people considered them to be good-looking. The twins were recruited via newspaper advertisements.

Identical twins were more likely to share similar attitudes on 26 of 30 attitude items than were dizygotic twins. Table 3.2 illustrates the concordance rates for the twins' attitudes and personality traits.

Does this suggest that there are genes for such attitudes? This is highly unlikely. Instead, the authors suggest that there may be more general traits of factors which reflect specific attitudes. For example, when they took personality into account, they found that the trait of sociability was highly associated with five of the six attitude factors, perhaps suggesting that sociability may be the underlying 'cause' of such attitudes and which may be the heritable factor. Participants' attitudes towards leadership correlated with self-reported physical attractiveness, sociability and aggressiveness, but interpreting this relationship is difficult. For example, it could be argued that very attractive, sociable or aggressive people achieve leadership more easily and readily than do their less attractive, less sociable and less aggressive counterparts and that attitudes to leadership became more positive as a consequence. Conversely, participants may have been favourable towards leadership and made themselves more attractive, sociable or aggressive in order to achieve the status of leader.

The researchers note that while their study showed a high degree of heritability of attitudes, the greatest predictor of variability in the attitude scores was variation in the experiences of individual pair members. For example, having a good football coach might make a physically able person more posi-

Table 3.2 Similarities in attitudes of monozygotic and dizygotic twins

Attitude	Correlations	
	MZ	DZ

tive about their physical strength and help them develop more positive attitudes towards sports; similarly, poor reinforcement from teachers or criticism of performance might lead to a child's withdrawal into shyness and subsequent negative attitudes towards leadership.

Conclusion

While there is a strong relationship between the attitudes of each of a pair of identical twins, there are events that both twins experience which could shape such attitudes.

Sociobiology

Sociobiology has been defined as ‘the systematic study of the biological basis of all social behaviour’ (Wilson, 1975). It represents the synthesis of research findings regarding social behaviour from many other fields of science, including those from evolutionary psychology, anthropology and behaviour genetics. Evolutionary psychology and behaviour genetics are more specific fields than sociobiology in the sense that both are concerned with phenomena such as intelligence and cognition, in addition to social behaviour.

Sociobiologists are especially interested in understanding the evolutionary roots of our modern-day social actions. More often than not, sociobiologists study the evolutionary bases of social behaviour in non-human animals and then extrapolate from those species to humans (Barash, 1982). Sociobiology represents an interface between the biological sciences and psychology. However, not all psychologists are convinced of the sociobiologists’ claims, arguing that sociobiology is too simplistic and that its emphasis on genetics inadequately explains the complexities of human behaviour.

Reproductive strategies and the biological basis of parenting

Perhaps the most important social behaviours related to the survival of a species are those related to reproduction and parenting. A focal point of sociobiological research and theory has been understanding more about the different kinds of social organisation that result from particular **reproductive strategies** – systems of mating and rearing offspring.

We assume that most Western sexual relationships are monogamous: the mating of one female and one male. If mating is successful, the individuals share in the raising of the child or children. But **monogamy** is just one of several reproductive strategies sexual creatures employ in mating and rearing of offspring (Barash, 1982). Three other major classes of reproductive strategy are also possible:

- **Polygyny**: one male mates with more than one female.
- **Polyandry**: one female mates with more than one male.
- **Polygynandry**: several females mate with several males.

Figure 3.9 illustrates the combinations of partners that give rise to these classes.

According to Trivers (1972), these four reproductive strategies evolved because of important sex differences in the resources that parents invest in conceiving and rearing their offspring. **Parental investment** is the time, physical

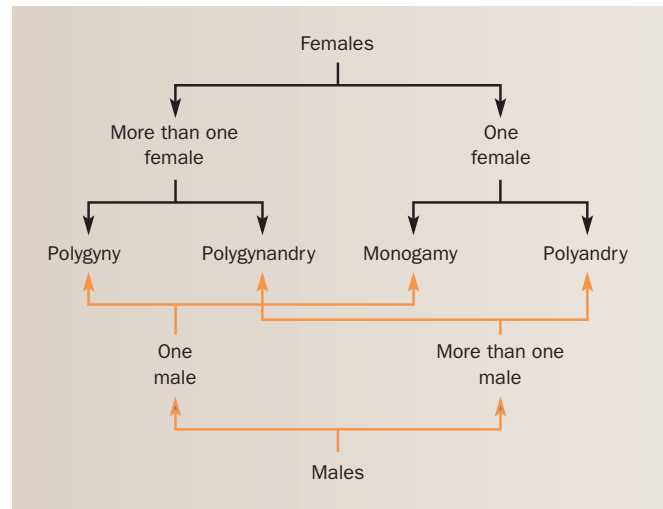

Figure 3.9 Reproductive strategies. Different numbers of males mating with different numbers of females yields the four reproductive strategies of monogamy, polygyny, polyandry and polygynandry.

effort and risks to life involved in procreation and in the feeding, nurturing and protecting of offspring. According to sociobiologists, parental investment is a critical factor in mate selection. An individual who is willing and able to make a greater investment is generally more sought after as a mate and is often more selective or discriminating when selecting a mate (Trivers, 1972). Given that a human female will gestate for nine months, she should be highly selective about choosing a mate. On the basis of Trivers’s theory, it is possible to predict that women will express an (evolved) preference for men who have high status and will divorce those who do not contribute the expected resources or who divert them to other women and children (Buss, 1995).

In some species, competition for mates leads to **sexual selection** – selection for traits specific to sex, such as body size or particular patterns of behaviour. For example, in some animals, such as buffalo, females select mates based on the male’s ability to survive the skirmishes of the rutting (mating) season. In general, the larger and more aggressive males win these battles and gain access to more females and enjoy greater reproductive success.

Polygyny is by far the most common reproductive strategy among humans. Eighty-four per cent of human societies practise polygyny or allow men who are either wealthy or powerful to practise it (Badcock, 1991). Monogamy is the next most popular reproductive strategy, with about 15 per cent of all human cultures practising it. Polyandry and polygynandry are both rare: combined, these two reproductive strategies dominate in fewer than 1 per cent of all human cultures.

Polygyny: high female and low male parental investment

In many species, the female makes the greater parental investment. According to sociobiological theory, whether one is an ova producer or a sperm producer defines the nature of one's parental investment. The fundamental asymmetry between the sexes has been aptly captured by sociobiologists Daly and Wilson (1978, p. 48):

Although each parent contributes almost equally to the genetic resources of the new creature they create, not all contributions are equitable. The female provides the raw materials for the early differentiation and growth of their progeny. Here at the very fundament of sexuality, is love's labour divided, and it is the female who contributes the most.

Among most mammals (including humans), the costs associated with reproduction are higher for females than for males. First, females have fewer opportunities than males to reproduce. Generally, females produce only one ovum or a few ova periodically, whereas males produce vast quantities of sperm over substantially shorter time intervals. Secondly, females carry the fertilised ovum in their bodies during a long gestation period, continuously diverting a major portion of their own metabolic resources to nourish the rapidly growing foetus. Females also assume all the risks that accompany pregnancy and childbirth, including physical discomfort and possible death. The male's contributions to reproduction are, at a minimum, the sperm and the time needed for intercourse. Thirdly, after the offspring is born, females may continue to devote some of their metabolic resources to the infant by nursing it. Just as important, they usually devote more time and physical energy than males to caring for the newborn.

In addition, a female can only bear a certain number of offspring in a lifetime, regardless of the number of males with whom she mates. In contrast, a male is limited in his reproductive success only by the number of females he can impregnate. For example, consider the differences between females and males in our species. If a woman became pregnant once a year for ten years, she would have ten children – only a fraction of the number of children that a man is capable of fathering over the same interval. If a man impregnated a different woman every month for ten years, he would have fathered 120 children. This example is hardly an exaggeration. According to the *Guinness Book of World Records*, the largest number of live births to one woman is 69 (she had several multiple births). In contrast, King Ismail of Morocco is reported to have fathered 1,056 children.

In many polygynous species, intense competition for the opportunity to mate occurs among males. The competition almost always involves some sort of physical confrontation: that is, males fight among themselves for the opportunity to mate. Usually, the larger, stronger and more aggressive male wins, which means that only he will mate with the available females in the vicinity. If one of the smaller, weaker males attempts to mate with a female, he is generally chased away by the victorious male.

Because females in polygynous species invest so heavily in their offspring, they are – according to sociobiologists – usually highly selective of their mates, choosing to mate only with those males who possess specific attributes, such as physical size, strength and aggressiveness. Such selectivity makes adaptive sense for both the female and her progeny. After all, bearing the offspring of the victor means that her male offspring will tend to possess the same adaptively significant attributes as their father and thus be more likely to win their own quests for mating privileges. And, as a result, genes for large size, increased strength and aggressiveness will continue to have greater representation in future generations than will genes for less adaptive attributes. The theory also works the other way – the male will select a female that he considers attractive and healthy and would, therefore, be a fit mother for a child. This interpretation, however, rests on the assumption that mate selection is governed by the perceived ability to reproduce successfully. In essence, it is, like the assumptions made about the evolution of our ancestors: speculative. This view does not explain why some couples decide to forgo the opportunity to have children. Physical attraction is also heavily culture-bound, as the International Perspective section shows.

Facial and bodily attractiveness

As the International Perspective section below shows, some studies find that body mass index (BMI) is more important than shape to ratings of physical attractiveness, especially when full-frontal figures are rated. Shape may be more important if a figure is seen in profile.

To test this hypothesis, Tovee and Cornelissen (2001) asked 40 male and 40 female undergraduates in the UK to rate a set of photographs of real women with obscured faces. The authors criticise previous studies for using unrealistic stimuli, such as (poor) line drawings of female figures presented in front view only, hence the use of real photographs and two views. There were 50 front-view figures and 50 in profile. BMI, not waist-to-hip ratio, was the best predictor of attractiveness for figures seen from the front or in profile. Both men and women gave similar ratings, thus supporting the second hypothesis, and both sexes preferred the figures with the lowest waist-to-hip ratio (a curvaceous figure).

Physical attraction – An international perspective

In the developed world, physically attractive women are considered to be those with a low **waist-to-hip ratio (WHR)**; this WHR is achieved because more fat is deposited on the buttocks and hips than the waist (this, in turn, is the result of women having higher levels of oestrogen than testosterone) (Singh, 1995).

This apparent universal preference for women with low WHR would seem to bolster the sociobiologist's argument that mates are selected for their health and fitness. However, these preferences are not universal. Yu and Shepard (1998) compared the body shape preferences of American men and men from the Matsigenka people in south-east Peru. The Matsigenka's culture is basically agrarian: they engage in slash and burn agriculture and supplement this food production with game and fruit gathered using traditional tools. Only scientists and official visitors are allowed to visit the village. The men had lived in the village since birth and would not, therefore, have been exposed to Western civilisation (no television, film, newspapers and so on).

Whereas the Western sample predictably preferred those females with low WHR, the Matsigenka men preferred overweight females and those with high WHR, rating these as the more attractive, healthy and more desirable as a spouse. The authors repeated the experiment on two other groups living outside the Matsigenka's village and who had been exposed to more Western influences. Here, the findings were mixed. One group showed the same pattern whereas the other gave comparable ratings to the Americans. These findings cannot be explained in terms of individuals selecting the fittest, most convincing-looking baby-producing machines. The non-Westernised group regarded a high WHR as healthier than a low WHR; the opposite effect was seen in the American group.

In a similar study, Frank Marlowe and Adam Wetsman, two American anthropologists, presented a series of frontal drawings of women which varied in their WHR to the Hazda group of hunter-gatherers who inhabit mixed savannah woodland in Tanzania (Marlowe and Wetsman, 2001). A previous study had shown that the men in this group were more swayed by women's weight than their WHR and strongly disliked thin women. In their new study, the images varied only by WHR, not weight. The group's responses were compared with those of a group of American men.

The researchers found that whereas the American men preferred a low WHR and especially liked the intermediate image showing a WHR of 0.7, the Hazda men preferred a higher WHR. The authors argue that this choice reflects a preference for heavier women and further speculate that 'the more subsistence-oriented a society is, and the more energetically expansive women's work, the more men will find fatter women attractive. Among foragers, thinness probably indicates poorer health.'

A study of physical attraction in Britain and Malaysia has found that participants in both countries consider body mass

index (BMI), weight adjusted for height (see Chapter 13 to see how you calculate this), to be a better index of female attractiveness than waist-to-hip ratio (Swami and Tovee, 2005a). The researchers asked 682 participants to rate the photographs of real women. The study found that those who lived in urban areas preferred lower BMIs than did those living in the country, perhaps reflecting the greater exposure of urbanites to slimmer women. Geographical differences were also found when British and Malaysian people rated photographs of men (Swami and Tovee, 2005b). People who lived in urban areas preferred men with low **waist-to-chest ratio** (BMI or waist-to-hip ratio were not good predictors). In rural areas, however, BMI was the primary predictor of attractiveness. Urban raters preferred a men with an 'inverted triangle' shaped torso, whereas rural raters preferred heavier men with a less triangular shape. Swami and colleagues have also reported an interaction between WHR and breast size. South African men preferred high-WHR black figures with large breasts, whereas white British men and British Africans preferred high-WHR black figures with small breasts and high-WHR white figures with large breasts (Swami *et al.*, 2009).

Is women's waist-to-hip ratio and men's waist-to-chest ratio the key to physical attractiveness?

Source: © Mitchell Gerber/Corbis.

What this might suggest is that BMI and WHR reflect different aspects of female health and fitness. BMI may reflect general fitness and fertility whereas WHR is a 'more specific cue to fertility and pubertal status' although the authors acknowledge that this cue has its limitations. The WHR of anorexic and healthy women is similar, for example, although the anorexic group (which is amenorrheic, i.e. not menstruating) is not fertile whereas the healthy group is.

The same research group has also investigated what makes the ideal male body shape (Maisey *et al.*, 1999). They asked 30 female undergraduates to rate the attractiveness of 50 men. Each man was measured for waist-to-chest ratio (WCR), WHR and BMI. They found that the best predictor of a man's attractiveness was his waist-to-chest ratio. Unlike men, who prefer a certain body size, women prefer a certain shape. This is the 'inverted triangle' (narrow waist, broad shoulders). The researchers suggest that if the desirable WHR in women signifies health and reproductive potential, then a desirable WCR in men signifies physical strength.

The preference for the triangular shape in urban dwellers is probably influenced, in part, by the muscular quality that the shape presents. If men believe that a muscular body is attractive, then attaining a muscular torso should improve their body image. In a study where men and women engaged in a 12-week muscular training exercise programme, men who trained were significantly happier with their body image at the end than at the beginning (Ginis *et al.*, 2005). Interestingly, this improvement correlated with physical improvements in strength in men but with both physical improvements and subjective ratings of physical improvement in women.

Homosexual men also judge muscularity to be more important than weight when they rate their own attractiveness (Levesque and Vichesky, 2006). Men's weight, however, can influence people's judgement of their personality. Wade *et al.* (2007) found that thinner men were rated as more socially desirable than overweight men. Thin men and men of normal weight also received higher ratings for friendliness, trustworthiness, intelligence and mate potential.

Bodies are often covered and we may not be able to perceive their exact shape; faces, however, are almost always exposed and offer an immediate source of information about physical attractiveness. Furnham *et al.* (2001) asked 100 young men to rate the images of women for attractiveness, sexiness, and health. The images had been morphed so that bodies varying in WHR either featured an attractive or unattractive face (as determined in a pilot study).

Contrary to what one might expect, images with attractive faces were rated as healthier, sexier, more attractive and more fertile regardless of WHR. The evi-

dence is contrary to what we would expect from the 'first pass filter' theory of mate selection. This refers to the notion that WHR is the first feature we focus on to determine our attraction to a partner; if it is acceptable, we then focus on other features and behaviours to further refine our choice.

People also find facial symmetry (where the left and right sides are almost totally symmetrical) attractive and healthy. Men with more symmetrical bodies have been reported to display more direct, sexual, competitive tactics when trying to win their date (Simpson *et al.*, 1999) and symmetrical movers are judged to be significantly better dancers than are asymmetrical ones (Brown *et al.*, 2005b).

Of course, physical beauty is stereotypically (and self-evidently) skin-deep. A study by Swami *et al.* (2007) asked participants to rate line drawings of women which varied in body weight, waist-to-hip-ratio and personality (extravert, introvert). Extraverted 'women' were judged to be more attractive and sociable than introverted ones, indicating that non-physical features are also an important determinant of attractiveness.

The perils of being beautiful

Is there a disadvantage to being very attractive? Research suggests that there is. When female students were asked to judge the suitability of an attractive, average and unattractive man as a long-term partner in tandem with a lonely heart advertisement implying high, medium or low socio-economic status, who do you think the women chose? If you said high-status, attractive men, you'd be wrong. If you'd said attractive men of medium status, you'd be right. Why? According to the authors (Chu *et al.*, 2007) the women regarded attractive, high-status men as pursuing a mating strategy (simply put, they were after sex), rather than a parenting strategy (wanting to settle down). High-status, attractive men would, therefore, be far more likely to be the recipient of other women's attention (and, therefore, be at greatest risk of yielding to this attention). Women – well, UK undergraduates – it seems, don't want Mr Perfect, just Mr Almost Perfect.

They might also settle for Mr Average. In one study women engaged in speed-dating were asked how important they thought a man's physical attractiveness and earning prospects were (Eastwick and Finkel, 2008). In an ideal partner, these were considered to be important. However, this preference did not predict their mate choice at the dating evening, neither did it predict their choice of real-life partners when the researchers contacted them after the study.

One theory of attractiveness (the topic of romantic attraction is considered further in Chapter 16) suggests that we choose a mate who is similar in attractiveness to

ourselves (even if we prefer busty blondes or six-packed hunks). This is called the matching phenomenon (Walster *et al.*, 1966), but no model can explain this satisfactorily – is it because we are more anxious or insecure, or fear rejection, or have low self-esteem? Some social psychologists argue that we view others through our own egotistical lens. ‘The self provides the frame of reference from which all else is observed’, state Combs and Snygg (1959), ‘People are not really fat unless they are fatter than we.’ This would suggest that our ratings of others’ physical attractiveness is affected by our assessment of our own physical attractiveness (whether this view is shared by others or not). Montoya (2008) found that people don’t seem to settle. In their study, participants’ ratings of

another person’s attractiveness decreased with the increasing, objective, physical attractiveness of the rater. People rating themselves moderate in attractiveness paired themselves with people they thought were attractive. There is support for his finding. A recent study found that people rated their partners as being significantly more attractive than themselves – there was no difference between men or women (Swami *et al.*, 2009). Are these people deluding themselves? Or are we all physically attractive and beauty is in the eye of the beholder? Remember that these studies focused on physical attractiveness, not the attractiveness of a partner’s personality or outlook or love of cats or helping old ladies with their shopping. Why do you think these percentages are so high?

Cutting edge – Can I have your number?

Can times of high and low fertility influence a woman’s acceptance of a romantic overture? Nicolas Guegen, from the University of Bretagne-Sud, set up an experiment in which a 20-year-old confederate approached women in a pedestrianised zone of the city of Vannes and said: ‘Hello. My name’s Antoine. I just want to say that I think you’re really pretty. I have to go to work this afternoon, and I was wondering if you would give me your phone number.’ (Guegen, 2008)

He then waited for 10 seconds, gazed at his prey, smiled and waited for a response. Thirty to forty seconds after the woman departed, she was approached by a researcher who explained that the man was part of study and that they were interested in her responses to certain questions: 455 women participated.

The preference for Gallic *fromage* aside, did women’s menstrual cycle influence their likelihood of accepting the overture? Yes, it did. Those in the fertile phase of their cycle were more likely to furnish their number, but only if they were not taking oral contraceptives. Guegen (2008) suggests that this might be explained by the fact that young French women are likely to use the pill when in a relationship, but stop when this ends. The combination of availability and high fertility may have led to the increased willingness to give a strange, attractive man their number.

This research is one in a line of studies exploring the effects of point of menses on women’s feelings of sexual attractiveness. Women are judged to be more attractive when they are in the follicular stage of their cycle and men find their body odour more attractive. Women’s appetite decreases during ovulation. They also make themselves look more attractive during this period. For example, Haselton *et al.* (2007) asked men and women to judge the attractiveness of 30 women who had partners and who were in the luteal or follicular stage of their cycle. More women in the follicular stage were judged as ‘trying to

look more attractive’. The closer the women were to ovulation (when the photograph was taken), the more likely the photograph was chosen as signifying someone attractive. These women were judged to wear more fashionable clothes, nicer clothes and show more upper body skin.

Figure 3.10 Example of an outfit illustration drawn by the same participant at low fertility (a) and high fertility (b).

Source: Durante, K.M., Li, N.P. and Haselton, M.G. (2008) Changes in women’s choice of dress across the ovulatory cycle: Naturalistic and laboratory task-based evidence. *Personality and Social Psychology Bulletin*, 34, 11, 1451–60.

Cutting edge – Continued

This perception is mirrored in women's own behaviour. Women were asked to report to a laboratory on high or low fertility days (confirmed by a hormone test) and to pose for photographs and draw an outfit that they would prefer to wear that evening (Durante *et al.*, 2008). Women were more likely to sketch sexier outfits during the high fertility period – they drew more revealing outfits, as the example in Figure 3.10 shows. The more sexually experienced the woman, the skimpier the outfit. Single women drew more revealing outfits than those who had partners but the more satisfied the women were with their partners, the more revealing the outfit they drew (suggesting that they were confident to express their sexuality in the context of a secure relationship).

Psychologists from the University of Tromsø, Norway, have also recorded the way in which women's pupils reacted as they watched photographs of either their boyfriends or celebrities (Laeng and Falkenberg, 2007). Fourteen women participated during three menstrual periods – luteal, ovulatory and menstrual. An eye-tracking device measured pupil size. (Pupil diameter increases when people are sexually aroused.)

Women during the fertile phase of their cycle showed larger pupil diameter when viewing photographs of their boyfriends, but this effect was found only on those who did not use oral contraceptives.

Monogamy: shared, but not always equal, parental investment

Around 3 per cent of the relationships in mammals are monogamous. Monogamy has evolved in those species whose environments have favoured the contributions of both parents to the survival and reproductive success of their offspring. In other words, under some conditions, two individuals sharing parental duties enjoy more reproductive success than does one individual who must do it all alone.

Although both parents in monogamous species share offspring-rearing duties, each parent may not make an equal contribution towards that end. Like females in polygynous species, females in monogamous species generally have greater parental investment in the offspring, for many of the same reasons: the limited opportunity for mating relative to that for males, pregnancy and its accompanying risks, providing milk to the newborns, and the time and energy spent in caring for them. As a result, very few monogamous species, including our own, are exclusively monogamous. In fact, there is a strong tendency in most monogamous species towards patterns of reproductive behaviour and parental investment that resemble those of polygynous species.

For example, in monogamous species, females tend to be more careful than males in selecting a mate, and males tend to be more sexually promiscuous than females (Badcock, 1991). In our own species, men tend to engage in premarital sexual intercourse more often than do females (Kinsey *et al.*, 1948, 1953; Hunt, 1974), although this gap appears to be decreasing. Men also tend to have more premarital and extramarital sexual partners (Symons, 1979), although recent studies show that over 90 per cent of male and female undergraduate respondents want to settle down with one partner exclusively at some point (Pedersen *et al.*, 2002).

Reproductive success today may not be thought of in terms merely of the number of children we have (although among some religious subcultures this is still an important measure of success), but in terms of how well individuals raise healthy, happy and well-adjusted children. Although most people have the biological capacity to produce a large number of children, many do not have the psychological or financial wherewithal to do so. Some people fear that a large family will reduce the amount of money they can make and will therefore lower their quality of life. Others see a large family as an impediment to obtaining career goals and other life aspirations. And still others simply have no desire to have any children at all.

Monogamy and hormones

Some scientists have hypothesised that monogamy may be attributable to chemicals called hormones, described in detail in the next chapter (Young *et al.*, 1998). These are generated by a region in the brain which sends signals to organs of the body to react in a certain way. The proposed relationship between hormones and monogamy has been based on studies of a type of rodent, the vole. Researchers have found that two types of vole show very different patterns of mating: the prairie vole is largely monogamous, forming lasting partnerships; the montane vole, however, is promiscuous and not a particularly social species. The male montane vole is not parental and does not form a bond with its partner; the female montane vole abandons its offspring around two to three weeks after birth (Young *et al.*, 1998).

Two key hormones have been identified that could underpin these behaviours: oxytocin (OT) and vasopressin (AVP). In prairie voles, vaginal-cervical copulation leads to an increase in the release of OT. This release may promote intense mating in females but has little effect on

males. Vasopressin, however, does affect male prairie voles. Administering this hormone in these male voles leads to a preference for an exclusive partner, aggression towards strangers and an increase in paternal care (Young *et al.*, 1998). In the montane male vole, the effect of the hormones is not aggression but self-grooming. The receptor distribution for these hormones in the brain of the prairie vole is similar to that in other monogamous types of vole; conversely, the distribution of receptors in montane voles is similar to other promiscuous vole types. Levels of oxytocin have recently been associated with trustworthiness and trustworthy behaviour in humans (Zak *et al.*, 2005).

Together, these findings suggest that there may be some hormonal basis to the monogamy seen in certain species and that this hormonal basis arises from receptor distributions which, in turn, arise from the expression of a gene. The idea is controversial and provocative but interesting. It is unclear, with primates' high degree of (largely) sophisticated social interaction, whether such endocrinal expressions could explain monogamy and promiscuity in humans.

Infidelity

It has been estimated that between 20 and 50 per cent of people who are married will be unfaithful to each other at some point (Thompson, 1983; Wiederman, 1997), and men claim to want a greater number of sexual partners across a lifetime than do women.

For various evolutionary reasons, evolutionary psychologists suggest that men and women respond differently to different types of infidelity. Heterosexual men, for example, are more likely to show jealousy in response to sexual infidelity (a partner having sex with another man), whereas heterosexual women are more likely to show jealousy in response to emotional infidelity (a partner having a very deep, loving, yet non-sexual, relationship with another woman). A study in which male and female undergraduates were asked whether they would forgive the two types if infidelity in their partner conformed to the expected pattern and found that men were less likely to forgive sexual than emotional infidelity whereas women showed the opposite pattern (Shackelford *et al.*, 2002). Men were also more likely to terminate a relationship if their partner committed sexual infidelity.

Harris (2002) examined men's and women's responses to infidelity by giving them a scenario to respond to. As in most other studies, participants were asked whether they would be more upset if they found out that their partner was trying different sexual positions with another or if their partner was falling in love with another. Some 196 participants, with a mean age of 37, were recruited via newspaper advertisements and flyers. Harris was also interested in whether responses would be similar in

homosexual and heterosexual men and women and so recruited roughly equal numbers of each. Participants were asked if they had been 'cheated' on, whether they focused on the emotional or sexual consequences of the cheating and whether the relationship ended as a result.

As predicted by evolutionary psychology, heterosexual men were more likely to find sexual infidelity more upsetting than they would emotional infidelity when responding to the forced-choice question. The reverse pattern was found for women. When participants recalled actual examples of infidelity, however, no sex differences were found. Regardless of sexual orientation, both men and women were more likely to focus on a partner's emotional than sexual infidelity as the source of distress. No relationship was found between participants' responses to hypothetical and actual infidelity.

Harris (2002) concludes:

If emotional jealousy was selected for because it helps women prevent loss of a mate's resources, then how did men come by such a mechanism? . . . the farther one moves away from asking college students the forced-choice question regarding hypothetical infidelity toward assessing real infidelity with adults, the less support one finds for the [evolutionary] hypothesis.

People who are married to disagreeable, undependable and emotionally unstable partners are less satisfied with their marriage (Shackelford and Buss, 2000). Low agreeableness, low emotional stability and low conscientiousness in women is associated with low marital satisfaction in men. Disagreeable, emotionally unstable men were also more likely to abuse their wives than their agreeable, emotionally stable counterparts. Furthermore, mate-guarding tactics such as threatening infidelity, threatening to punish infidelity and emotional manipulation (i.e. the factors which inflict costs on a relationship) were associated with lower marital satisfaction in the people at the receiving end of these tactics.

What makes a mate poacher? When infidelity occurs, are there factors that can dispose a person to being unfaithful and to wanting to have a relationship with a person who already has a partner? One study found that 84 per cent of undergraduates reported that attempts had been made to poach them from their partners (Schmitt and Buss, 2001). Of those who were romantically linked (just over 55 per cent), 20 per cent of men and 28 per cent of women stated that their partners had been poached from someone else. In terms of personality, agreeable and conscientious people were least likely to be mate poachers, a finding that is found internationally (Schmitt, 2004). Those who did not regard relationships

Cutting edge – Jealousy, infidelity and the brain

Although romantic jealousy seems more common in men than women, the sexes may also differ in what they become jealous about. Men are more likely to be jealous, angry and upset about sexual infidelity whereas women are more likely to be upset by emotional infidelity (their partner engaging in a warm and fulfilling friendship with another woman). These differences might have a neural basis (Takahashi *et al.*, 2006).

Twenty-one men and women read the statements in Table 3.3 silently as brain activation was recorded. They read the statements again after scanning and were asked how they would feel if their boyfriend or girlfriend was the protagonist.

Men and women did not differ significantly in terms of the types of infidelity they felt jealous about – both sexes became

equally jealous under both conditions (emotional or sexual infidelity). However, brain activation did differ by sex. Men showed greater activation in the amygdala during sexual jealousy and in the hypothalamus during emotional infidelity. These are structures involved in sexuality and reproduction, amongst other functions. Women showed greater activation in the posterior superior temporal sulcus, an area the authors suggest is implicated in ‘the detection of others’ intention or violation of social norms’.

The data from this small group of healthy young adults suggest that subtle neural differences might underlie jealous responses to certain types of infidelity.

Table 3.3 Examples of the jealousy-arousing sentences used in Takahashi *et al.*’s study

Neutral

My girlfriend stayed in a twin-bed room in a hotel with her female friend
 My girlfriend wrote a new year’s card to her female friend
 My girlfriend spent a night in her female friend’s room
 My girlfriend meets her best female friend frequently
 My girlfriend had her coat taken off by her female friend
 My girlfriend telephones her parents on the weekend
 My girlfriend e-mailed her mother yesterday.

Sexual infidelity

My girlfriend stayed in a double-bed room in a hotel with her ex-boyfriend
 My girlfriend took a bath with another man
 My girlfriend had her underwear taken off by another man
 My girlfriend spent a night in her ex-boyfriend’s room
 My girlfriend kissed another man deeply
 My girlfriend passionately embraced another man
 My girlfriend took an overnight trip with another man
 My girlfriend was naked with her ex-boyfriend in his bed.

Emotional infidelity

My girlfriend wrote a love letter to another man
 My girlfriend had dinner with another man on my birthday
 My girlfriend supplied another man with all the money she had saved
 My girlfriend telephones her ex-boyfriend every day
 My girlfriend always talks with delight about her ex-boyfriend in front of me
 My girlfriend emails to her ex-boyfriend every night
 My girlfriend gave gorgeous birthday presents to her ex-boyfriend
 My girlfriend meets another man more frequently than she does me

as exclusive and described themselves as having erotophilic tendencies – a constant desire to satisfy sexual needs – were more likely to poach. These individuals also scored high on sexual attractiveness: it appears that the poacher may have to be sexy, as well as adulterous.

Extraverts were more likely than introverts to be recipients of poaching attempts. Those who rated themselves as sexually attractive, as not relationship exclusive and as emotionally investing (loving) were those who were most likely to be poached.

Physical attractiveness was more important for men than it was for women. Women, conversely, were more likely to view resource acquisition as a benefit of poaching, especially in short-term relationships. Because men value physical attractiveness in women, women pay greater attention to using physical characteristics as cues to attraction. Women, on the other hand, placed greater value on resources. Men, consequently, emphasised cues that indicate that they are resource-laden (such as expensive clothes, cars, jewellery and so on). Women who thought they could make themselves more attractive by disparaging the partner of the person they wanted to poach were not as effective as enhancing physical attractiveness.

As predicted, men were found to be more successful than women at poaching when they displayed resources. Men who showed displays of dominance were also more likely to be effective at poaching in the short term, but this factor was not rated very highly. Getting a mate drunk was an ineffective poaching cue in the long term but one with moderate success in the short term, especially when used by women. Men were more effective at using humour as a poaching cue than were women in the short and long term. Women employed a tactic that was significantly more effective when used by them than by men: boosting the partner's ego.

When the relationship of the person who was being poached was long-distance, not committed or about to end, poaching was effective; when the relationship involved marriage, great commitment, living together or just beginning, poaching was seen as ineffective.

Although based on a sample of undergraduates, and assessing perceived effectiveness rather than actual effectiveness of poaching, this series of studies shows that poaching is a common phenomenon and that men and women use different cues with varying degrees of success to poach a mate from their existing partner.

Promiscuity

Promiscuity – the tendency to engage in sexual activity with multiple partners (not necessarily at the same time) – has been associated with specific personality types. Sensation-seekers, for example, have more partners than

low sensation-seekers; and the unconscientious, extravert, the less agreeable and more antagonistic similarly report having more sexual partners than the conscientious, the less extravert and the more agreeable/less antagonistic. A new study has associated two other factors with this behaviour (Markey and Markey, 2007). In a study of 105 young men and 105 young women, people who were dominant had significantly more sexual partners than did those who were less so. Curiously, people who were personally warm were also more likely to have had more sexual partners than the less warm. 'This indiscriminate behaviour [promiscuity]', the authors conclude, 'may not always be ill-intentioned but, in some cases, may be an expression of warmth.' Commenting on the findings regarding dominance, the authors suggest that 'selective participation in sexual behaviours may be a reflection of an individual's submissiveness, not their "moral piety"'.

A related study examined whether men who engaged in unrestricted sexual activity – engaging in transient sexual relations – perceived women's attractiveness differently from men who were more restricted (Swami *et al.*, 2008). Men self-described as restricted or unrestricted rated the attractiveness of drawings of women who differed according to Body Mass Index and waist-to-hip ratio. The men, regardless of type, used BMI rather than WHR as the basis of their judgement but unrestricted men found women with lower BMI to be more attractive and healthy than did restricted men. The unrestricted men also preferred women with a low WHR.

Polyandry: high male and low female parental investment

Polyandry is a rare reproductive strategy among humans and non-existent in other mammals. It is more prevalent among species that lay eggs. Once the eggs are laid, then either the male or the female may take care of them, although in many instances the male makes the greater investment of time and effort.

An example of polyandry in humans is found among some of the people who live in remote Himalayan villages. These people are extremely poor and live in a harsh environment, which makes their primary livelihood, farming, difficult. In order to prevent the dissolution of family farms through marriage, families that have more than one son limit the number of marriages to only one per generation – several brothers may share the same wife. A female tends to marry more than one man (most often brothers) to guarantee that she will be adequately supported. In other words, the male's primary investment – the farm, which is the source of food and some income for the family – is guarded jealously through polyandry.

Infidelity – An international perspective

While some of the psychological characteristics of mate poachers and mate poaching are well documented, the extent of the behaviour cross-culturally is less well documented. Evolutionary psychologists argue that the nature and degree of mate poaching/poachers should be similar across cultures but with some provisos. Studies show that men are more likely than women to engage in short-term mate poaching and so we might expect this finding across cultures.

However, we might also expect cultures which observe traditional sex roles to show a bigger difference between men and women than cultures that are more liberal and egalitarian. In demanding environments (those that afford fewest resources), there may be less of an opportunity or a desire for mate poaching because the difficulties involved in raising a family require commitment from both partners. These predictions were tested by Schmitt and colleagues (Schmitt *et al.*, 2004) in a study of 16,954 individuals from 53 nations, divided into 10 world regions (North America, South America, western Europe, eastern Europe, southern Europe, the Middle East, Africa, Oceania, South/Southeast Asia, and East Asia).

Mate poaching overall was very common – 70 per cent reported that they had been the object of a poaching attempt. Eighty per cent of poaching attempts were apparently successful with 10 per cent of such attempts leading to a long-term relationship. Mate poaching was most common in southern Europe, South America and western Europe and was least common in Africa, South/Southeast Asia and East Asia, a finding that is consistent with the prediction regarding demanding environments. The number of attempts at mate poaching by members of various cultures can be seen in Figure 3.11.

Also consistent with the study's predictions, men were more vigorous mate poachers than were women, with 60 per cent of men reporting that they had attempted to mate poach and 40 per cent of women reporting so. In cultures where men and women were regarded as equals, this sex difference was smaller.

In keeping with previous studies, the personality measures showed that poachers were extraverted, disagreeable, uncon-

Figure 3.11 The degree of mate-poaching across nations and cultures. Europeans and Americans seem especially keen on it.

Source: D.P. Schmitt, Patterns and universals of mate poaching across 53 nations: The effects of sex, culture and personality on romantically attracting another person's partner, *Journal of Personality and Social Psychology*, 2004, 86 (4), 560–84, Figure 2.

scientious, slightly narcissistic and (no surprise here) unfaithful. The poached were likely to be extraverted, open, attractive and disagreeable. Both groups were likely to be highly sexual.

Of course, the majority of the study's participants were young undergraduates and the authors note that mate poaching may be more common in this younger group than in an older sample. They also note that studying young married couples would be informative because men are reported to be highly jealous if an attempt is made to woo their wives. These men also appear to be more vigilant in observing such attempts. It would also be useful to measure the degree of satisfaction with a poacher's current relationship and whether this, rather than some personality profile, is the key predictor of poaching.

Polygynandry: group parental investment

Many primates, such as chimpanzees, live in colonies in which few or no barriers are placed on which female mates with which male. In other words, the colonies are promiscuous – during periods of mating, intercourse is frequent and indiscriminate. What is the advantage of such a reproductive strategy?

The primary advantage seems to be the cooperation of males and females in the colony with respect to rearing offspring. Because the males in the colony are not sure which

offspring belong to them, it is in their best interest to help rear and protect all the offspring and defend their mothers. The unity in the colony and the lack of aggression among the males contributes directly to the general welfare of all colony members. Females and males have access to many mates, and the offspring are well cared for.

However, a form of monogamy called a consortship is sometimes observed in polygynandrous species. For instance, a particular male chimpanzee may ward off other male suitors from a particular female, resulting in an exclusive sexual union. If successful, he is guaranteed

the certainty of which offspring are his, albeit at some cost. There is a chance that he could be seriously injured in protecting his mate from other males, and therefore he becomes less useful as a parental investor in his offspring or those of the colony.

Incestuous relationships: a universal taboo

All reproductive strategies seem to have one element in common: avoidance of incest. Incest is the mating of kin who share many of the same genes. Avoidance of incest appears to have evolved for a very good reason: closely related relatives are likely to share the same recessive genes that cause genetic disorders. Thus, animals that avoid incestuous matings have an evolutionary advantage over those that do not; they produce healthier offspring who themselves are more likely to live to sexual maturity and produce offspring of their own.

All human cultures have taboos against incest. A taboo is a societal rule prohibiting the members of a given culture from engaging in specific behaviours – in this case, mating with a genetically related individual. Taboos are products of cultural evolution and are socially transmitted through language from one generation to the next.

Incest taboos are probably of secondary importance, serving to reinforce the aversion we have towards incest or mating with non-relatives with whom we were raised. For example, in one study (Shepherd, 1983), the elders actually encouraged the children of the kibbutz to marry so that the children would not end up living far from home. Despite the absence of a taboo and the encouragement of the elders, none of the children married each other.

Altruism and kin selection

A particularly interesting and important social behaviour in terms of evolution is **altruism**, the unselfish concern of one individual for the welfare of another. Examples of altruistic behaviour abound and its most extreme form is when one person risks their life to save the life of another. Examples of altruism are also common throughout the animal kingdom. The honey bee, for example, sacrifices its life on behalf of its hive-mates by stinging an intruder. Here, the altruist's chances of survival and reproductive success are lowered while that of the other individuals are raised.

Sociobiologists seek out ultimate causes, especially the consequences of natural selection, to explain altruism. They assert that natural selection has favoured the evolution of organisms that show altruistic tendencies. However, there is an important problem here. On the surface, altruism poses an enigma to evolutionary theory. Recall that according to natural selection only phenotypes that enhance one's reproductive success are

favoured. How could altruistic behaviour have evolved given that, by definition, it is less adaptive than selfish or competitive behaviour?

The geneticist William D. Hamilton (1964, 1970) suggested an answer to this question in a series of mathematical papers. Hamilton's ideas stemmed from examining natural selection from the perspective of the gene instead of from the perspective of the whole, living organism. He argued that natural selection does not favour mere reproductive success but rather **inclusive fitness**, or the reproductive success of those individuals who share many of the same genes. Altruistic acts are generally aimed at close relatives such as parents, siblings, grandparents and grandchildren. The closer the family relation is, the more likely the genetic similarity among the individuals involved. Such biological favouritism towards relatives is called **kin selection** (Maynard Smith, 1964).

The message here is clear: under the proper circumstances, individuals behave altruistically towards others with whom they share a genetic history, with the willingness to do so decreasing as the relative becomes more distant. In this view, altruism is not necessarily a conscious act but rather an act driven by a biological prompt that has been favoured by natural selection. Natural selection would favour this kind of altruism simply because organisms who share genes also help each other to survive.

Parenting is a special case of kin selection and an important contributor to one's survival and reproductive success. In the short run, parents' altruistic actions promote the continued survival of their offspring. In the long run, these actions increase the likelihood that the offspring, too, will become parents and that their genes will survive in successive generations. Such cycles continue according to biological schedule, generation after generation. In the words of sociobiologist, David Barash (1982, pp. 69–70):

It is obvious why genes for parenting have been selected: all living things are the offspring of parents who themselves were [the offspring of] parents! It is a guaranteed, unbroken line stretching back into time. [Genes] that inclined their bearers to be less successful parents left fewer copies of themselves than did those [genes] that were more successful.

What is at stake is not the survival of individual organisms but the survival of the genes carried by those organisms. Genes allow organisms to maximise their inclusive fitness through altruistic behaviour directed at other organisms sharing the same genes (Dawkins, 1986). Inclusive fitness refers to the idea that reproduction and natural selection occurs because a species' success is

measured through the production of offspring. You carry copies of genes that have been in your family line for thousands of years. When the opportunity presents itself, you will most likely carry on the tradition – reproducing and thus projecting your biological endowment into yet another generation. But you did not reach sexual maturity on your own; the concern for your welfare by your parents, brothers, sisters, grandparents and perhaps an aunt or uncle has contributed to your chances of being reproductively successful. Genes not projected into the next generation simply disappear.

Another variable may mediate altruism, however: emotional closeness. Emotional closeness is defined as having a sense of concern and caring for another and enjoying a comforting, emotional relationship with them. One study asked participants to rate how willing they would be to behave altruistically towards members of their family when the family member could live or die, and when helping would be at a cost to the participant (Korchmaros and Kenny, 2001). Participants also indicated how emotionally close they were to these family members.

People were more likely to help family members with whom they shared a close relationship, regardless of the genetic closeness of the relationship, than with those with whom they shared a less close relationship. The findings suggest that emotional closeness may be a mediating cause of altruistic behaviour.

Evidence from step-relations' behaviour supports the idea of inclusive fitness. It has been reported, for example, that a disproportionate number of children in stepfamilies suffer physical harm, especially assault (Daly and Wilson, 1988). Child battering is more common in stepfamilies, as is the incidence of child abuse (Daly and Wilson, 1996). This evidence, the sociobiologists argue, supports the notion that non-genetic relatives are not disposed to invest resources in offspring that are genetically unrelated.

There is also evidence to suggest that cohabitation is a greater risk factor for spousal murder than is marriage. Canadian research published at the beginning of the 1990s suggested that women in cohabiting relationships were more likely than married women to be murdered by their partner (Wilson *et al.*, 1993, 1995). Data from specific US cities show the same pattern (e.g. Wilbanks, 1984). According to the Wilson *et al.* studies, women in their early twenties were at greater risk of homicide if they were married; for cohabiting women, women in their mid-thirties to forties were at greatest risk. A national study of over 400,000 US homicides committed between 1976 and 1994 found that women in cohabiting relationships were nine times more likely than married women to be murdered by their partner (Shackelford, 2001). The risk for married women decreased as they became older. Middle-aged women, however, were at greatest risk if they were in a cohabiting relationship.

Young men were more likely to murder their wives whereas middle-aged men were more likely to murder their cohabiting partners.

One explanation for these findings is that men may tend to feel significantly and abnormally proprietorial about their partners, especially about their partner's sexuality. A man in a cohabiting relationship is more insecure than is a married man because the possibility of either partner leaving the relationship is more likely and is easier to do. The cohabiting man may, therefore, go to more extreme lengths to prevent his partner from leaving him than would a married man because cohabiting relationships are more likely to break than are marriages. There is some evidence in support of this interpretation. Daly and Wilson (1988), for example, cite their partner data showing that men who kill their partners are more likely to do so because they suspect that their partner has been unfaithful or may be about to terminate their relationship.

Reciprocal altruism

Kin selection explains altruism towards relatives, but what about altruism directed towards non-relatives? According to Trivers (1971), this kind of altruism, called **reciprocal altruism**, exists because humans (and other organisms) can function more effectively if they work together. Human groups are hierarchical and cooperative (Buss, 1995), whether at the level of the family, canoe club or workplace. There is also evidence that kindness, dependability, emotional stability and intelligence (all traits one would associate with altruism) are the most valued personality characteristics in potential mates (Buss, 1995). Cooperation between groups is a fundamental survival strategy (Brewer and Caporael, 1990), and is seen in many higher primates (Byrne, 1995). For example, in order to win a mate from a dominant male savannah baboon, a male will engage the help of another baboon who will distract the dominant male and enter into a fight with him. This leaves the other, non-dominant male free to mate with the female. The altruism is reciprocal because the favour will be reciprocated by the successfully paired male in the future (Haufstater, cited in Byrne, 1995). Another primate example where reciprocal altruism can be seen is in food sharing and also in a task called the prisoner's dilemma.

The prisoner's dilemma

An illustration of the way in which reciprocal altruism can work is provided by the 'prisoner's dilemma' (Axelrod and Hamilton, 1981). The **prisoner's dilemma** is a scenario in which individuals are allowed to cooperate or not cooperate. Two suspects are imprisoned separately and are asked to consider being silent (to cooperate) or sing (to defect).

If both prisoners cooperate then they both get lighter sentences; but if one sings then that prisoner gets off still more lightly. If the game is played once, defection is the best strategy; however, if the game is played repeatedly then staying silent might be the best option because the other player can return the favour or punish the defection. Nowak and Sigmund (1998) have suggested that cooperation can still be established even if there is no chance for the cooperation to be reciprocated. The reason for this is that an individual seen to be cooperative or having a reputation for being cooperative will be more likely to experience reciprocal behaviour from others in future. In short, helping will be rewarded by someone who acknowledges your good reputation.

The prisoner's dilemma may not be the most effective test of cooperation because it allows only cooperation or defection. In real life, however, cooperation is not an all-or-nothing behaviour. Some individuals may invest slightly less in cooperation, some slightly more, but they may all cooperate in some form. Imagine two individuals giving to charity: one gives £10, the other gives £100. Both are cooperating (being altruistic), but one is more altruistic than the other (one may be able to afford the £100 but the other is making a financial sacrifice by donating £10). Because of this variation in altruism, Roberts and Sheratt (1998) have suggested a 'raise the stakes' model of altruistic behaviour. This model argues that individuals would offer a small amount at the first meeting and if this amount is reciprocated, then more will be offered at the next opportunity. This model suggests that behaviour cannot be effectively exploited and so cooperation would be enhanced.

Sociobiology and evolutionary psychology as an explanation for human behaviour?

So far in this chapter you have seen that sociobiologists attempt to explain social behaviour by reference to natural selection and genetic inheritance. Evolutionary psychologists 'develop hypotheses about the psychological mechanisms that have evolved in humans to solve the particular adaptive problems that humans have faced under ancestral conditions' (Buss, 1995, p. 4).

Sociobiology has been at the centre of a fierce scientific controversy ever since E.O. Wilson published *Sociobiology: The new synthesis* in 1975, the official birth date of this discipline. Although Wilson's work, which is based chiefly on studies of non-human animal behaviour, has generated an enormous outpouring of scientific research, it has also roused a number of serious charges (Montagu, 1980). Wilson's *On Human Nature* (1978), which extended sociobiological theory to human affairs, ignited even more

criticism. Most of the criticism focuses on the extension of the theory to human behaviour. Two issues which have caused greatest controversy are inclusive fitness and the mechanisms of adaptation.

Recall that inclusive fitness theory argues that reproduction and natural selection occur because species' survival success is measured through the production of offspring. Those characteristics which help promote the transmission of genes (either directly or indirectly) will be naturally selected, akin to Dawkins's sieve mentioned at the beginning of the chapter. Sociobiologists see humans as 'fitness maximisers', or 'fitness strivers' (Alexander, 1979), constantly applying the mechanisms for maximising inclusive fitness. The evolutionary psychologists, however, call this the 'sociobiological fallacy' (Buss, 1991, 1995) because it confuses the theory of origins of mechanisms with the theory of the nature of mechanisms. As Buss argues, if humans were 'fitness maximising blobs', why are men not queuing up at sperm banks to donate their sperm? Why do some couples forgo reproduction? We have developed a preference for fatty foods but this is known to be detrimental to us. If we know this food is unhealthy, why do we eat it? More to the point, we can look at individuals or their behaviour and easily find maximising fitness reasons for this behaviour. The inclusive fitness theory, therefore, cannot account for natural selection and, because of its breadth (one can interpret almost any behaviour in terms of maximising fitness), is virtually limitless in its application.

Instead of seeing humans as fitness maximisers, evolutionary psychologists see humans as 'adaptation executors' or 'mechanism activators' (Tooby and Cosmides, 1990). That is, humans apply evolved solutions to adaptive problems (Buss, 1995). These solutions are domain-specific. That is, the types of solution one would need to reach to select a mate are different from those one needs to obtain food or to parent children. Adaptive problems are large, complex and varied; the success of individuals in solving these problems depends on sex, species, age, context and individual circumstances (Buss *et al.*, 1998). Sociobiology, however, seems to ignore this psychological level of interpretation and goes from evolution straight to patterns of social organisation.

The most intense criticism of sociobiology is political, not scientific. Opponents argue that sociobiology sanctions the superiority of one group over another, be it a race, a gender, or a political organisation. After all, they argue, if one group of individuals is genetically superior to another, then there are 'natural' grounds for justifying the 'survival of the fittest' and one group's unethical and immoral domination of another. An example is Hitler's quest for world domination in the name of Aryan superiority. Sociobiologists flatly deny such allegations and argue that it is the critics and not they who have confused the term

‘natural’ with the terms ‘good’ and ‘superior’. Are political objections to sociobiology scientifically acceptable ones? Do you think that psychologists should be concerned with political objections to their findings or theories?

Given the broad-sweep nature of sociobiological theory, it is not surprising that the theory fails to account

adequately for natural selection. Although kin selection and familial altruism could be interpreted as supporting the inclusive fitness theory, it is true that one could explain away a lot of behaviour by describing it as maximising fitness.

Chapter review

Natural selection and evolution

- Understanding behaviour requires that psychologists learn more about both proximate causes of behaviour – how animals adapt to environmental changes through learning – and ultimate causes of behaviour – historical events and conditions in the evolution of a species that have shaped its behaviour.
- Darwin’s voyage on the *Beagle* and his subsequent thinking and research in artificial selection led him to develop the idea of biological evolution, which explains how genetic and physical changes occur in groups of animals over time.
- The primary element of biological evolution is natural selection: the tendency of some members of a species to produce more offspring than other members do. Members of a species vary genetically; some possess specific traits to a greater or lesser extent than other individuals do. If any of these traits gives an animal a competitive advantage over other members of the species then that animal is also more likely to have greater reproductive success. Its offspring will then carry its genes into future generations.
- Two important adaptations during the course of human evolution are bipedalism – the ability to walk upright – and encephalisation – an increase in brain size. The combination of these two factors allowed early humans to explore and settle new environments and led to advances in tool making, hunting, food gathering and self-defence.
- Encephalisation appears to have been associated with language development and cultural evolution. The study of the evolution of our species suggests the nature of the circumstances under which adaptive behaviour first emerged and those circumstances that have been important for its continued expression to the present time.
- Such recombination makes for tremendous genetic diversity. Genetically diverse species have a better chance of adapting to a changing environment than do genetically non-diverse species because some members of the species may have genes that enable them to survive in a new environment.
- The expression of a gene depends on several factors, including its interaction with other genes (polygenic traits), the sex of the individual carrying the particular gene, and the environmental conditions under which that individual lives. Changes in genetic material caused by mutations or chromosomal aberrations lead to changes in the expression of a particular gene. For example, haemophilia, an increased tendency to bleed from even minor injuries, is the result of a mutation, and Down syndrome, which involves impaired mental, physical and psychomotor development, is the result of a chromosomal aberration.
- Behaviour genetics is the study of how genes influence behaviour. Psychologists and other scientists use artificial selection studies of animals, twin studies, and adoption studies to investigate the possible relationship between genes and behaviour in humans.
- Recent studies suggest that the attitudes and personalities of identical twins are more closely related than are those of fraternal twins.

Sociobiology

- The discovery of the biological basis for social behaviour is the primary goal of sociobiology. Sociobiologists have been especially interested in studying social behaviour related to reproduction and the rearing of offspring.
- Evolutionary psychology is a relatively new sub-field of psychology (and sociobiology) that is devoted to the study of how evolution and genetic variables influence adaptive behaviour.
- Different reproductive strategies are believed to have evolved because of sex differences in the resources that parents invest in procreative and child-rearing activities. These resources include the time, physical efforts and risks to life involved in procreation and in the feeding, nurturing and protection of offspring.
- A low waist-to-hip ratio appears to be preferred by Western heterosexual men; a waist-to-chest ratio that emphasises narrow hips and broad shoulders is preferred by Western heterosexual women. In some cultures, however, there is a

Heredity and genetics

- The instructions for the synthesis of protein molecules, which oversee the development of the body and all of its processes, are contained in genes. Genes are found on chromosomes, which consist of DNA and are found in every cell.
- Humans inherit 23 individual chromosomes, each of which contains thousands of genes, from each parent. This means that our genetic blueprint represents a recombination of the genetic instructions that our parents inherited from their parents.

preference for heavier, larger women. One reason for this is that these cultures may not have been exposed to the Western ideals of physical beauty, those which emphasise the curvaceousness of women.

- Recent research suggests that facial attractiveness may be a more important determinant of mate selection than is waist-to-hip ratio.
- Polygynous and monogamous strategies tend to require greater female investment, polyandrous strategies tend to require greater male investment, and polygynandrous strategies tend to require investment on the part of members of a large group, such as a colony of chimpanzees. Despite these differences, all reproductive strategies entail avoidance of incest, either through migration or the recognition of closely related genetic kin or those individuals with whom one was raised. All human cultures have taboos about incest.
- Altruism is difficult to explain by appealing to natural selection. Altruistic behaviour generally involves one organism risking its life for others with whom it shares some genes (kin selection)

or who are likely subsequently to be in a position to return the favour (reciprocal altruism).

- Inclusive fitness theory argues that reproduction and natural selection occur because species' survival success is measured through the production of offspring. Those characteristics which help promote the transmission of genes (either directly or indirectly) will be naturally selected.
- Sociobiology has been criticised on the grounds that natural selection is no longer a factor in human evolution, that research on animal social behaviour is not relevant to understanding human social behaviour, that environmental factors play a greater role in shaping human behaviour than genetic factors, and that sociobiology is simply a way to justify the superiority of one group over another. Sociobiologists reply that natural selection has shaped and continues to shape the evolution of culture, that findings from animal research can be generalised to humans, that genes and environment interact to determine behaviour, and, finally, that sociobiology is an attempt to understand human behaviour, not to justify it.

Suggestions for further reading

Evolution: Popular accounts

- Scerif, G. and Karmiloff-Smith, A. (2005) The dawn of cognitive genetics? Critical developmental caveats. *Trends in Cognitive Sciences*, 9, 3, 126–36.

These items give a useful introduction to behavioural genetics (and objections to behavioural genetics).

Evolutionary psychology and sociobiology

- Buss, D.M. (2008) *Evolutionary psychology: The new science of mind* (3rd edn). Boston: Allyn & Bacon.
- Matsuzawa, T. (2008) *Primate origins of human cognition and behaviour*. New York: Springer.
- Pigliucci, M. (2006) Is evolutionary psychology a pseudoscience? *Skeptical Inquirer*, 30, 2, 23–4.
- Rose, H. and Rose, S. (2000) *Alas, Poor Darwin*. London: Jonathan Cape.
- Wilson, E.O. (1975) *Sociobiology: The new synthesis*. Cambridge, MA: Harvard University Press.
- Workman, L. and Reader, W. (2004) *Evolutionary psychology*. Cambridge: Cambridge University Press.

These selected readings are a good introduction to sociobiology and evolutionary psychology. Donald Buss is a highly active researcher and thinker in evolutionary psychology; his book is a very good review of the limits and frontiers of this controversial sub-area. The Workman and Reader book is similar. Wilson's book is a classic in this area. The Roses' edited book is a collection of tendentious essays on evolutionary psychology, with Pigliucci also providing a critical perspective.

Comparative evolution

Byrne, R. (1995) *The Thinking Ape: Evolutionary origins of intelligence*. Oxford: Oxford University Press.

Richard Byrne's excellent little book is a provocative and detailed account of the evolution of intelligence in primates from the perspective of evolutionary psychology.

Psychobiology and neuroscience

Found: the brain's centre of wisdom

Jonathan Leake, Science Editor

Scientists have identified the seat of human wisdom by pinpointing parts of the brain that guide us when we face difficult moral dilemmas.

Sophisticated brain scanning techniques have found that humans respond by activating areas associated with the primitive emotions of sex, fear and anger as well as our capability for abstract thought.

The findings, to be published in the *Archives of General Psychiatry*, represent a significant incursion into territory once regarded as the domain of religion and philosophy.

Explore the accompanying videos, simulations, and animations on MyPsychLab. This chapter includes activities on: Brain structure and function • Brain damage • The autonomic nervous system • The endocrine system • Check your understanding and prepare for your exams using the multiple choice, short answer and essay practice tests also available.

WHAT YOU SHOULD BE ABLE TO DO AFTER READING CHAPTER 4

- Describe the major parts of the nervous system and its principal components.
- Describe and understand the most important functions of these components.
- Describe the parts of a nerve cell and how it functions.
- Understand how nerve cells communicate with each other.
- Describe the various techniques used in neuroscience and psychobiology to study behaviour, from lesioning to heart rate recording to neuroimaging.
- Describe the lobes of the brain and their function.
- Be aware of the effects of drugs on behaviour and how they act on the brain to produce these behaviours.
- Be able to understand some of the psychobiological causes and correlates of behaviour.

QUESTIONS TO THINK ABOUT

- Are two human brains exactly alike?
- Do psychological functions such as language, memory or visual perception reside in specific parts of the brain?
- Do different sides of the brain undertake different functions? If they do, what purpose would this serve?
- What do you think scientists mean by 'nature v. nurture' explanations? Is this concept a sensible one?
- How can we measure the brain and body's responses to external and internal stimuli?
- Is any chemical that has an effect on our body and brain 'a drug'?
- Why do certain drugs have different effects on our behaviour?
- If a person needs a drug to function efficiently, in what way could he or she be said to 'abuse' it?

Psychobiology and neuroscience

In Chapter 1 you saw that psychology is a discipline with many subdivisions. Sometimes these subdivisions are further subdivided into more specific areas of study. Psychologists who study the role of physiology in behaviour, for example, may be interested only in specific behaviours, organisms and techniques. Consequently, psychologists who specialise in researching the role of the brain and body in behaviour are known by different names.

Psychobiology is the study of the role of physiology and anatomy in the regulation and execution of behaviour – these topics can range from the role of hormones in sexual reproduction, the effect of glucose deprivation on hunger, the relationship between hormone secretion and stress, the effect of relaxing music on heart rate, or the activation of the brain while a person is engaged in a particular task. Neuroscientists study similar processes but limit themselves to studying certain parts of the body – the brain and spinal cord. Together these parts are known as the **central nervous system (CNS)**, so called because not only do they occupy the central position of the body but they are also the most important part of the nervous system for maintaining and producing behaviour. Neuroscientists study the CNS of any organism that possesses one.

Neuropsychologists, as you saw in Chapter 1, study the relationship between the brain and its function. A goal of neuropsychology is localisation of function – the idea that parts of the brain perform specific functions. Although much of the research in neuropsychology derives from the effects of brain damage on behaviour, neuropsychologists also study psychological function in healthy individuals by using modern neuroimaging techniques (described later on). Psychophysicists study physiological processes such as heart rate, hormone secretion, brain electrical activity and skin conductance and the conditions in which changes to these processes arise.

The nervous system: the brain and its components

The brain looks like a lump of porridge and has the consistency of blancmange. This organ, weighing an average 1400 g in an adult human, is the most important part of the body (it was not always so – Aristotle, for example, believed that the heart was more important to behaviour). It contains an estimated 10 to 100 billion nerve cells and about as many supporting cells, which take care of important support and ‘housekeeping’ functions. The brain

contains many different types of nerve cell which differ in shape, size and the kinds of chemicals they produce.

Although nerve cells of the brain are organised in modules – clusters of nerve cells that communicate with each other – individual modules do not stand alone. They are connected to other neural circuits, receiving information from some of them, processing this information and sending the results on to other modules. In his famous book *The Modularity of Mind*, the philosopher Jerry Fodor (Fodor, 1983) argues that particular modules have particular functions – just as the transistors, resistors and capacitors in a computer chip do – and are relatively independent of each other. Although this idea – **modularity** – is still controversial, the evidence broadly supports some degree of modularity in the brain. The aim of psychobiology and neuroscience is to understand how individual nerve cells work, how they connect with each other to form modules, and just what these modules do.

The central nervous system

The brain has two primary functions: the control of behaviour and the regulation of the body's physiological processes. The brain cannot act alone – it needs to receive information from the body's sense receptors and it must be connected with the muscles and glands of the body if it is to affect behaviour and physiological processes. The spinal cord is a long, thin collection of nerve cells attached to the base of the brain and running the length of the spinal column (see Figure 4.1). It contains circuits of nerve cells that control some simple reflexes, such as automatically pulling away from a painfully hot object. The central nervous system communicates with the rest of the body through the nerves – bundles of fibres that transmit information in and out of the central nervous system. The nerves, which are attached to the spinal cord and to the base of the brain, make up the **peripheral nervous system**.

The human brain has three major parts: the brain stem, the cerebellum and the cerebral hemispheres. Figure 4.2 shows photographs of the side (a), top (b), cross-section (c) and bottom/underneath (d) of the human cerebral hemispheres. The lower part of the cerebellum and brain stem projects beneath the cerebral hemisphere (see the bottom left of Figure 4.2 (a)); the upper part is normally hidden. If the human brain is removed from the skull, it looks as if it has a handle or stem. The brain stem is one of the most primitive regions of the brain, and its functions are correspondingly basic – primarily control of physiological functions and automatic behaviours such as swallowing and breathing. The brains of some animals, such as amphibians, consist primarily of a brain stem and a simple cerebellum.

Figure 4.1 The central nervous system (brain and spinal cord) and the peripheral nervous system (cranial nerves and spinal nerves).

The two **cerebral hemispheres** constitute the largest, and most recently developed, part of the human brain. The cerebellum, attached to the back of the brain stem, looks like a miniature version of the cerebral hemispheres. Its primary function is to control and coordinate movements, although recent research has highlighted its role in language

and thinking, too. The cerebellum in cross-section is on the bottom right of Figure 4.2 (c).

Because the central nervous system is vital to an organism's survival, it is exceptionally well protected. The brain is encased by the skull, and the spinal cord runs through the middle of a column of hollow bones known as **vertebrae**. Both the brain and the spinal cord are enclosed by a three-layered set of membranes called the **meninges** (meninges is the plural of *meninx*, the Greek word for 'membrane'; meningitis is an inflammation of the meninges). The brain and spinal cord do not come into direct contact with the bones of the skull and vertebrae. Instead, they float in a clear liquid called **cerebrospinal fluid (CSF)**. This liquid fills the space between two of the meninges, thus providing a liquid cushion surrounding the brain and spinal cord and protecting them from being bruised by the bones that encase them.

The surface of the cerebral hemispheres is covered by the cerebral cortex (the word cortex means 'bark' or 'rind'). The **cerebral cortex** consists of a thin layer of tissue approximately 3 mm thick. It is often referred to as **grey matter** because of its appearance. It contains billions of nerve cells and is the structure where perceptions take place, memories are stored and plans are formulated and executed. The nerve cells in the cerebral cortex are connected to other parts of the brain by a layer of nerve fibres called the **white matter** because of the shiny white appearance of the substance that coats and insulates them. Figure 4.3 shows a slice of the brain. As you can see, the grey matter and white matter are distinctly different.

The human cerebral cortex is wrinkled in appearance; it is full of bulges separated by grooves. The bulges are called **gyri** (singular 'gyrus'), and the large grooves are called **fissures**. Fissures and gyri expand the amount of surface area of the cortex and greatly increase the number of nerve cells it can contain. Animals with the largest and most complex brains, including humans and the higher primates, have the most wrinkled brains and, thus, the largest cerebral cortices.

The peripheral nervous system

The peripheral nervous system consists of the nerves that connect the central nervous system with sense organs, muscles and glands. Nerves carry both incoming and outgoing information. The sense organs detect changes in the environment and send signals through the nerves to the CNS. The brain sends signals through the nerves to the muscles (causing behaviour) and the glands (producing adjustments in internal physiological processes).

Nerves are bundles of many thousands of individual fibres, all wrapped in a tough, protective membrane. Nerve fibres transmit messages through the nerve, from a sense organ to the brain or from the brain to a muscle or gland.

Figure 4.4 The principal parts of a neuron and its connections with other neurons (synapses).

As we saw earlier, some nerves are attached to the spinal cord and others are attached directly to the brain. The spinal nerves, attached to the spinal cord, serve all of the body below the neck, conveying sensory information from the body and carrying messages to muscles and glands. The twelve pairs of **cranial nerves**, attached to the brain, serve primarily muscles and sense receptors in the neck and head. For example, when you taste food, the sensory information gets from your tongue to your brain through one set of cranial nerves. Other sets of cranial nerves bring sensory information to the brain from the eyes, ears and nose. When you chew food, the command to chew reaches your jaw muscles through another set of cranial nerves. Still other cranial nerves control the eye muscles, the tongue, the neck muscles and the muscles we use for speech.

Cells of the nervous system

Neurons, or nerve cells, are the elements of the nervous system that bring sensory information to the brain, store memories, reach decisions and control the activity of the muscles. They are assisted in their task by another kind of cell: the **glia**. **Glia** (or **glial cells**) get their name from the Greek word for glue and 90 per cent of cells in the brain are glial cells. At one time, scientists thought that glia simply held neurons – the important elements of the nervous system – in place. They do not, however, literally stick neurons together but they do provide important physical support to neurons as well as providing other forms of mechanical support. During development of the brain, some types of glial cells form long fibres that guide developing neurons from their place of birth to their final resting place. Other types of glia manufacture chemicals that neurons need to perform their tasks and absorb chemicals that might impair neurons' functioning. Others form protective insulating sheaths around nerve fibres. Still others serve as the brain's immune system, protecting it from invading micro-organisms that might infect it.

Research suggests that they may play a more important part in brain development than was originally thought. For example, one study has shown that glial cells may determine the number of junctions between neurons – called **synapses** – generated in the brain (Ullian *et al.*, 2001). This finding followed an experiment by researchers from the same laboratory which found that synapses of neurons grown with a certain type of glial cell were ten times more active than those grown without. The mere proximity of glial cells to neurons made the neurons more responsive. In their most recent experiment, neurons that were exposed to glial cells formed seven times as many synapses as those that were not exposed. This is important because it indicates that glial cells have a much greater role to play in the formation of

synapses in the CNS than had previously been thought. The next step is to identify how the glial cells produce this increase.

The four principal parts of a neuron are shown in Figure 4.4.

- 1 The **soma**, or cell body, is the largest part of the neuron and contains the mechanisms that control the metabolism and maintenance of the cell. The soma also receives messages from other neurons.
- 2 The **dendrites**, the tree-like growths attached to the soma, function principally to receive messages from other neurons (dendron means 'tree'). They transmit the information they receive down their 'trunks' to the soma.
- 3 The nerve fibre, or **axon**, carries messages away from the soma towards the cells with which the neuron communicates. These messages, called action potentials, consist of brief changes in the electrical charge of the axon. For convenience, an action potential is usually referred to as the firing of an axon.
- 4 The **terminal buttons** are located at the ends of the 'twigs' that branch off the ends of axons. Terminal buttons secrete a chemical called a transmitter substance whenever an action potential travels down the axon, i.e. whenever the axon fires. These chemicals are called **neurotransmitters**. The transmitter substance affects the activity of the other cells with which the neuron communicates. Thus, the message is conveyed chemically from one neuron to another. Most drugs that affect the nervous system and hence alter a person's behaviour do so by affecting the chemical transmission of messages between cells.

Neurotransmitters

There are currently around 50 or so identifiable neurotransmitters and all are important to behaviour in some way. Some, however, play a greater role than others. The amine group of neurotransmitters, for example, which includes dopamine, noradrenaline and serotonin (5-hydroxytryptamine), appears especially important to psychologists because they are involved in a range of behaviours – emotional expression, decision-making, response to reward, inhibiting inappropriate actions, drug-taking and many others.

A part of the brain, called the nucleus accumbens, appears to be part of a reward system in the front and midpart of the brain, which evaluates how salient or important events in the outside world are. It and the system it belongs to are also implicated in impulsive behaviour – the inability to delay reward and to be aware of the consequences of actions, and so on (Pothuizen *et al.*, 2005). Drugs which act on serotonin receptors here, for example, increase impulsivity (Pattij and Vanderschuren,

2008). Such impulsivity, according to some scientists, is linked to the initiation and maintenance of drug-seeking (Krishnan-Sarin *et al.*, 2007).

The events the nucleus accumbens responds to can include rewarding stimuli (food, water, sex), aversive stimuli (ice, shock) and novel stimuli. Dopamine release increases here, as does the firing of dopamine receptors when an organism is rewarded with food or water (Schultz, 2007; Iversen and Iversen, 2007). Dopamine can increase by as much as 20–100 per cent and last for up to 100 minutes (Schultz, 2007). If an organism expects a reward there is a release of dopamine in these regions, but if an organism is completely rewarded there seems to be little dopamine activation. Dopamine is also released in freely moving organisms, which suggests that it is important for motor movement and the motivation to move. Of course, the movement disorder Parkinson's disease, discussed a little later, is treated by a dopamine precursor (called Levodopa), and excessive dopamine is thought to be implicated in some of the symptoms of schizophrenia (described in Chapter 18).

Like all the amines, dopamine receptors begin projecting from the brain stem and certain dopamine receptors terminate (end their projections) in the front part of the brain (called the prefrontal cortex, described below). These receptors, called D1 receptors, appear to be very important to cognitive performance and influence tasks such as our ability to store and manipulate non-verbal information over very short periods of time (a type of memory called working memory, described in Chapter 8). Some people have a mutation of an allele which directly affects dopamine (by inactivating it) with the consequence that their cognitive function is impaired (Turbridge *et al.*, 2006). Another type of dopamine receptor, D2, seems to be reduced in the striatum of drug addicts (Kalivas and Volkow, 2005).

Myelination

Many axons, especially long ones, are insulated with a substance called **myelin**. The white matter located beneath the cerebral cortex gets its colour from the myelin sheaths around the axons that travel through these areas. Myelin, which is part protein, part fat, is produced by special cells that individually wrap themselves around segments of the axon, leaving small bare patches of the axon between them. The principal function of myelin is to insulate axons from each other and thus to prevent the scrambling of messages. It also increases the speed of the action potential.

In some cases, people's immune systems go awry and begin to attack parts of their own bodies. One of these disorders is called multiple sclerosis – an autopsy of the brain and spinal cord will show numerous patches of hardened, damaged tissue (*skleros* is Greek for 'hard'). The immune systems of people who have multiple sclerosis

attack a protein in the myelin sheath of axons in the central nervous system, stripping it away. Although most of the axons survive this assault, they can no longer function normally, and so, depending on where the damage occurs, people who have multiple sclerosis suffer from various sensory and motor impairments.

There is also evidence to suggest that the central nervous system becomes fully mature when myelination is complete; speed of information processing in children, for example, seems to mirror cortical development and ongoing myelination (Travis, 1998).

The action potential

The message carried by the axon – the **action potential** – involves an electrical current, but it does not travel down the axon the way electricity travels through a wire. Electricity travels through a wire at hundreds of millions of metres per second. The axon transmits information at a much slower rate – less than 100 metres per second.

The membrane of an axon is electrically charged. When the axon is resting (that is, when no action potential is occurring), the outside is charged at +70 millivolts (mV, thousandths of a volt) with respect to the inside. An action potential is an abrupt, short-lived reversal in the electrical charge of an axon. This temporary reversal begins at the end of the axon that attaches to the soma and is transmitted to the end that divides into small branches capped with terminal buttons.

The electrical charge of the axon occurs because of an unequal distribution of positively and negatively charged particles inside the axon and in the fluid that surrounds it. These particles, called **ions**, are produced when various substances – including ordinary table salt – are dissolved in water. Normally, ions cannot penetrate the membrane that surrounds axons. However, the axonal membrane contains special submicroscopic proteins that serve as **ion channels** or **ion transporters**. Ion channels can open or close; when they are open, a particular ion can enter or leave the axon. Ion transporters work like pumps. They use the energy resources of the cell to transport particular ions into or out of the axon, as seen in Figure 4.5.

The outside of the membrane is positively charged (and the inside is negatively charged) because the axon contains more negatively charged ions and fewer positively charged ions. When an axon is resting, its ion channels are closed, so ions cannot move into or out of the axon. An action potential is caused by the opening of some ion channels in the membrane at the end of the axon nearest the soma. The opening of these ion channels permits positively charged sodium ions to enter, which reverses the membrane potential at that location. This reversal causes nearby ion channels to open, which produces another

reversal at that point. The process continues all the way to the terminal buttons located at the other end of the axon.

Note that an action potential is a brief reversal of the membrane's electrical charge. As soon as the charge reverses, the ion channels close and another set of ion channels opens for a short time, letting positively charged potassium ions out of the axon. This outflow of positive ions restores the normal electrical charge. Thus, an action potential resembles the 'Mexican wave' that football fans often make in a stadium. People in one part of the stadium stand up, raise their arms over their heads, and sit down again. People seated next to them see that a wave is starting, so they do the same – and the wave travels around the stadium. Everyone remains at the same place, but the effect is that of something circling in the stands around the playing field. Similarly, electricity does not really travel down the length of an axon. Instead, the entry of positive ions in one location reverses the charge at that point and causes ion channels in the adjacent region to open, and so on, as seen in Figure 4.6. The ion transporters pump sodium ions out of the axon and pump potassium ions back in, restoring the normal balance.

Figure 4.6 Movement of sodium and potassium ions during the action potential. Sodium ions are represented by orange arrows, potassium ions by green arrows.

Figure 4.5 Ion channels and ion transporters. These structures regulate the number of ions found inside and outside the axon. An unequal distribution of positively and negatively charged ions is responsible for the axon's electrical charge.

Synapses

Neurons communicate with other cells by means of synapses. A **synapse** is the conjunction of a terminal button of one neuron and the membrane of another cell – neuron, muscle cell or gland cell. The terminal button belongs to the **presynaptic neuron** – the neuron that sends the message. When terminal buttons become active, they release a chemical called a transmitter substance. The neuron that receives the message (detects the transmitter substance) is called the **postsynaptic neuron**. A neuron receives messages from many terminal buttons, and in turn its terminal buttons form synapses with many other neurons. The drawing in Figure 4.4 is much simplified; thousands of terminal buttons can form synapses with a single neuron.

Figure 4.7 illustrates the relation between a motor neuron and a muscle. A **motor neuron** is one that forms synapses with a muscle and controls its contractions. When the axon of a motor neuron fires, all the muscle fibres with which it forms synapses will contract with a brief twitch. A muscle consists of thousands of individual muscle fibres. It is controlled by a large number of motor neurons, each of which forms synapses with different groups of muscle fibres. The strength of a muscular contraction, then, depends on the rate of firing of the axons that control it. If they fire at a high rate, the muscle contracts forcefully; if they fire at a low rate, the muscle contracts weakly.

Figure 4.7 Synapses between terminal buttons of the axon of a motor neuron and a muscle.

Excitation and inhibition

There are broadly two types of synapse: excitatory synapses and inhibitory synapses. Excitatory synapses do just what their name implies. When the axon fires, the terminal buttons release a transmitter substance that excites the postsynaptic neurons with which they form synapses. The effect of this excitation is to make it more likely that the axons of the postsynaptic neurons will fire. Inhibitory synapses do just the opposite. When they are activated, they lower the likelihood that the axons of the postsynaptic neurons will fire.

The rate at which a particular axon fires is determined by the activity of the synapses on the dendrites and soma of the cell. If the excitatory synapses are the more active, the axon will fire at a high rate. If the inhibitory synapses are the more active, the axon will fire at a low rate or perhaps not at all, as seen in Figure 4.8.

How do molecules of transmitter substance exert their excitatory or inhibitory effect on the postsynaptic neuron? When an action potential reaches a terminal button, it causes the terminal button to release a small amount of transmitter substance into the **synaptic cleft**, a fluid-filled space between the terminal button and the membrane of the postsynaptic neuron. The transmitter substance causes

reactions in the postsynaptic neuron that either excite or inhibit it. These reactions are triggered by special submicroscopic protein molecules embedded in the postsynaptic membrane called **receptor molecules** (see Figure 4.9).

A molecule of a transmitter substance attaches to a receptor molecule the way a key fits in a lock. After their release from a terminal button, molecules of transmitter substance find their way to the receptor molecules, attach to them and activate them. Once they are activated, the receptor molecules produce excitatory or inhibitory effects on the postsynaptic neuron. They do so by opening ion channels. The ion channels found at excitatory synapses permit sodium ions to enter the neuron; those found at inhibitory synapses permit potassium ions to leave it (see Figure 4.10).

The excitation or inhibition produced by a synapse is short-lived; the effects soon pass away, usually in a fraction of a second. At most synapses, the effects are terminated by a process called **reuptake**. The transmitter substance is released by the terminal button and is quickly taken up again. It has, therefore, only a short time to stimulate the postsynaptic receptor molecules, as you can see from Figure 4.11. The rate at which the terminal button takes back the transmitter substance determines how prolonged the effects of the chemical on the postsynaptic neuron will be. The faster the transmitter substance is taken back, the shorter its effects will be on the postsynaptic neuron. As we will see, some drugs affect the nervous system by slowing down the rate of reuptake, thus prolonging the effects of the transmitter substance.

Figure 4.8 Interaction between the effects of excitatory and inhibitory synapses. The rate of firing of the axon of the neuron is controlled by these two factors.

Figure 4.9 The release of a transmitter substance from a terminal button. *Top:* Before the arrival of an action potential. *Middle:* Just after the arrival of an action potential. Molecules of transmitter substance have been released. *Bottom:* Activation of receptor molecules. The molecules of transmitter substance diffuse across the synaptic cleft and some of them activate receptor molecules in the postsynaptic membrane.

Figure 4.10 Detailed view of receptor molecules in the postsynaptic neuron. When activated by molecules of a transmitter substance, the receptor molecules allow sodium ions to enter the postsynaptic neuron, causing excitation, or allow potassium ions to leave, causing inhibition.

Figure 4.11 Reuptake of molecules of transmitter substance.

A simple neural circuit

The interconnections of the billions of neurons in our central nervous system provide us with the capacities for perception, decision-making, memory and action. It has been estimated that there are 13 trillion such connections. Although we do not yet know enough to draw a ‘neural wiring diagram’ for such complex functions, we can do so for some of the simpler reflexes that are triggered by certain kinds of sensory stimuli. For example, when your finger touches a painfully hot object, your hand withdraws. When your eye is touched, your eyes close and your head draws back. When a baby’s cheek is touched, it turns its mouth towards the object, and if the object is of the appropriate size and texture, the baby begins to suck. All these activities occur quickly, without thought.

A simple withdrawal reflex, which is triggered by a noxious stimulus (such as contact with a hot object), requires three types of neuron. **Sensory neurons** detect the noxious stimulus and convey this information to the spinal cord. **Interneurons**, located entirely within the brain or spinal cord, receive the sensory information and in turn stimulate the motor neurons that cause the appropriate muscle to contract, as seen in Figure 4.12.

The sequence is simple and straightforward. A noxious stimulus applied to the skin produces a burst of action

potentials in the sensory neurons. Their axons fire, and their terminal buttons, located within the spinal cord, release an excitatory transmitter substance. The chemical stimulates the interneurons and causes them to fire. The interneurons excite the motor neurons, and these neurons cause the muscle to contract.

The next example adds a bit of complexity to the circuit. Imagine that you have removed a hot casserole dish from the oven. As you move over to the table to put it down, the heat begins to penetrate the rather thin oven gloves you are using. The pain caused by the hot dish triggers a withdrawal reflex that tends to make you drop it. And yet you manage to keep hold of it long enough to get to the table and put it down. What prevented your withdrawal reflex from making you drop the dish on the floor?

As you saw earlier, the activity of a neuron depends on the relative activity of the excitatory and inhibitory synapses on it. The pain from the hot casserole dish increases the activity of excitatory synapses on the motor neurons, which tends to cause the hand to open. However, this excitation is counteracted by inhibition from another source – the brain. The brain contains neural circuits that recognise what a disaster it would be if you dropped the casserole dish on the floor. These neural circuits send information to the spinal cord that prevents the withdrawal reflex from making you drop the dish. Figure 4.13 shows how this information

Figure 4.12 Schematic representation of the elements of a withdrawal reflex. Although this figure shows just one sensory neuron, one interneuron and one motor neuron, in reality many thousands of each type of neuron are involved.

reaches the spinal cord. As you can see, an axon from a neuron in the brain reaches the spinal cord, where it forms a synapse with an inhibitory interneuron. When the neuron in the brain becomes active, it excites this inhibitory interneuron. The interneuron releases an inhibitory transmitter substance, which decreases the rate of firing of the motor neuron, preventing your hand from opening. This circuit provides an example of a contest between two competing tendencies: to drop the casserole dish and to hold onto it. Complex decisions about behaviour are made within the brain by much more complicated circuits of neurons, but the basic principles remain the same.

Neuromodulators: action at a distance

Terminal buttons excite or inhibit postsynaptic neurons by releasing transmitter substances. These chemicals travel a very short distance and affect receptor molecules located on a small patch of the postsynaptic membrane. But some neurons release chemicals that get into the general circulation of the brain and stimulate receptor molecules on many thousands of neurons, some located a considerable distance away. The chemicals these neurons release are called **neuromodulators**, because they modulate the activity of the neurons they affect.

We can think of neuromodulators as the brain's own 'drugs'. Because these chemicals diffuse widely in the

brain, they can activate or inhibit many different circuits of neurons, thus exerting several behavioural and physiological effects. These effects act together to help achieve a particular goal.

The best-known neuromodulator is a category of chemicals called endorphins, or opioids ('opium-like substances'). **Opioids** are neuromodulators that stimulate special receptor molecules (opioid receptors) located on neurons in several parts of the brain. Their behavioural effects include decreased sensitivity to pain and a tendency to persist in ongoing behaviour. Opioids are released while an animal is engaging in important species-typical behaviours, such as mating or fighting. The behavioural effects of opioids ensure that a mating animal or an animal fighting to defend itself is less likely to be deterred by pain; thus, conception is more likely to occur and a defence is more likely to be successful.

Many years ago, people discovered that eating or smoking the sap of the opium poppy decreased their sensitivity to pain, so they began using it for this purpose. They also discovered that the sap produced pleasurable effects: people who took it enjoyed the experience and wanted to take more. In recent times, chemists have discovered that the sap of the opium poppy contains a class of chemicals called opiates. They also learned how to extract and concentrate them and to produce synthetic versions with even greater potency. In the mid-1970s, neurobiologists learned that opiates produce their effect

Figure 4.13 Schematic representation of a withdrawal reflex being inhibited by the brain.

by stimulating special opioid receptor molecules located on neurons in the brain (Pert *et al.*, 1974). Soon after that, they discovered the brain's opioids (Terenius and Wahlström, 1975). Thus, opiates mimic the effects of a special category of neuromodulators that the brain uses to regulate some types of species-typical behaviours.

The brain produces other neuromodulators. Some help organise the body's response to stress, while others reduce anxiety and promote sleep. Some promote eating, while others help end a meal.

Techniques in psychobiology and neuroscience

Until relatively recently, most of our knowledge of the functions of the nervous system was obtained through research using laboratory animals. This research produced important discoveries about the causes and treatments of neurological and mental disorders, many of which are discussed in this book. It led to the development of drugs and surgical techniques that help people with neurological disorders, such as Parkinson's disease, and mental disorders, such as schizophrenia, depression and obsessive-compulsive disorders.

Physiological psychologists now have at their disposal a range of research methods to study the function of the brain and body that would have been impossible to imagine just a few decades ago. We have ways to identify neurons that contain particular chemicals. We have ways to take photographs of particular ions entering neurons when the appropriate ion channels open. We have ways to inactivate individual genes to see what happens to behaviour when they no longer function. We can also witness the activity of the brain as it behaves, through the technique of neuroimaging.

Lesioning

The earliest of research methods in psychobiology – and one that is still the most commonly used – involves correlating a behavioural deficit with damage to a specific part of the nervous system. The damage can be studied in one of two ways. For example, a neuropsychologist may examine the effects of brain damage on function, such as the effect of damage to the front part of the brain on a person's ability to create and adhere to plans.

The second way involves the investigator producing an **experimental brain lesion**, an injury to a particular part of the brain, but only in an animal's brain. Of course, neurosurgeons do lesion parts of the brain to alleviate some forms of suffering. One recent, successful treatment for the movement disorder Parkinson's disease, for example, has

involved lesioning a small structure deep within the brain. A similar technique 'lesions' in another way (the procedure is called deep brain stimulation, DBS). In Parkinson's disease, a person may behave rigidly or be unable to walk properly or exhibit tremors or engage in excessive, repetitive, involuntary motor behaviour. Treatment by Levodopa (mentioned earlier) provides some respite but there are off periods when the drug does not work. DBS overstimulates parts of a collection of structures called the basal ganglia, described below. This has been found to be more successful than lesioning the parts directly (Liu *et al.*, 2008). Why lesioning *and* overstimulation seem to work (i.e. produce the same effect) is still a mystery. One theory is that surgery reduces the inhibitory effects of neurons in the basal ganglia and increases them in another structure, the thalamus and cortex (Liu *et al.*, 2008).

When an animal's brain is experimentally lesioned, the investigator hypothesises that this lesion might have specific consequences; they then study the effects of the lesion on the animal's behaviour. If particular behaviours are disrupted, the reasoning suggests, the damaged part of the brain must be involved in those behaviours.

Some lesioning techniques are used in both experimental and neurosurgical work. For example, to reach the region to be lesioned, the experimenter or surgeon uses a device called a **stereotaxic apparatus** to insert a fine wire (called an electrode) into a particular location in the brain, as Figures 4.14 and 4.15 show. The term 'stereotaxic' refers to the ability to manipulate an object in three-dimensional space. The researcher passes an electrical current through the electrode, which produces heat that destroys a small portion of the brain around the tip of the electrode. After a few days, the animal recovers from the operation, and the researcher can assess its behaviour.

A stereotaxic apparatus can also be used to insert wires for recording the electrical activity of neurons in particular regions of the brain. But an electrode placed in an animal's brain can also be used to lead electrical current into the brain as well as out of it. If an electrical connector on the animal's skull is attached to an electrical stimulator, current can be sent to a portion of the animal's brain. This current activates neurons located near the tip of the electrode. The experimenter can then see how this artificial stimulation affects the animal's behaviour.

Neurosurgeons sometimes use stereotaxic apparatus to operate on humans. For example, as you read earlier, destruction of a particular region near the centre of the cerebral hemispheres can alleviate the tremors (trembling) that occur in some cases of Parkinson's disease (Krack *et al.*, 1998; Samuel *et al.*, 1998) (see Figure 4.16). Neurosurgeons can also insert electrodes into the human brain and record the electrical activity of particular regions to try to find locations that might be responsible for triggering epileptic seizures.

Figure 4.14 A stereotaxic apparatus, used to insert a wire into a specific portion of an animal's brain.

Studying brain injury: clinical neuropsychology

Although we can, under very careful conditions, experimentally lesion the brains of non-humans, we cannot do this in humans, for very obvious reasons. We have, therefore, relied on studies of accidental brain injury to help us build a picture of the role of damaged brain regions in specific functional impairments.

This approach usually utilises the single-case study design, described in Chapter 2. Brain injury usually results from accident or disease and, because it is more difficult to obtain information of this kind, scientists have studied a small number of individuals intensively over a long period of time. The approach allows neuroscientists to observe how fairly localised brain damage can impair intellectual or emotional function.

Most human brain lesions are the result of natural causes, such as a stroke. A stroke (also known as a cerebrovascular accident, or CVA) occurs when a blood clot obstructs an artery in the brain or when a blood vessel in the brain bursts open. In the first case, the clot blocks the supply of oxygen and nutrients to a particular region and causes that region to die. In the second case, the blood that accumulates in the brain directly damages neural tissue, partly by exerting pressure on the tissue and partly through its toxic effects on cells. The most common causes of strokes are high blood pressure and high levels of cholesterol in the blood. We consider these factors and their effect on health in Chapter 17.

The brain injury in such patients has given rise to a large number of neuropsychological disorders which have helped shape theories of cognitive function. These disorders include the inability to produce or comprehend speech (aphasia), inability to produce speech (fluent or Broca's aphasia), inability to comprehend speech, specifically (Wernicke's aphasia), inability to recognise objects (agnosia), inability to follow motor commands (apraxia), reading impairment (acquired dyslexia), inability to recognise familiar faces (prosopagnosia), inability to attend to stimuli in one half of the visual field (spatial neglect), and a lack of awareness of visual objects, among many others (and you will read more about them in later chapters). Other impairments have no specific name but involve an inability to perform a specific function, such as recognising specific emotions in faces and voices; placing events in sequence; planning; learning new material or retrieving old material from memory.

One of the most famous – if not the most famous – single-case study in neuropsychology is HM. You will find more about HM in the chapter on memory but, briefly, HM underwent surgery for uncontrollable epilepsy in the late 1950s. The surgery involved removal of a part of the brain called the temporal lobe which includes a structure called the hippocampus (this has been implicated in various

memory functions). After the surgery and beyond, HM exhibited a form of memory impairment called anterograde amnesia – he was unable to learn new material. The intensive study of HM led to a neurobiological theory of human memory which involved the temporal lobe and the hippocampus and the study has since been supplemented by other case studies and neuroimaging studies of memory in healthy participants.

There have been arguments for and against the single-case study approach in neuropsychology. Some researchers argue that damage to a brain region does not necessarily demonstrate that this region is responsible for any function that is disrupted following injury. Other areas connected to the damaged region may be responsible for the specific function but connections to the intact areas from the lesioned area have been disrupted. There is also the need to specify exactly what function is being measured (this is a problem for psychology in general, rather than neuropsychology in particular). When we say that a region may be 'responsible' for phonological processing, what exactly is meant by phonological processing? Could the region be responsible for some other function which allows phonological processing, rather than being responsible for phonological processing itself?

There are also obvious methodological and practical problems such as the extent and locus of the lesion – because the brain injury is accidental or the result of a disease, the extent of damage is uncontrollable. There is also great variation in regional brain structure between individuals. Amunts *et al.* (1999), for example, found that the size of Broca's area varied enormously in a group of ten individuals: there was a tenfold difference between participants in some cases. When such injury occurs it is also unlikely to be limited to one specific region or structure; it may extend to more than one and so conclusions drawn about the significance of findings in studies such as these need to be done circumspectly. There are also other factors such as sex, personality, handedness and intellectual ability which may need to be taken into account.

Rehabilitation after brain damage

Rehabilitation is an 'active process whereby people who are disabled by injury or disease work together with professional staff, relatives and members of the wider community to achieve their optimum physical, psychological, social and vocational well-being' (McLellan, 1991, p. 785) and programmes have been designed for reading disorders resulting from brain injury (acquired reading disorders) (Patterson, 1994), the inability to produce or understand speech (aphasia) (Berndt and Mitchum, 1995), an inability to attend to or 'see' one half of the world (spatial neglect) (Robertson *et al.*, 1993) and memory disorders (Wilson and Powell, 1994; Glisky, 1997).

The *Top Gear* television presenter Richard Hammond, crashed his car while attempting to break the British land-speed record. His jet-powered vehicle was travelling at 314 mph when a tyre burst. Hammond was hospitalised with brain injury. Although he made a good physical recovery, he still reports periods of severe depression, emotional problems such as becoming angry or scared and not knowing how to cope with these states, and short-term memory loss, including forgetting the PINs of his credit cards.

Source: Alamy Images/Mirrorpix

The most common type of rehabilitation programme is cognitive rehabilitation (Parente and Stapleton, 1997). In this, the patient is encouraged to engage in two types of activity: (1) 'the reinforcing, strengthening or establishing of previously learned behaviour', and (2) the establishment of 'new patterns of cognitive activity or mechanisms to compensate' for the impairment (Bergqvist and Malec, 1997). It shows consistently successful results in the majority of cases of mild to severe brain injury (Ho and Bennett, 1997).

A common form of impairment following brain injury is memory disorder. Specific problems include deficits in

learning new material and in retaining other kinds of information (Wilson and Powell, 1994). Some techniques of rehabilitation used to improve memory include exercises and drills, use of external aids, and the use of mnemonic strategies. The patients 'JC' and Julia Cogan are good examples of how rehabilitation strategies can work effectively in reducing problems in everyday life in individuals with severe memory impairment (Wilson, 1991, 1995; Wilson *et al.*, 1997; Oddy and Cogan, 2005). JC, for example, is a self-employed French-polisher who, during the second year at university, suffered an epileptic seizure and collapsed during a tutorial. Doctors, family and friends noted that JC showed severe loss of memory and could not remember anything 'from one minute to the next'.

JC used external aids, such as a diary or notebook, mnemonics and chaining – where tasks are broken down into smaller steps or stages and which can, for example, help patients to find their way around when planning short journeys. These benefited JC but were developed by him into a more elaborate strategy: he has been using and refining this strategy for at least 10 years following his impairment. During the early stages, he began to use a pocketbook kept in his shirt and used a watch with an alarm that sounded every hour – he would note what he was doing in his notebook when this sounded (Wilson *et al.*, 1997). He would create weekly and daily sheets on which he would write down all appointments and lists of things to do or done. He bought a Dictaphone whose content he would transcribe at the end of everyday. His aunt noted how a new watch helped him because it was capable of 15 programmed weekly alarms and 15 one-off alarms. He would use the one-off alarms for reminding him of individual events. He would role-play some social situations to avoid the embarrassment of not being able to remember in public. He would make a log of all phone calls so that he didn't ring someone twice with the same message.

JC's success is mirrored by that of Julia Cogan, a 23-year-old first class graduate in physics who was studying for a Ph.D. in neuroimaging and oncology when she suffered brain injury (Oddy and Cogan, 2005). She made a full physical recovery but her memory was severely impaired. Her everyday problems are familiar ones; she is unable to remember what she had for breakfast, for example, and relies on the strategies she has developed so that she can lead as normal a life as possible. Like JC, she makes extremely good use of her Filofax and if she cannot remember a piece of information, she can find it quickly in her pad. The pad has extensive notes on people she's met, her travel arrangements, recipes and so on (you can see an example in Figure 4.17). If she is asked how work is going, she can flick to a page which describes her last assignment and her next.

Julia is young, well motivated, intelligent and very well organised. All of these characteristics can make rehabilitation easier.

Psychology in action – Using brain activity to overcome physical disability

A man in a wheelchair looks at a computer monitor. His arms and legs are still. He cannot speak. Without moving a limb, limbs which cannot move, he is able to move a cursor – not quickly, not effortlessly, but demonstrably – on the screen in front of him. Laboriously, but not without motivation, he spells out a word.

In what seems like a vignette from the most trite science fiction fantasy, he is using the electrical potentials generated by his brain to guide the cursor. This, however, is no third-rate SF make-believe. It is an example of real technology in action: brain–computer interface (BCI).

BCI is a method of controlling electronic or mechanical devices using brain activity. This is useful for people who have suffered illnesses which render them incapable of basic motor behaviour and for whom traditional types of assistive technology are inappropriate because they rely on voluntary motor movement. People who are paralysed, for example, might restore very basic movement through the manipulation of muscles or external devices via signals generated by the brain (Birbaumer, 2006). Those who might benefit include people with amyotrophic lateral sclerosis (ALS) who require artificial respiration and live in a completely ‘locked in’ state, multiple sclerosis, cerebral palsy, stroke, muscular dystrophy and brain injury who have a severe motor disability/paralysis. The first

of these ‘neural prostheses’ was inserted into the brain of a patient by US surgeon, Philip R. Kennedy, and his team in 1996. The patient was a teacher and artist who had been paralysed (Kennedy and Bakay, 1998). Two months after the surgery, he had learned how to turn lights on and off (Brown, 2008). A second patient eventually learned to pick out icons on a computer screen and to spell out a small number of words. Figures 4.18 a and b show you a patient in receipt of BCI and a schematic representation of the process.

It is based on the the non-invasive recording of electrical activity (EEG) from the brain’s neurons. A person can be trained to use and alter this EEG activity to effect simple changes in motor behaviour. The EEG is ‘translated’ into output such as moving a cursor around a monitor to indicate ‘yes’ or ‘no’ to produce a certain change in the environment, such as switching a light on or off or turning the temperature up or down, spelling out the letters of a word on a monitor, sending an email, accessing the internet, opening and closing a prosthetic hand, or operating a wheelchair (Birbaumer *et al.*, 2007; Daly and Wolpaw, 2008; Pfurtscheller *et al.*, 2003a, b). Research has also found that by changing the appearance of certain types of EEG rhythm, patients can control their epileptic seizures (Sterman, 1981). According to Birbaumer (2006), extensive training can lead to almost 100 per cent control over these seizures.

Psychology in action – Continued

Figure 4.18 (a) Dr Phil Kennedy, one of the pioneers of BCI technology, with one of his patients (Kennedy is in the blue shirt).
Source: Landor Media: David Kamerman/The Boston Globe

The process involves two stages. The first is feature extraction and this involves the identification of the type of signal – its rhythm and amplitude, the neuron’s firing rate – that will influence output. The second involves using an algorithm which translates these signals into commands which specify outputs – the selection of letters, the movement of a cursor, etc. The patient might use the beta rhythm recorded over the sensorimotor cortex to make a movement. The algorithm takes into account that activity in a certain EEG frequency range should enable the person to move a cursor to left or right of a monitor. With repeated training and practice, the process becomes less

Figure 4.18 (b) A diagram showing the stages and processes involved in brain computer interface.
Source: University of Florida: Arturo Sinclair

‘effortful’ and becomes automatic, in the way that many initially difficult behaviours become automatic with practice.

That said, despite advances in technology and research, the advances are impressive but modest – typing on screen amounts to three to four words per minute, for example. Currently, these techniques are also vision-based: people must be able to see and need to maintain gaze for the technology to work but auditory versions are now being investigated (Nijboer *et al.*, 2008). It is an unusual and innovative way of harnessing the power of the brain.

Psychophysiology: measuring CNS activity

When psychobiologists record brain electrical activity from deep inside the structure, the technique is invasive, i.e. it invades some part of the body (in this case, the brain). Recording the electrical activity of neurons, for example, may involve inserting electrodes into the brain. However, electrical activity of neurons can also be recorded from the scalp non-invasively. Both methods involve a technique called **electroencephalography (EEG)**, the recording of the brain’s electrical impulses. Electrodes attached to the scalp can record the activity of groups of millions of neurons (Andreassi, 2001; Martin, 2006). The number of electrodes used in brain research tends to be at the discretion of the experimenter. Some use two or three, others use a lot more (over one hundred in some cases), but in all cases researchers use a map showing where each elec-

trode should be placed on the scalp. This avoids errors and inconsistencies in the application of electrodes.

EEG activity is seen in the form of a line-tracing or **electroencephalogram (EEG or ‘brainwave’)**, although some modern EEG recording machines allow the conversion of EEG data into ‘brainmaps’ – these are two-dimensional representations of the EEG activity. They can be coloured or in greyscale which means that areas of high and low activity can be represented by darker or lighter colours. There are different types of EEG waves – called frequencies – and these are thought to represent different psychological states. Some large, slow EEG waves, for example, are characteristic of deep sleep. One type of activity, called alpha, is the resting adult EEG; when we are engaged in thinking or making rapid movements, alpha activity changes to another type of activity (Andreassi, 2001). In Chapter 9, you will see how different types of EEG brain activity occur during different stages of sleep and wakefulness.

One benefit of the EEG technique is that, as well as being non-invasive, it provides a measure of the brain's activity in real time, as it happens. We can, therefore, match the presentation of a stimulus or a task with the brain activity associated with it. In this way, we can measure how the brain responds while it is engaged in tasks such as deciding whether two figures rotated in three-dimensional space are the same or different (Williams *et al.*, 1995), watching pleasant or unpleasant visual stimuli (Davidson, 1992), smelling food odour (Martin, 1998) or recognising faces and words (Burgess and Gruzelier, 1997), among many other behaviours.

Sometimes, however, this electrical signal can be messy or noisy: it is difficult to distinguish between the brain's normal background activity and the activity produced by the perception of, or response to, a stimulus. The effect of perceiving a sound, for example, may be so small as to be invisible in an EEG tracing. To overcome this, psychophysiologicals have devised the technique of averaging signals across trials. They can do this by recording **event-related potentials** or ERPs (these are sometimes also called evoked potentials). These are electrical signals recorded to a repeatedly presented stimulus (or set of stimuli). Each EEG response to a stimulus is added and averaged to produce one clearer signal or evoked potential. The potentials are event-related because they are related to a specific event that is external or internal to the individual such as decision-making (internal stimulus) or perceiving a flash of light (external stimulus). The point of averaging is to make the effect of a stimulus on the EEG clearer; background noise is reduced and the effect of the stimulus becomes more obvious.

Some ERPs measure sensory responses to stimuli (this is called the N100 (or N1), so called because it appears 100 milliseconds after the onset of a stimulus), others are thought to be associated with more cognitive functions such as understanding words or being able to distinguish one type of visual or auditory stimulus from another. These ERPs occur later, at around 300 or 400 milliseconds after stimulus onset (the P300 or P3 and N400 or N4), perhaps reflecting the time the brain takes to undertake these cognitive operations (Polich and Kok, 1995).

The N400, for example, was the first ERP to be specifically linked with language processing and is elicited when participants read sentences in which the last word is semantically surprising or inappropriate, although linguistically legal (Kutas and Hillyard, 1980). For example, the sentence, 'A man who has lost ninety per cent of his brain is called a widower' is legal but surprising whereas the sentence, 'A man who has lost ninety per cent of his brain is called a zombie' is legal but not surprising. The amplitude of the N400 is associated with processing difficulty such that the more difficult the task, the greater the amplitude of the N400 (Kutas and Van Petten, 1994). The N400

declines when congruous sentences are presented – the last word is predictable – but not when incongruous ones are presented (Van Petten and Kutas, 1990). Some researchers have suggested that the N400 reflects a difficulty in integrating words into a sentence (Kutas *et al.*, 2000): the greater the difficulty, the larger the N400.

ERPs have been used to investigate a number of psychological functions such as decision-making, sentence comprehension, recognition memory and visual, tactile and auditory perception. They are not as good as other techniques at localising activity to a specific brain area but they are good at measuring responses to stimuli in real time. The absence of an evoked potential indicates an impairment in function or a failure to attend to stimuli. Figure 4.19 shows the difference between ERPs evoked by a decision-making task in healthy volunteers and individuals with dementia. Note the reduction in the amplitude (size) of the wave in the demented group.

Psychophysiology: measuring activity outside the CNS

Psychophysiologicals can also record electrical activity in the peripheral (or autonomic) nervous system – from the heart, muscles and skin. Some of the most common techniques are EMG, ECG and GSR.

Electromyography (EMG)

The body possesses three types of muscles – skeletal, smooth and cardiac. Skeletal muscles are those such as biceps, triceps and flexor muscles of the upper arm and forearm. These are usually under voluntary control – they make up the voluntary motor system; we decide when to flex and tense our arms (such as when picking up a cup), legs (kicking a ball) or fingers (writing or typing at a keyboard). There are other muscles which are not under voluntary control. Smooth muscles are those over which we have little or no voluntary control – the constriction and dilation of blood vessels, for example. The third type of muscle is cardiac and, as the name suggests, this muscle makes up the heart and its valves. Smooth and cardiac muscles comprise about 10 per cent of total body weight; the skeletal muscles make up around 40 per cent of this weight.

When the muscles of the body contract, they generate electrical potentials. Often, muscles contract for psychological reasons – responding to stress, emotional stimuli, pictures, sounds, faces, and so on – and they sometimes contract for these reasons in ways that are undetectable to the eye. The technique used for measuring skeletal muscles' electrical activity is **electromyography (EMG)**. EMG activity is recorded by electrodes – circular disks of around 10 mm in diameter – from the surface of the skin. The greater the muscle contraction and the closer the elec-

Figure 4.19 Examples of EPs measured in healthy individuals and those with Alzheimer's disease. When a participant is asked to undertake a task such as detecting the number of low tones in a series of high and low tones (where there are always fewer low tones), the ERPs illustrated here are found. The waves on the right show the brain's response to the high tones (the common ones); the N1 sensory and P2 components can be clearly seen. However, when the participant has to make a decision (discriminating between high and low tones) a late wave – the P3 – appears in response to the low tones (the rarer ones). This wave is thought to reflect the brain's decision-making processes. Note how the amplitude (height) of the P3 is lower than that seen in healthy individuals.

trode is to the skin, the greater the electrical activity generated (in fact, EMG records activity from motor units just prior to muscle contraction). For example, imagine a simple behaviour such as gripping an object like a hammer or a handle. The harder you grip the object, the greater the electrical activity produced by musculature and this activity can be picked up as EMG activity from the recording electrode.

Imagining pleasant thoughts results in increased muscle activity in the cheek area responsible for smiling (the zygomatic muscle). A different set of muscles at the eyebrows – called corrugator muscles – are more active during the imagining of unpleasant thoughts (Schwartz, Brown and Ahern, 1980). Activity in the zygomatic muscles has also been found to increase when participants listen to stories with a sexual content rather than a non-sexual content but that corrugator activity is greater

when the stories were sexual and unpleasant (Sullivan and Brender, 1986).

Electrocardiography (ECG/EKG)

Cardiac muscle activity is recorded in a similar way to that of skeletal muscle but the differences between the recordings are greater than the similarities. **Electrocardiography (ECG)** refers to the study of the electrical potentials generated by the working of the heart. Before understanding how biological psychologists measure heart activity, it's useful to know a little about how the heart works.

When the heart contracts, it produces an electrical current (as do all other muscular contractions). By placing electrodes near the source of the current, scientists can measure the electrical activity of the heart. The contraction of the heart is the consequence of the organ's chief

function – to pump blood around the body. The heart is made up of four chambers which pump blood to the body's tissues. The two chambers at the top of the heart are the atria; the two at the bottom are the ventricles. The atria receive blood returned by the body's veins; the ventricles pump blood away from the heart via arteries (a useful way of remembering the direction in which the blood goes is to think of arteries taking blood away). When you feel – or record – your heartbeat, you are feeling or recording the contraction of the heart as it pumps blood. It beats, on average, 72 times a minute (72 bpm or beats per minute) and, therefore, about 100,000 times a day. The contraction phase of the heart's activity is called systole; the relaxation phase is called the diastole.

The activity of the heart recorded by electrodes can be seen in a typical type of electrical wave. The wave is made up of various characteristic deflections (the direction of the wave characterises various points leading to and during the contraction) – these are the P, Q, R, S and T waves. The P wave is a small deflection produced by the current generated before contraction of the atria; the QRS complex of waves is produced by what is known as depolarisation (more on this later in the chapter) prior to the contraction of the ventricles. The R wave is the largest, most prominent wave. The T wave is the next, small blip-like, deflection after the large R wave and occurs as a result of activity in the ventricles. The P–Q interval lasts about 160 milliseconds; the Q–T interval lasts around 300 milliseconds. It takes around 370 milliseconds to go from the T wave to the next contraction. Figure 4.20 illustrates a typical ECG.

In a study of cardiovascular activity and competitiveness, Harrison *et al.* (2001) asked male and female undergraduates to play a motor racing game either alone,

Figure 4.20 This is the PQRST complex of the ECG which represents a heartbeat. Each peak and trough of this complex represents some activity of the heart as it contracts and relaxes.

Source: Daniel Sambras/Science Photo Library Ltd.

in competition with the experimenter or in cooperation with the experimenter. The competitive condition was associated with significant increases in blood pressure and heart rate whereas the cooperative condition produced barely discernible changes in activity, a finding that echoes reports in the literature of reduced or stable cardiovascular activity in response to stress in the presence of a supportive person (what is known as social affiliation).

Heart rate changes can be seen in response to a number of psychological variables. The promise of financial reward for persuading others (Smith *et al.*, 1990), fear of needles (Shapiro, 1975) and playing Space Invaders (Turner *et al.*, 1983) have all been found to increase heart rate.

Electrodermal response (EDR)/galvanic skin response (GSR)

The measurement of electrical activity of the skin – **electrodermal response (EDR)** or **galvanic skin response (GSR)** – may seem to be completely irrelevant to the study of psychology. The technique, however, is surprisingly useful because skin conductance changes can be influenced by experience of positive and negative emotion, the degree of thinking that goes into the processing of information, and in perceptual awareness. In fact, a French neurologist, Charles Fere, was the first to note in 1888 that changes in a person's mood and environment could lead to changes in the electrical activity recorded from the skin.

The recording of electrodermal activity is based on the properties of skin and what skin does. Human skin has two layers – the epidermis, the outer layer which is about 1 mm thick, and the dermis, the inner layer which varies in thickness depending on the part of the body; it is thinner in the eyelids than the palms of the hands or soles of the feet, for example. The dermis contains blood vessels, hair follicles, sensory nerves and, importantly for EDR, the secretory part of sweat glands. It is sweat which allows conductance to occur on the skin.

The body has two types of sweat glands – apocrine and eccrine. The larger of the two are the apocrine glands which are found in especially hirsute regions such as the armpits and genitals. Sweat is odourless and the odour we associate with it is the result of the reaction between sweat and bacteria on the skin. The eccrine glands are distributed widely and cover most of the skin, with some exceptions (such as lips, outer ear and glans penis, amongst others). Sweat glands are most numerous on the palms of the hands and soles of the feet with around one inch squared of skin having about 3,000 glands (Fowles, 1986). EDR recorded from fingers and palms responds more strongly to sensory stimulation than to physical stimuli such as heat; the opposite pattern is found for EDR recorded from the forehead, neck and back of the

hands which dictates the position of electrodes in EDR recording. Skin conductance increases with increased stress, arousal and cognitive activity and reduces when the organism's level of activity is low. During states of anxiety, for example, there is a great deal of sweating, especially in the palms.

To show how the EDR measure can record changes in behaviour that are not immediately visible, some studies have reported increases in arousal to stimuli that are familiar. For example, Tranel *et al.* (1985) found that when students viewed slides of familiar and unfamiliar faces, skin conductance response was higher when they viewed the familiar faces (even when the participants themselves reported not having seen the face before; they had, in fact, viewed the faces in a previous slide show, which suggests that the body can reveal more than can self-reports). In an intriguing study, Tranel and Damasio (1985) measured skin conductance response in prosopagnosics (remember from an earlier section that these patients are unable to recognise familiar faces such as those of family members). They found that although the patients could not recognise familiar faces, galvanic skin response (GSR) would increase during the presentation of familiar faces, perhaps suggesting a degree of unconscious processing in these patients.

Perhaps one of the more well-known, although poorly validated uses of GSR, is the polygraph, the so-called lie-detector. While its ability to detect actual liars is abysmal, GSR has been found to be a very useful technique when measuring the responses of some criminals – specifically, psychopaths – to emotional stimuli. Psychopaths are people who are utterly remorseless, superficially charming,

In *Meet the Parents*, Robert De Niro's character makes good use of the polygraph to intimidate his son-in-law, played by Ben Stiller. Research, however, indicates that the polygraph is a poor measure of deception.

Source: Universal/Everett/Rex Features.

manipulative and socially deviant. Jailed psychopaths have been found to show little GSR in response to emotional stimulation, a result that has also been found in studies of patients with damage to the front part of the brain (Raine, 1997). This is explored in the personality disorders section of Chapter 18.

Cutting edge – James Bond and the bloody consequences of *Mortal Kombat*

What man has not thought of spending a day in James Bond's shoes (and what woman has not guffawed at the thought that this is what men would like to do)? A recent study has investigated people's psychophysiological responses while they played James Bond in the game, *JB007: Nightfire* (Ravaja *et al.*, 2008). In the experiment, GSR and EMG were recorded while people either killed or wounded ne'er-do-wells, or were wounded and killed themselves. The aim was to discover the psychophysiological responses generated by different emotional and moral perspectives.

When an opponent was wounded or killed, participants' skin conductance increased but some of the muscles in the face (zygomatic, orbicularis oculi and corrugator muscles, all found around the eyes and mouth) decreased. The more psychotic the

participant, the less pronounced these changes were. When the protagonist was wounded or killed, there was a similar GSR increase but also an increase in two sets of facial muscles and a decrease in another set. These results suggest that the emotional consequences of attacking another or of being attacked can be characterised by subtle, facial muscle changes.

Continuing this theme, blood (or its appearance) can also elicit strong psychophysiological reactions. Bartlett *et al.* (2008) asked 65 men to play the *Mortal Kombat: Deadly Alliance* game as their heart rate was measured. The game differed in the amount of blood that was present in the game – a lot, a moderate amount, a low amount or none. Men in the high and moderate quantity conditions showed the greatest amount of heart rate and also the greatest levels of hostility.

Cutting edge – Continued

Men in the low or no-blood condition did not produce these increases. Moreover, in the high/moderate condition, the

players were more likely to use their character's weapon more often.

Playing at being James Bond. Putting yourself in the position of another, especially when this position is not normally encountered in real life, produces changes in physiology that are invisible to the human eye but can be recorded by psychophysicists. Subtle and not-so-subtle cues in the environment – such as the presence of blood – can influence the degree to which we become aggressive. Men playing a game with blood visible show a faster heart rate and greater hostility than do those who saw no blood.

Neuroimaging techniques

The development of machines which can be used to investigate the brain's structure and activity has revolutionised neuroscience. These sophisticated techniques, more than any of the others, have provided neuroscientists with the opportunity of measuring how the whole, living, healthy brain functions. They are called **neuroimaging** techniques because they allow us to visualise and obtain images of brain function and structure. These techniques include CT, MEG, PET, MRI and fMRI. PET and fMRI are measures of brain activity; CT and MRI are measures of brain structure. Figures 4.21 (a) and (b) show how studies using these techniques have increased during the period 1988 to 1998.

Computerised tomography (CT)

Computerised tomography (CT) is a technique used to display the structure of the brain (*tomos*, meaning 'cut', describes the CT scanner's ability to produce a picture that looks like a slice of the brain). The scanner sends a

narrow beam of X-rays through a person's head (see Figure 4.22(a)). The beam is moved around the patient's head, and a computer calculates the amount of radiation that passes through it at various points along each angle. The result is a two-dimensional image of a 'slice' of the person's head, parallel to the top of the skull.

Using the CT scanner, an investigator can determine the approximate location of a brain lesion in a living patient. Knowing the results of behavioural testing and the location of the brain damage, the neuropsychologist can compare them and make inferences about the normal function of the damaged brain tissue. Figure 4.22(b) shows CT scans of the brain of a patient with a lesion caused by a stroke.

Magnetoencephalography (MEG)

A more recently developed electrophysiological technique is **magnetoencephalography**. Neurons can generate magnetic as well as electrical currents and these magnetic fields can be measured from the surface of the head via a machine called a superconducting quantum interference

Figure 4.21 (a) The number of PET and fMRI studies of behaviour has increased significantly since 1988.

device (SQUID) which is immersed in liquid helium. The machine detects the activity of magnetic fields from a large number of neurons because the magnetic fields generated by single neurons are very weak. The subsequent recording is called the magnetoencephalograph or MEG. Unlike the EEG, MEG can be used to localise sources of activity fairly well and these sources can be plotted on a three-dimensional image of the participant's head. MEG has been used to study various functions from language to olfaction.

Positron Emission Tomography (PET)

Positron emission tomography (PET) is an invasive measure of brain metabolism, glucose consumption and blood flow. The procedure for undergoing a PET scan goes something like this. A person is given a harmless dose of a radioactive substance (a form of glucose) which enters the brain (this is why the technique is invasive; the radioactive substance is injected into the participant's arm). The chemical accumulates in particular regions of the brain (the location depends on the specific chemical) but usually goes to active cells. PET measures brain activity by examining the amount of oxygen consumed by, or blood flow travelling to, neurons. The radioactive parts of the glucose emit positrons (hence positron emission) which are detected by a PET scanner, a large, doughnut-shaped piece of equipment which accommodates the prostrate participant's head. This activity is then represented in the form of coloured maps. Because of the radioactivity involved, only certain participants are allowed to take part in PET research. Premenopausal women and children, for example, cannot take part, which limits the use of PET when investigating how brain function develops during the early years. See Figure 4.23.

It is difficult to overestimate the early contribution of PET research to the study of brain function, however. PET has allowed researchers to undertake investigations of the workings of the brain that were thought unrealisable 30 years ago. It is an expensive technique (the scanner's costs run into millions) but a number of PET laboratories now

exist around the world and the results from these laboratories have allowed us to see whether the technique shows a consistent pattern of findings (Cabeza and Nyberg, 2000). In later chapters, you will see how PET research has helped us to understand the neural basis of functions such as speech perception, speech comprehension, memory, reading, attention and many others. It has been used to localise the parts of the brain active during word and speech recognition (Petersen *et al.*, 1988; Zatorre *et al.*, 1992; Castro-Caldas *et al.*, 1998; Karbe *et al.*, 1998), face perception (Sergent *et al.*, 1992), language tasks performed by dyslexic individuals (Rumsey *et al.*, 1997; Brunswick *et al.*, 1999), problem-solving (Baker *et al.*, 1996; Nagahama *et al.*, 1996) and remembering events (Fletcher *et al.*, 1998 a, b), among others.

Magnetic Resonance Imaging (MRI) and functional Magnetic Resonance Imaging (fMRI)

A **magnetic resonance imaging (MRI)** scanner provides more detailed images of the structure of the brain than does CT (see Figure 4.24). It does so with the use of magnetic fields and radio waves rather than with X-rays. When a magnetic field is passed over the head, reverberations are produced by hydrogen molecules. These reverberations are picked up by the scanner which can convert the activity into a structural image. This image appears in a form like that seen in Figure 4.25.

Figure 4.23 A PET scanner.

It is also possible to use MRI in a functional capacity, to examine the brain's function as well as its structure (Frackowiak *et al.*, 1997). This is called **functional magnetic resonance imaging (fMRI)** and the technique is a measure of the amount of deoxygenated blood in parts of the brain (giving what is called the BOLD signal). The BOLD signals are converted into a form of pixel (in fMRI they are called voxels). Each image contains between 40,000 and 500,000 voxels and each voxel covers between 1 and 123 mm³ of brain tissue (Vul *et al.*, 2009). Unlike PET, which is invasive (radioactively labelled substances are introduced into the body), MRI and functional MRI are non-invasive, which means that they can be used to investigate the development of function (in, for example, children). fMRI has been used to investigate similar functions to those investigated using PET: language, attention, vision, memory and so on. Both PET and MRI can be used in combination. However, while both have the advantage of good spatial resolution (you can see images and structures more precisely), they also have the disadvantage of poor temporal resolution – it is difficult to match the psychological and neural event in time precisely. The reason for this is that in PET and fMRI a number of scans are recorded and then averaged (see Caveats below).

Figure 4.25 An MRI scan taken from a patient with damage to Wernicke's area, following a stroke (the right side of the image represents the left side of the brain).

Source: Figure 4.27 from *Human Neuropsychology*, 2nd edn, p. 36, Pearson/Prentice Hall (Martin, G.N., 2006).

Functional MRI has been used to understand the cerebral correlates of a variety of topics, from being in love (Bartels and Zeki, 2000), to naming animate and inanimate objects (Martin and Chao, 2001), to driving (Horikawa *et al.*,

2005), to navigating a virtual London (Spiers and Maguire, 2007), to friendship and the understanding of magic. The last two in this list form the two Cutting Edge sections.

Cutting edge – Love, friendship and neuroscience

Researchers from the US and Switzerland used fMRI to see how quickly people would respond to words when the name of a loved one, a friend or a 'passionate hobby' (e.g. dance) was subliminally presented before the words (Ortigue *et al.*, 2007). When the word was preceded by a loved one's name or a favoured hobby, reaction time was faster – and activation was greater in areas near the frontal lobe, called the fusiform gyrus and angular gyri. The results suggest that a photograph of a loved one acts as a motivating prime but that it activates a network of brain regions not normally associated with reward.

This motivated attention is also seen in ERP studies. Psychologists from the Netherlands used event-related potentials to see whether stimuli related to a loved one would elicit a late, positive-going brainwave normally found when people are exposed to emotional stimuli (Langeslag *et al.*, 2007). This is what they found – the wave was larger to the face of a loved one than to a friend or that of an unknown, beautiful person.

Friendship, of course, is one aspect of love. In another study, also from researchers in the Netherlands, participants were asked to approach or withdraw from photographs of faces of liked and disliked peers, friends and familiar celebrities, as

fMRI measured brain activation (Guroglu *et al.*, 2008). In the task, a face was presented on screen and, using a joystick, participants moved a stimulus on screen towards instructions that read 'I want to approach', 'neutral' and 'I want to go away'. Liked stimuli were approached more than disliked ones and peers more than celebrities. During interaction with friends, four regions were especially activated (the amygdala, hippocampus, nucleus accumbens and ventromedial prefrontal cortex; see below), regions known to be implicated in empathy.

Two of these regions were also activated in a study from the UK and US where people played a videogame in which they either (i) shot an aggressive humanoid or healed a passive, wounded person or (ii) shot the wounded and helped the assailant (King *et al.*, 2006). The aim was to discover the neural substrates of compassionate and violent behaviour, or 'doing the right thing'.

Activation was found in the amygdala and the ventromedial prefrontal cortex regardless of whether the participants helped the wounded or attacked an assailant, suggesting that both regions are implicated in our ability to 'do the right thing' and our understanding of what it is to behave appropriately.

Cutting edge – The magic of neuroimaging or 'You'll like this, not a lot, but you'll like this'

How do we and our brains cope with a violation of what we consider to be normal? Psychologists from the Universities of Durham and Exeter used fMRI to measure how the brain responded to these violations (Parris *et al.*, 2009). A group of young men and women watched video clips of various elementary magic tricks – such as the disappearing coin, where the magician leaves a coin on the table, covers it, and lifts the cover to reveal it has disappeared; a levitation trick where a paper cup is made to levitate, and a cigarette torn and then restored to its intact state. They also watched clips of sequences that were similar but which did not violate expectations.

When they saw the magic trick, there was significant activation in a part of the frontal lobe, called the dorsolateral prefrontal cortex, and a nearby area, the anterior cingulate cortex. Activity was also greater here than when a person watched a clip of something that was surprising – activity seemed to be dependent on the unfathomable nature of the trick rather than on its surprise value. (See Figure 4.26). The unusual study highlights a part of the brain that may be involved in the understanding of causal relations in what we perceive. Chapter 11 has more on the role of this region during reasoning.

Cutting edge – Continued

Source: Parris, B.A., Kuhn, G., Mizon, G.A., Benattayallah, A. and Hodgson, T.L. (2009). Imaging the impossible: An fMRI study of impossible causal relationships in magic tricks. *Neuroimage*, 45, 1033–39.

Caveats

Of course, neuroimaging techniques, although providing us with a new way of viewing brain activation, are not measures of actual neural functioning. Instead, they measure the processes associated with neural function – such as blood flow or oxygen and glucose consumption. They also provide data that are correlational. Researchers draw associations between the stimulus or task they present and the differences in activation in the brain they observe that are not seen at baseline. These data are not particularly time-sensitive because fMRI and PET use the technique of averaging and subtraction – several experimental scans are taken, usually in a mixed order, and then averaged to produce a scan for this condition/group. A scan is taken approximately every three seconds. The average experimental condition is subtracted from the control scan. This means that you cannot associate a scan with a specific event in time. Also, because any task will activate all of the brain to some extent, researchers focus on a region of interest (ROI) and compare activation between two tasks in this area.

These scans are also very persuasive tools. Examine any newspaper report involving the brain and the chances are

that the story either involves some new ground-breaking drug or neuroimaging (see the opening vignette for an example). The appeal of neuroimaging is seductive. It is immediate, visual and allows us to see something that was previously unattainable: a pictorial, anatomically correct representation of the living brain. And, as humans, we are very swayed by visual seduction, as McCabe and Castel (2008) have demonstrated in their study.

They asked people to judge the degree of scientific reasoning in three articles about cognitive neuroscience. The articles were accompanied by either bar graphs, topographical maps (brain scans) or no image. Despite there being no difference between the content of the articles, the piece accompanied by a brain map was judged to be more scientific. These images, say McCabe and Castel, ‘provide a physical basis for abstract cognitive processes, appealing to people’s affinity for reductionistic explanations for cognitive phenomena’ (p. 343).

Neuroimaging is being applied to some novel areas of behaviour. A new line of research has examined a particularly controversial topic: the use of neuroimaging to predict lying. The evidence is reviewed in the Controversies in Psychological Science section.

Controversies in Psychological Science – Can brain scanners detect deception?

The issue

If all it took to identify a liar was to examine their extending, Pinnocchio-like proboscis, we would encounter a lot less deception and the police and the courts could probably take a day off. But we do not yet have a Pinnocchioian 'tell' that can do this (you read about the evidence in Chapter 1). Some scientists, however, have tried to identify one. And, controversially, it involves the brain.

The evidence

Psychology has a long history of using physiological measures to identify deception. The polygraph, described in the section earlier, is one measure. This has its critics – it has rightly been taken to task for being methodologically questionable (the polygraph is a measure of arousal, rather than deception).

The key to identifying a neurophysiological marker of deception is attractive to those who could exploit it. This tell-tale activation may not be under conscious control – the liar may not be able to control their brain activation – and it may be present only when a person is lying. It is almost like using neuroimaging as a mind-reading tool, where the observation of a scan would reveal your innermost thoughts and predict your thinking and behaviour. This, however, is currently pie in the sky – the *Eternal Sunshine of the Spotless Mind* is a long way off, if possible at all – but psychologists and neuroscientists have worked at constructing ways in which the brain's behaviour can be measured during acts of deception (Langleben, 2008; Spence, 2008; Sip, Roepstorff, McGregor and Frith, 2007).

According to Vrij (2004a, b), deception involves 'a deliberate attempt, without forewarning, to create in another a belief which the communicator considers to be untrue'. This definition embodies two important points: (i) a liar deliberately and purposefully intends to deceive another person and (ii) deception does not involve instructing the liar to lie – he or she will do this spontaneously.

Around 16 peer-reviewed studies using fMRI to study deception had been published by 2007 (Spence, 2008). Almost all of these studies have implicated one particular part of the brain in deception – the frontal lobes. The majority of the reports specifically find activation in certain areas of the frontal lobes: the ventromedial prefrontal cortex (VPC), dorsolateral prefrontal cortex (DFC) and the anterior cingulate cortex (ACC). For example, researchers have asked participants to lie to the experimenter (Abe *et al.*, 2007), or given them two cards and asked them to lie about having one of them (Gamer *et al.*, 2007) or asked volunteers to malingering – feign a memory impairment (Lee *et al.*, 2002; 2005), or instructed them to 'steal' a watch or ring and then reward them for successfully lying about it (Kozel

Headlines such as these are becoming more common (but no more accurate)

Source: Guardian News and Media Ltd.: Charles O'Rear/Corbis

et al., 2005), or asked them to lie about autobiographical events (Spence *et al.*, 2001; Nunez *et al.*, 2005). All activated the prefrontal cortex and some activated the medial temporal gyrus. These activations were not observed when the person was telling the truth or when baseline recordings were taken. According to Spence *et al.* (2008), the VPC may support deceptive behaviour by suppressing a person's ability to tell the truth.

It seems that deception can, therefore, be measured by fMRI. Or can it?

According to Sip *et al.* (2007), fMRI studies of deception are hamstrung by several methodological problems or confounds. They argue that what deception experiments primarily measure are the functions needed for lying, such as inhibiting behaviour (telling the truth), mentalising (reading others' states of mind or intentions) and relating action or behaviour to the outcome (monitoring behaviour). The authors suggest that deception involves keeping track of the lies and truth being told (information management), building trust with the deceived (impression management), appreciating that the gains from lying are greater than the losses and the risks of being found out (risk management) and an intention that lying is done for some good or can be justified in some way (reputation management). All of these behaviours recruit the areas found to be active during deception. See Figure 4.27.

Controversies in Psychological Science – *Continued*

Figure 4.27 Some of the areas of the brain, principally involving the frontal lobe, which become active during the act of lying.

Source: Spence, S.A., Kaylor-Hughes, C., Farrow, T.F.D. and Wilkinson, I.D. (2008). *Neuroimage*, 40, 1411–18.

The problem, however, is that in all fMRI experiments, the participants are instructed to lie by the experimenter. That is, they do not spontaneously lie and, furthermore, do not lie about anything significant (lying about having a playing card is in a different order to lying about running someone over in a car). These participants lack one of the key features of deception – the intention to lie, although it is possible that a person can be instructed to lie on someone's behalf (i.e. provide a false alibi for a criminal). But, then again, the person is motivated to do this – it has a purpose.

The protocols used also neglect the context in which lying occurs and the negative consequences of lying – a person who lies faces no punishment or no censure at all in these experiments. Again, the paradigms used can be regarded as basic and artificial.

Because of these problems, Sip *et al.* have identified a number of related problems in the interpretation of fMRI studies. The first is that although a characteristic of mentalising, emotion and risk-taking is activation in a particular part of the brain, the presence of such activation does not mean that a person is lying. The second is that fMRI deception

studies are based on groups – individual responses may vary greatly (depending on the seriousness of the wrongdoing and the individual's predisposition to lie or intention to lie). A third is that instructions to lie 'lift moral sanctions against lying' – there are no real consequences of lying. The fourth is that different people will have different attitudes to deception. At the extreme, think of the psychopath (described in detail in Chapter 18). A psychopath lies effortlessly and shows no empathy – he (and it is usually a he) shows reduced frontal lobe volume and activation, not more. Psychopaths' behaviour stems from their attitude to their victim – they do not regard what they say as wrong when they lie.

Conclusion

In the US, some scientists, entrepreneurs and patent specialists are busying themselves setting up and protecting companies that they claim will use fMRI to detect deception (for example, NoLieMRI in San Diego). However, what the studies to date have done is not so much measure deception but the cognitive processes involved in deception.

Importantly, these studies have a flaw – the liar does not spontaneously lie or has the intention of lying, unlike genuine deception. Future studies, therefore, need a way of allowing a person to decide whether to lie. Of course, these studies will be so tightly straightjacketed that another important element will still be missing – the belief that lying will spare some punishment or will achieve some other, very significant goal. As Sip *et al.* conclude, 'paradigms are still inadequate. The problems that bedevilled old techniques have not been eliminated by the new'. It seems as if there is still no room for Pinocchio's nose inside the scanner.

Modern brain stimulation: transcranial magnetic stimulation (TMS)

Despite having its origins in the nineteenth century, a relatively new, non-invasive, technique for studying localisation is **transcranial magnetic stimulation (TMS)**. TMS involves modulating cortical activity by passing alternating magnetic fields across the scalp (Burt *et al.*, 2002). The consequence of exposure to these fields is that electrical currents are induced in the cortex and the excitability of the cortex is subsequently increased or decreased. These effects can last a few seconds or minutes to a few weeks. The technique's benefits to neuropsychol-

ogy are that it can produce transient impairment or improvements in cognition non-invasively.

In practice, a metal coil is placed on a participant's scalp, as you can see in Figure 4.28. The alternating electrical current in the coil produces an alternating magnetic field at right angles to the current generated in the coil. This alternating magnetic field then passes through to the cortex and creates an electrical current in the part of the brain (around 1 to 2 cms worth) beneath the coil. The technique is apparently safe – the most likely danger, if a danger occurs, is of a seizure being generated during repeated stimulation. Sometimes headaches can follow and slight periods of mania; scalp facial muscles might twitch.

Figure 4.28 A typical rTMS procedure.

Source: University of Durham/Simon Fraser/Science Photo Library Ltd.

In TMS, the magnetic fields – or ‘pulses’ – can be presented either singly, in pairs a few seconds apart or in quick succession over a period of minutes. These are called single-pulse TMS, paired-pulse TMS and repetitive (r)TMS, respectively. Testing sessions normally last between 20 minutes and an hour. If the stimulation is high frequency, an increase in blood flow is observed; if stimulation is low, excitability is reduced (Chen *et al.*, 1997). Blood flow and cortical excitability are thought to be correlates in this sense although the change in blood flow may occur away from the region that is cortically excited.

The effect of TMS in normal, healthy individuals is analogous to the effect of a lesion – the transient stimulation

produces a transient brain disruption of function (although, obviously, with no damage, permanent or otherwise). Unlike neuroimaging, where activation is correlated with behaviour and may not be necessary to produce it, TMS directly stimulates brain regions and the consequences can be observed. The technique has been found to disrupt verbal working memory (Mottaghy *et al.*, 2002), verb generation (Shapiro *et al.*, 2001) and speech (Stewart *et al.*, 2001). Other studies have reported improvements in picture naming following TMS stimulation of Wernicke’s area (Topper *et al.*, 1998).

Repetitive TMS has been used in a very novel way. Fregni *et al.* (2008) used it to stimulate a part of the front

region of the brain – the dorsolateral prefrontal cortex (DPFC) – while participants were exposed to foods such as chocolate cake, toast and sweets, or a film of foods that strongly induced craving. Participants rated how much they desired food before and after stimulation.

Right-sided stimulation reduced craving after watching food whereas stimulation of the left side reduced the time that participants fixated on the food. Stimulation on both sides of the brain reduced the amount of food that people ate afterwards, compared to a sham condition (in which participants thought they were receiving brain stimulation but did not).

This part of the brain is associated with cravings for other types of substances – such as nicotine. Smokers watching a video involving smoking showed increased activation in several brain regions, including the prefrontal cortex (McBride *et al.*, 2006) and stimulating the right DPFC reduces risk-taking behaviour (Knoch *et al.*, 2006). Perhaps, the authors suggest, modulating activity in this part of the brain inhibits neural circuits involved in reward.

Control of behaviour

The brain has two roles: controlling the movements of the muscles and regulating the physiological functions of the body. The first role looks outwards towards the environment and the second looks inwards. The outward-looking role includes several functions: perceiving events in the environment, learning about them, making plans, and acting. The inward-looking role requires the brain to measure and regulate internal characteristics such as body temperature, blood pressure and nutrient levels.

Organisation of the cerebral cortex

We become aware of events in our environment by means of the five major senses: vision, audition, olfaction (smell), gustation (taste) and the somatosenses ('body' senses: touch, pain and temperature). Three areas of the cerebral cortex receive information from the sensory organs. The **primary visual cortex (V1)**, which receives visual information, is located at the back of the brain, on the inner surfaces of the cerebral hemispheres. The **primary auditory cortex**, which receives auditory information, is located on the inner surface of a deep fissure in the side of the brain. The **primary somatosensory cortex**, a vertical strip near the middle of the cerebral hemispheres, receives informa-

tion from the body senses. Different regions of the primary somatosensory cortex receive information from different regions of the body. In addition, the base of the somatosensory cortex receives information concerning taste. See Figure 4.29.

Primary sensory and motor cortex

The three regions of primary sensory cortex in each hemisphere receive information from the opposite side of the body. Thus, the primary somatosensory cortex of the left hemisphere learns what the right hand is holding, the left primary visual cortex learns what is happening towards the person's right, and so on. The connections between the sensory organs and the cerebral cortex are said to be contralateral (contra 'opposite', lateral 'side').

The region of the cerebral cortex most directly involved in the control of movement is the primary motor cortex (MI), located just in front of the primary somatosensory cortex. Neurons in different parts of the primary motor cortex are connected to muscles in different parts of the body. The connections, like those of the sensory regions of the cerebral cortex, are contralateral; the left primary motor cortex controls the right side of the body and vice versa. Thus, for example, damage to the left primary motor cortex will result in paralysis in

Figure 4.29 The lobes of the brain and the association areas of the cortex, together with the primary functions undertaken by these areas.

the contralateral hand and sometimes in the left hand (Haaland and Harrington, 1989). The hand that one predominantly uses (and this usually means to write with) appears to be related to the side of the brain that is involved in speech production (we'll discuss handedness more in Chapter 10).

Association cortex

The regions of primary sensory and motor cortex occupy only a small part of the cerebral cortex. The rest of the cerebral cortex accomplishes what is done between sensation and action: perceiving, learning and remembering, planning, and acting. These processes take place in the association areas of the cerebral cortex. The central fissure provides an important dividing line between the **anterior** (front) part of the cerebral cortex and the **posterior** (back) regions. The anterior region is involved in movement-related activities, such as planning and executing behaviours. The posterior part is involved in perceiving and learning.

The cerebral cortex is divided into four areas, or lobes, named after the bones of the skull that cover them: the frontal lobe, parietal lobe, temporal lobe and occipital lobe. The brain contains two of each lobe, one in each hemisphere. The **frontal lobe** (the 'front') includes everything in front of the central fissure. The **parietal lobe** (the 'wall') is located on the side of the cerebral hemisphere, just behind the central fissure, behind the frontal lobe. The **temporal lobe** (the 'temple') juts forward from the base of the brain, beneath the frontal and parietal lobes. The **occipital lobe** (*ob* 'in back of', *caput* 'head') lies at the very back of the brain, behind the parietal and temporal lobes. The lobes and association regions of the brain can be seen in Figure 4.30 (a) and an overview of the brain's motor functions can be seen in Figure 4.30 (b).

Temporal sequencing of events

Each primary sensory area of the cerebral cortex sends information to adjacent regions, called the **sensory association cortex**. Circuits of neurons in the sensory association cortex analyse the information received from the primary sensory cortex; perception takes place there, and memories are stored there. The regions of the sensory association cortex located closest to the primary sensory areas receive information from only one sensory system. For example, the region closest to the primary visual cortex analyses visual information and stores visual memories. Regions of the sensory association cortex located

far from the primary sensory areas receive information from more than one sensory system; thus, they are involved in several kinds of perception and memory. These regions make it possible to integrate information from more than one sensory system. For example, we can learn the connection between the sight of a particular face and the sound of a particular voice.

Just as regions of the sensory association cortex of the posterior part of the brain are involved in perceiving and remembering, the frontal association cortex is involved in the planning and execution of movements. The anterior part of the frontal lobe – known as the prefrontal cortex – contains the motor association cortex. The motor association cortex controls the primary motor cortex; thus, it directly controls behaviour. Obviously, we behave in response to events happening in the world around us. Therefore, the sensory association cortex of the posterior part of the brain sends information about the environment to the **motor association cortex** (prefrontal cortex), which translates the information into plans and actions (see Figure 4.30).

Lateralisation of function

Although the two cerebral hemispheres cooperate with each other, they do not perform identical functions. Some functions show evidence of **lateralisation**, that is, they are located primarily on one side of the brain (this is also called **functional hemispheric asymmetry**). It is commonly suggested that the left hemisphere participates in the analysis of information (making it good at recognising series of events) whereas the right hemisphere is good at putting items together (making it good at 'holistic' activities). This distinction may, however, be too simplistic. The left hemisphere does appear to be significantly more involved in aspects of language processing such as speech production and comprehension and the appreciation of the sounds in speech than is the right hemisphere. However, as you will see in more detail in Chapter 10 (Language), the right hemisphere is better than the left hemisphere at comprehending metaphors and may undertake the linguistic duties of the left hemisphere when the left is damaged. The right hemisphere also appears to be superior to the left at recognising faces, perceiving emotion and mentally rotating three-dimensional images in space. In the following chapters you will read about these and other examples of function that are lateralised in the brain; you will see that lateralisation of function does not occur in the whole of one hemisphere but in specific parts of it.

Figure 4.30 (a) The relation between the association cortex and the regions of primary sensory and motor cortex. Arrows refer to the flow of information. **(b)** A motor homunculus. This shows how some parts of the brain are disproportionately involved in certain bodily movements, such as those involving the lips and hands. This little figure illustrates the relative amount of cortex devoted to each body part's movement.

Source: Carlson, N.R., *Physiology of Behavior* (6th edn), p. 235. Boston: Allyn & Bacon, 1988. © Allyn & Bacon. Reproduced with permission.

The two cerebral hemispheres are connected by the **corpus callosum**, a large band of axons, seen in Figures 4.31 (a) and (b). In fact, it is the brain's largest collection of connective fibre. The corpus callosum connects corresponding parts of the left and right hemispheres: the left and right temporal lobes are connected, the left and right parietal lobes are connected, and so on. Because of the corpus callosum, each region of the association cortex

knows what is happening in the corresponding region of the opposite side of the brain. Some people have the corpus callosum surgically cut in order to alleviate the symptoms of epilepsy. So-called split-brain patients are interesting to psychologists because their two hemispheres do not appear to be able to communicate. We discuss the effects of split-brain surgery in more detail in Chapter 9 (Consciousness).

Vision: the occipital lobe

The primary business of the occipital lobe – and the lower part of the temporal lobe – is seeing. Total damage to the primary visual cortex, located in the inner surface of the posterior occipital lobe, produces cortical blindness (to distinguish it from other forms of blindness such as congenital blindness). Because the visual field is 'mapped' onto the surface of the primary visual cortex, a small lesion in the primary visual cortex produces a 'hole' in a specific part of the field of vision.

The visual association cortex is located in the rest of the occipital lobe and in the lower portion of the temporal lobe. Damage to the visual association cortex will not cause blindness. In fact, visual acuity may be very good; the person may be able to see small objects and may even be able to read. However, the person will not be able to recognise objects by sight. For example, when looking at a drawing of a clock, the person may say that they see a circle, two short lines forming an angle in the centre of a circle, and some dots spaced along the inside of the circle, but will not be able to recognise what the picture shows. On the other hand, if the person is handed a real clock, they will immediately recognise it by touch. This fact tells us that the person has not simply forgotten what clocks are. Similarly, the person may fail to recognise their spouse by sight but will be able to do so from the sound of the spouse's voice. This deficit in visual perception is called **visual agnosia** (*a-* 'without', *gnosis* 'knowledge') and we return to it in Chapter 6 (Perception).

Audition: the temporal lobe

The temporal lobe contains both the primary auditory cortex and the auditory association cortex. The primary auditory cortex is hidden from view on the inner surface of the upper temporal lobe. The auditory association cortex is located on the lateral surface of the upper temporal lobe. Damage to the primary auditory cortex leads to hearing losses, while damage to the auditory association cortex produces more complex deficits. Damage to the left auditory association cortex causes severe language deficits. People with such damage are no longer able to

Figure 4.31 (a) A view of the brain that has been sliced through the midline (this is called a sagittal view). The corpus callosum unites the cerebral cortex of the two hemispheres. (b) A cross-section of a human head. You can clearly see the general structures of the brain: the neocortex, the corpus callosum, the cerebellum, the pons and the medulla.

Source: (b) Image P330/382 Tissuepix/Science Photo Library Ltd.

comprehend speech, presumably because they have lost the circuits of neurons that decode speech sounds. However, the deficit is more severe than that. They also lose the ability to produce meaningful speech; their speech becomes a jumble of words. Language deficits produced by brain damage are described in more detail in Chapter 10 (Language). See Figure 4.32.

Damage to the right auditory association cortex does not seriously affect speech perception or production, but it does affect the ability to recognise non-speech sounds, including patterns of tones and rhythms. The damage can also impair the ability to perceive the location of sounds in the environment. As we will see later, the right hemisphere is important in the perception of space. The contribution of the right temporal lobe to this function is to participate in perceiving the placement of sounds.

Somatosensation and spatial perception: the parietal lobe

The primary sensory function of the parietal lobe is perception of the body. However, the association cortex of the parietal lobe is involved in much more than somatosensation. Damage to a particular region of the association cortex of the left parietal lobe can disrupt the ability to read or write without causing serious impairment in the ability to talk and understand the speech of other people. Damage to another part of the parietal lobe impairs a person's ability to draw. When the left parietal lobe is damaged, the primary deficit seems to be in the person's ability

to make precise hand movements; their drawing looks shaky and sloppy. In contrast, the primary deficit produced by damage to the right parietal lobe is perceptual. The person can analyse a picture into its parts but has trouble integrating these parts into a consistent whole. Thus, they have difficulty drawing a coherent picture. We will look at disorders such as these in Chapter 6 (Perception).

Most neuropsychologists believe that the left parietal lobe plays an important role in our ability to keep track of the location of the moving parts of our own body, whereas the right parietal lobe helps us to keep track of the space around us. People with right parietal lobe damage usually have difficulty with spatial tasks, such as reading a map. People with left parietal lobe damage usually have difficulty identifying parts of their own bodies by name. For example, when asked to point to their elbows, they may actually point to their shoulders. There is also evidence showing that this region of the brain, together with the frontal lobe, is involved in our ability to perform mental arithmetic (Menon *et al.*, 2000; Cowell *et al.*, 2000). This region is smaller in children with mathematical deficits when compared with children with normal maths performance (Isaacs *et al.*, 2001).

The **posterior part of the parietal cortex (PPC)** appears to be specialised for storing representations of motor actions (Milner, 1998). Snyder *et al.* (1997) found that some neurons in the PPC of two adult macaque monkeys were active before and during visually guided arm movements whereas others were active during eye movements. However, rather than directing attention to objects in space, the PPC seems to be responsible for the intention

Figure 4.32 Broca's area, located just in front of the face region of the primary motor cortex. This region is involved in the control of speech.

to move. There may be visual neurons in the PPC which are responsible for visually guided movement (Sakata, 1997). Manipulation of body part information appears to involve the left frontal and parietal lobes whereas manipulation of numbers appears to involve the right parietal lobe (Le Clec'H *et al.*, 2000).

Neurons in a part of the brain called the superior temporal sulcus become active when an animal detects head and body movement. In humans, a similar area on the right side of the brain becomes activated when watching the movement of living things – whether in films, or of animals or schematic versions of human beings. One particular area, the extrastriate body area (EBA) seen in Figure 4.32 appears to become active selectively to the sight of human bodies and body parts and is also activated when we imitate the body actions of others (Jackson *et al.*, 2006). Does this region integrate information from a moving human image and process the dynamic elements of human movement, or does it simply process static images?

Researchers from the University of Bangor in North Wales used fMRI to measure brain activation while people watched single frames presented in the correct order from one whole body action (e.g. punching, kicking) or a series of frames involving several actions that were unrelated (Downing *et al.*, 2006). They found that the EBA responded more strongly to the second set of images than the first, suggesting that this region may not be responsible for the representation of dynamic movement/biological motion but, instead, is involved in processing static images of movement.

Planning and moving: the frontal lobe

Because it contains the motor cortex, the principal function of the frontal lobe is to mediate motor activity (it also includes the area responsible for speech perception, Broca's area, seen in Figure 4.32). There is also evidence that the premotor area of the frontal lobes (and a part of the parietal lobe) contains **mirror neurons** (Rizzolatti *et al.*, 1988). Mirror neurons are those which fire when we watch someone perform an action and also fire when we execute that action; they seem to mirror the activity of neurons that are involved in 'doing'. For example, neurons in one part of this area are activated in monkeys when they make a grasping movement with their hand. However, a different set in the same region is also activated when the monkey sees another making reaching movements (Ferrari *et al.*, 2003). Some people have associated dysfunction in these mirror neurons with autism, and the evidence for this is considered in Chapter 12. The frontal lobes are involved in a variety of 'higher' functions including planning, changing strategies, being

aware of oneself, empathising with others, evaluating emotional stimuli, inhibiting inappropriate behaviour and behaving spontaneously (some of these are called executive functions).

Damage to the primary motor cortex produces a very specific effect: paralysis of the side of the body opposite to the brain damage. If a portion of the region is damaged, then only the corresponding parts of the body will be paralysed (Passingham, 1995). However, damage to the prefrontal cortex produces more complex behavioural deficits. For example, the person with frontal lobe damage will react to events in the environment but show deficits in initiating behaviour. When a person with damage to the prefrontal cortex is asked to say or write as many words as possible or is asked to describe as many uses for an object as possible, they will have great difficulty in coming up with more than a few, even though they have no problem understanding words or identifying objects by name (Eslinger and Grattan, 1993).

People with damage to the frontal lobe also tend to have difficulty changing strategies. If given a task to solve, they may solve it readily. However, if the problem is changed, they will fail to abandon the old strategy and learn a new one. The Wisconsin Card Sorting Task, for example, presents patients with packs of cards on which are printed symbols of different shape, colour or number (see page 474, Chapter 11). The experimenter decides on a sorting criterion (shape, for example) and the patient has to detect which criterion it is by sorting the cards into piles, receiving feedback from the experimenter. When the criterion unexpectedly shifts, some patients are unable to detect this shift and carry on responding as if the previous criterion still applied. This is called **perseveration**. However, not all frontal lobe patients will exhibit this behaviour (Anderson *et al.*, 1991), only those with damage to a specific region of the frontal lobe.

People with damage to certain areas of the frontal lobe often have rather bland personalities. They seem indifferent to events that would normally be expected to affect them emotionally (Stuss *et al.*, 1992). For example, they may show no signs of distress at the death of a close relative and do not show the typical physiological response to stress (see Martin 2006 for a comprehensive description). They have little insight into their own problems and are uncritical of their performance on various tasks (Stuss *et al.*, 1992; Brazzelli *et al.*, 1994; Hornak *et al.*, 1996; Cicerone and Tanenbaum, 1997). The most famous case study of frontal lobe damage resulting in shifts in emotional and social behaviour is that of Phineas Gage, a man you read about in Chapter 1 and to whom we return in Chapter 13.

In terms of daily living, the most important consequences of damage to the frontal lobe are probably lack of foresight and difficulty in planning. A person with

injury to part of the frontal lobe might perform fairly well on tests of intelligence but be unable to hold down a job or organise their day (Eslinger and Damasio, 1985; Wood and Rutterford, 2004). Sequencing – the organisation of material in logical, correct or learned order – is grossly impaired in frontal patients (Sirigu *et al.*, 1995). Often, when given tasks that tap everyday activities (such as undertaking an errand or following a recipe), patients with frontal lobe damage perform poorly (Shallice and Burgess, 1991; Fortin *et al.*, 2003) and may engage in obsessive collecting behaviour (Anderson *et al.*, 2005).

Patients with damage to different regions of the frontal lobe exhibit different symptoms. For example, patients with damage to the orbitofrontal cortex (the tip of the frontal lobes) tend to exhibit impairments in social behaviour, personality and emotional expression but have relatively intact intellect. They are impulsive and don't care what others think or feel. Eslinger and Damasio's (1985) patient, EVR, is a good example. EVR, an ex-accountant who had a tumour removed from the same part of the brain injured in Phineas Gage, has superior intellect but an impaired ability to plan and organise his daily life. He performs at normal levels on tests such as the Wisconsin Card Sorting Task and he has superior IQ. However, his ability to maintain close relationships and a job and his ability to plan and organise his life are grossly impaired. Chapter 13 looks at EVR's case in greater depth.

Control of internal functions and automatic behaviour

The cortex consists of only the outer 3 mm of the surface of the cerebral hemispheres. There are other structures such as the brain stem, the cerebellum and the interior of the cerebral hemispheres which are important to the regulation of behaviour. The cerebellum helps the cerebral hemispheres to control movement and to initiate some automatic movements, such as postural adjustment, on its own. The brain stem and much of the interior of the cerebral hemispheres are involved in homeostasis and control of species-typical behaviours. **Homeostasis** (from the root words *homoios* 'similar', and *stasis* 'standstill') refers to maintaining a proper balance of physiological variables such as temperature, concentration of fluids, and the amount of nutrients stored within the body. **Species-typical behaviours** are the more-or-less automatic behaviours exhibited by most members of a species that are important to survival, such as eating, drinking, fighting, courting, mating and caring for offspring.

The brain stem

The brain stem contains three structures: the medulla, the pons and the midbrain. Figure 4.33 shows a view of the left side of the brain. The brain has been rotated slightly so that we can see some of the front of the brain stem, and the cerebral hemispheres are shown lightly so that the details of the brain stem can be seen. We also see the thalamus, the hypothalamus and the pituitary gland.

The brain stem contains circuits of neurons that control functions vital to the survival of the organism in particular and of the species in general. For example, circuits of neurons in the **medulla**, the part of the brain stem closest to the spinal cord, control heart rate, blood pressure, rate of respiration, and – especially in simpler animals – crawling or swimming motions. Circuits of neurons in the **pons**, the part of the brain just above the medulla, control some of the stages of sleep, and circuits of neurons in the **midbrain** control movements used in fighting and sexual behaviour and decrease sensitivity to pain while engaged in these activities.

The cerebellum

The **cerebellum** plays an important role in the control of movement. It receives sensory information, especially about the position of body parts, so it knows what the parts of the body are doing. It also receives information from the cortex of the frontal lobes, so it knows what

Figure 4.33 The divisions of the brain stem: the medulla, the pons and the midbrain. The thalamus, hypothalamus and pituitary gland are attached to the end of the brain stem.

movements the frontal lobes intend to accomplish. The cerebellum is basically a computer that compares the location of the body parts with the intended movements and assists the frontal lobes in executing these movements. Without the cerebellum, the frontal lobes would produce jerky, uncoordinated, inaccurate movements – which is exactly what happens when a person's cerebellum is damaged. Besides helping the frontal lobes to accomplish their tasks, the cerebellum monitors information regarding posture and balance, to keep us from falling down when we stand or walk, and produces eye movements that compensate for changes in the position of the head.

Some studies have suggested that the cerebellum may also be involved in a variety of other functions such as cognition and language (Schmahmann and Sherman, 1998). The ability to produce words fluently and to solve problems are impaired in patients whose cerebellum has been damaged (Grafman *et al.*, 1992; Appollonio *et al.*, 1993). Neuroimaging studies show that various parts of the cerebellum become active during tasks involving movement and touch, language and verbal memory, spatial memory, executive function and emotional processing (Stoodley and Schmahmann, 2009). Language has been associated with activation on the right and spatial awareness with the left, which is opposite to that pattern seen at the cortical level presumably because projections to it are crossed. Some psychologists have also implicated the cerebellum in the reading disorder, developmental dyslexia, (see Chapter 10, page 417).

Subcortical structures

The thalamus

If you stripped away the cerebral cortex and the white matter that lies under it, you would find a collection of brain structures. These are called subcortical brain structures and are some of the oldest in the brain. One of the most important is the **thalamus**, located in the heart of the cerebral hemispheres (*thalamos* is Greek for 'inner chamber'). The thalamus is divided into two parts, one in each cerebral hemisphere. Each part looks rather like a football, with the long axis oriented from front to back.

The thalamus performs two basic functions. The first, and most primitive, is similar to that of the cerebral cortex. Parts of the thalamus receive sensory information, other parts integrate the information, and still other parts assist in the control of movements through their influence on circuits of neurons in the brain stem. However, the second role of the thalamus, that of a relay station for the cortex, is even more important. As the cerebral hemispheres

evolved, the cerebral cortex grew in size and its significance for behavioural functions increased. The thalamus took on the function of receiving sensory information from the sensory organs, performing some simple analyses, and passing the results on to the primary sensory cortex. Thus, all sensory information (except for olfaction, which is the most primitive of all sensory systems) is sent to the thalamus before it reaches the cerebral cortex.

The hypothalamus

Hypo- means 'less than' or 'beneath', and, as its name suggests, the **hypothalamus** is located below the thalamus, at the base of the brain. The hypothalamus is a small region, consisting of less than 1 cubic centimetre of tissue (smaller than a grape). Its relative importance far exceeds its relative size.

The hypothalamus, like the brain stem, participates in homeostasis and species-typical behaviours. It receives sensory information, including information from receptors inside the organs of the body; thus, it is informed about changes in the organism's physiological status. It also contains specialised sensors that monitor various characteristics of the blood that flows through the brain, such as temperature, nutrient content and amount of dissolved salts. In turn, the hypothalamus controls the **pituitary gland**, an endocrine gland attached by a stalk to the base of the hypothalamus.

Hormones are chemicals produced by endocrine glands (from the Greek *endo-* 'within', and *krinein* 'to secrete'). **Endocrine glands** secrete hormones into the blood supply, which carries them to all parts of the body. Hormones are similar to transmitter substances or neuromodulators, except that they act over much longer distances. Like transmitter substances and neuromodulators, they produce their effects by stimulating receptor molecules. These receptor molecules are located on (or in) particular cells. The presence of a hormone causes physiological reactions in these cells, which are known as **target cells**. Almost every cell of the body contains hormone receptors of one kind or other. This includes neurons; hormones that affect behaviour do so by altering the activity of particular groups of neurons in the brain. For example, the sex hormones have important effects on behaviour and are discussed in later chapters.

The pituitary gland has been called the 'master gland' because the hormones it secretes act on target cells in other endocrine glands; thus, the pituitary gland controls the activity of other endocrine glands. By controlling the pituitary gland, the hypothalamus controls the entire endocrine system. Figure 4.34 shows some of the endocrine glands and the functions they regulate.

Figure 4.34 The location and primary functions of the principal endocrine glands.

The hypothalamus also controls much of the activity of the **autonomic nervous system (ANS)**, which consists of nerves that control the functions of the glands and internal organs. The nerves of the autonomic nervous system control activities such as sweating, shedding tears, salivating, secreting digestive juices, changing the size of blood vessels (which alters blood pressure) and secreting some hormones. The autonomic nervous system has two branches. The **sympathetic branch** directs activities that involve the expenditure of energy. For example, activity of the sympathetic branch can increase the flow of blood to the muscles when we are about to fight someone or run away from a dangerous situation. The **parasympathetic branch** controls quiet activities, such as digestion of food. Activity of the parasympathetic branch stimulates the secretion of digestive enzymes and increases the flow of blood to the digestive system, as seen in Figure 4.35.

The homeostatic functions of the hypothalamus can involve either internal physiological changes or behaviour. For example, the hypothalamus is involved in the control of body temperature. It can directly lower body

temperature by causing sweating to occur, or it can raise it by causing shivering to occur. If these measures are inadequate, it can send messages to the cerebral cortex that will cause the person to engage in a learned behaviour, such as turning on an air conditioner or putting another log on the fire. Damage to the hypothalamus can cause impaired regulation of body temperature, changes in food intake, sterility and stunting of growth.

The limbic system

The **limbic system**, a set of structures located in the cerebral hemispheres, plays an important role in learning and in the expression of emotion. Originally, this area was termed *rhinencephalon* (or 'smell brain') because the areas within it were thought to be involved primarily in the sense of smell.

The limbic system consists of several regions of the **limbic cortex** – the cerebral cortex located around the edge of the cerebral hemispheres where they join with the brain stem (*limbus* means 'border'; hence the term 'limbic system'). Besides the limbic cortex, the most important

Figure 4.35 The autonomic nervous system and the organs it controls.

components of the limbic system are the amygdala and the hippocampus. The amygdala and the hippocampus get their names from their shapes; amygdala means 'almond' and hippocampus means 'sea horse'.

Figure 4.36 shows a view of the limbic cortex, located on the inner surface of the cerebral hemisphere. The left hippocampus and amygdala, located in the middle of the temporal lobe, are shown projecting out into the place where the missing left hemisphere would be. You can also see the right hippocampus and amygdala, 'ghosted in'.

The amygdala

Damage to the **amygdala**, a cluster of neurons located deep in the temporal lobe, affects emotional behaviour, especially negative emotions such as those caused by painful, threatening or stressful events. Some patients are unable to recognise fear in a person's voice or face (Adolphs *et al.*, 1995, 1999; Morris *et al.*, 1996). In a review of neuroimaging studies, however, Sergerie (2008) found that the amygdala responded to positive and nega-

tive emotional visual stimuli and responded more strongly to faces showing emotion than other emotional stimuli that were visual in nature. When the researchers looked at the data closely, they found that the effect sizes – the strength of the phenomenon under study – were larger for studies using positive than negative stimuli, a finding that is consistent with recent studies showing that although the neurons in the amygdala of monkeys respond to negative and positive stimuli, a greater number respond to positive than negative ones (Paton *et al.*, 2006). While the review found no evidence of sex differences in this structure, another single study has found that, at rest, the right side of the amygdala showed greater connectivity with the rest of the brain in men; for women, the same pattern was found for the left side (Kilpatrick *et al.*, 2006). Interestingly, the regions with which the right hemisphere showed connections were different from those with which the left hemisphere showed connections.

Grezes *et al.* (2006) found that the amygdala (and a region called the human face area, described in Chapter 6) showed increased activity when people watched themselves being deceived. The authors attribute the increase to greater personal involvement by the participants when they make ‘emotional’ judgements that involve them – in this example, deceit is seen as a personal threat.

The amygdala also controls physiological reactions that help provide energy for short-term activities such as fighting or fleeing (LeDoux, 1996). However, if these reactions are prolonged, they can lead to stress-related illnesses. If an animal’s amygdala is destroyed, the animal no longer reacts emotionally to events that normally produce stress and anxiety. We might think that an

animal would be better off if it did not become ‘stressed out’ by unpleasant or threatening situations. However, research has shown that animals with damaged amygdalae cannot survive in the wild. The animals fail to compete successfully for food and other resources, and often act in ways that provoke attacks by other animals. The functions of amygdala are discussed further in Chapters 13 and 17.

The hippocampus

The **hippocampus** (or hippocampal formation) is a collection of structures located just behind the amygdala, and plays an important role in memory. People with lesions of the hippocampus lose the ability to learn anything new (Milner *et al.*, 1968; Keane *et al.*, 1995). For them, ‘yesterday’ is always the time before their brain damage occurred; everything after that slips away, just as the memory of dreams often slips away from a person soon after awakening. The hippocampus and regions around it also seems to be responsible for navigating one’s way around certain types of route (Maguire *et al.*, 1997, 1998). In healthy people whose brain activation is measured, this structure is selectively active when we have to find our way around a route, whether it is in our mind or in virtual space. The role of the hippocampus in memory is considered in more detail in Chapter 8.

The basal ganglia

One final group of subcortical structures that is crucial to behaviour is the **basal ganglia**. The basal ganglia is the collective name for a group of nuclei, specifically, the globus pallidus, substantia nigra, striatum (made up of the caudate nucleus and putamen) and subthalamic nucleus (see Figure 4.37).

Some of these receive inputs; some deliver output. The output nuclei, for example, send projections to the thalamus and two other subcortical regions (Utter *et al.*, 2008) and these influence sensory and cognitive behaviour, the movement of the head and the eyes and some aspects of locomotion and posture. (And, as you’ve seen, deep brain stimulation in Parkinson’s disease targets these nuclei.) When the nuclei become dysfunctional, they can produce Parkinson’s (the dopamine neurons degenerate in the substantia nigra); the motor disorder, Huntington’s disease (remember this from the genetic counselling section from the last chapter) where the defective gene produces degeneration in neurotransmitter-specific neurons in the striatum; extreme of convoluted posture (dystonia); Tourette’s syndrome (uncontrollable blinking and facial grimacing, plus

Figure 4.37 The location of the basal ganglia.

Source: Science Photo Library Ltd.

coprolalia – vigorous, unpredictable and involuntary swearing); and obsessive-compulsive disorder (described in Chapter 18), possibly because of dysfunctional loops linking the striatum with the tip of the frontal lobe.

Drugs and behaviour

Communication between neurons involves the release of transmitter substances. Neurons release many different kinds of transmitter substance, and various drugs can affect the production or release of one or more of these chemicals. Drugs can also mimic the effects of transmitter substances on receptor molecules, block these effects, or interfere with the reuptake of a transmitter substance once it is released. Via these mechanisms, a drug can alter the perceptions, thoughts and behaviours controlled by particular transmitter substances.

Stimulating or inhibiting the release of transmitter substances

Some drugs stimulate certain terminal buttons to release their transmitter substance continuously, even when the axon is not firing. Other drugs prevent certain terminal buttons from releasing their transmitter substance when the axon fires. The effects of most of these drugs are more or less specific to one transmitter substance. Because different classes of neuron release different transmitter substances, these drugs affect only a selected set of neurons. An example of a stimulating drug is the venom of the black widow spider, which causes the release of a transmitter substance called acetylcholine, as illustrated by Figure 4.38. In contrast, botulinum toxin, a poison that is sometimes present in improperly canned food, prevents the release of acetylcholine. An adult will almost certainly survive the bite of a black widow spider; the symptoms are severe abdominal cramps. However, an extremely small amount of botulinum toxin – less than one-millionth of a gram – is fatal. The victim becomes paralysed and suffocates to death.

Stimulating or blocking postsynaptic receptor molecules

Transmitter substances produce their effects by stimulating postsynaptic receptor molecules, which excite or inhibit postsynaptic neurons by opening ion channels and permitting ions to enter or leave the neurons. Some drugs duplicate the effects of particular transmitter substances by directly stimulating particular kinds of receptor mole-

Figure 4.38 Drugs that affect the release of a neurotransmitter, acetylcholine. Black widow spider venom causes acetylcholine to be released. Botulinum toxin prevents the release of acetylcholine from the terminal buttons.

cules. If we use the lock-and-key analogy to describe the effects of a transmitter substance on a receptor molecule, then a drug that stimulates receptor molecules works like a master key, turning the receptor molecules on even when the transmitter substance is not present. For example, nicotine stimulates acetylcholine receptors located on neurons in certain regions of the brain (see Figure 4.39). In low doses, this stimulation has a pleasurable (and addictive) excitatory effect; in high doses, it can cause convulsions and death.

Some drugs block receptor molecules, making them inaccessible to the transmitter substance and thus inhibiting synaptic transmission. A drug that blocks receptor molecules ‘plugs up’ the lock so that the key will no longer fit into it. A poison called curare, discovered by South American Indians, was used on the darts of their blowguns. This drug blocks the acetylcholine receptors that are located on muscle fibres. The curare prevents synaptic transmission in muscles. The paralysed victim is unable to breathe and consequently suffocates.

Some medically useful chemicals work by blocking receptor molecules. For example, antipsychotic drugs alleviate the symptoms of schizophrenia, a serious mental disorder, by blocking receptor molecules in the brain that are normally stimulated by a transmitter substance called dopamine. This fact has led some investigators to suggest that the symptoms of schizophrenia may be caused by malfunctions of neurons that release dopamine. We dis-

cuss antipsychotic drugs later in this chapter and in Chapter 18 (Abnormal psychology).

Inhibiting reuptake

The effects of most transmitter substances are kept brief by the process of reuptake. Molecules of the transmitter substance are released by a terminal button, they stimulate the receptor molecules in the postsynaptic membrane for a fraction of a second, and then they are pumped back into the terminal button. Some drugs inhibit the process of reuptake so that molecules of the transmitter substance continue to stimulate the postsynaptic receptor molecules for a long time. Therefore, inhibition of reuptake increases the effect of the transmitter substance. The excitatory effects of cocaine and amphetamine are produced by their ability to inhibit the reuptake of certain transmitter substances, including dopamine (see Figure 4.40).

Sedatives

Some drugs depress behaviour, causing relaxation, sedation, or even loss of consciousness. These are called **anti-anxiety** or **anxiolytic drugs**. In most cases, the depression is caused by stimulation of a class of receptor molecules that is normally activated by neuromodulators produced by the brain. **Barbiturates** depress the brain’s activity by stimulating a particular category of neuromodulator receptors. In low doses, barbiturates have a calming effect. In progressively higher doses, they produce difficulty in walking and talking, unconsciousness, coma and death. Barbiturates are abused by people who want to achieve the relaxing, calming effect

Figure 4.39 Drugs that interact with receptor molecules in the postsynaptic membrane. Nicotine directly stimulates the receptor molecules. Curare blocks receptor molecules and thus prevents acetylcholine from activating them.

Figure 4.40 Drugs that block reuptake. Cocaine and amphetamine block the reuptake of certain transmitter substances, thus prolonging their effects on the receptor molecules in the postsynaptic membrane.

of the drugs, especially to counteract the anxiety and irritability that can be produced by stimulants. They are occasionally prescribed as medication for sleep, but they are a poor choice for this purpose because they suppress dreaming and produce a particularly unrefreshing sleep. In addition, a dose of a barbiturate sufficient to induce sleep is not that much lower than a fatal dose. Ideally, the therapeutic dose of a drug is much lower than a fatal dose.

Many anti-anxiety drugs are members of a family known as the **benzodiazepines**, which include the well-known tranquilliser Valium (diazepam). These drugs, too, stimulate some sort of neuromodulator receptors located on neurons in various parts of the brain, including the amygdala. The benzodiazepines are effective in reducing anxiety and are sometimes used to treat people who are afflicted by periodic attacks of severe anxiety. In addition, some benzodiazepines serve as sleep medications. These behavioural effects suggest that they mimic the effects of neuromodulators involved in the regulation of mood and the control of sleep.

By far the most commonly used depressant drug is ethyl alcohol, the active ingredient in alcoholic beverages. This drug has effects similar to those of the barbiturates: larger and larger doses of alcohol reduce anxiety, disrupt motor coordination and then cause unconsciousness, coma and finally death. The effects of alcohol and barbiturates are additive: a moderate dose of alcohol plus a moderate dose of barbiturates can be fatal.

The primary effect of alcohol appears to be similar to that of the benzodiazepines: it stimulates some type of neuromodulator receptor. Suzdak *et al.* (1986) discovered a drug that reverses alcohol intoxication, presumably by blocking some type of neuromodulator receptor. Although the behavioural effects of alcohol may be mediated by neuromodulator receptors, alcohol has other, potentially fatal effects on all cells of the body. Alcohol destabilises the membrane of cells, interfering with their functions. Thus, a person who takes some of the anti-alcohol drug could go on to drink themselves to death without becoming drunk in the process.

Controversies in Psychological Science – What is drug addiction?

The issue

Some drugs have very potent reinforcing effects, which lead some people to abuse them or even to become addicted to them. Robbins and Everitt (1999) report that the annual costs of drug addiction in the USA alone stand at around \$80 billion. Many people – psychologists, health professionals and lay people – believe that ‘true’ addiction is caused by the unpleasant physiological effects that occur when an addict tries to stop taking the drug. For example, Eddy *et al.* (1965) defined physical dependence as ‘an adaptive state that manifests itself by intense physical disturbances when the administration of a drug is suspended’ (p. 723). In contrast, they defined psychic dependence as a condition in which a drug produces ‘a feeling of satisfaction and a psychic drive that requires periodic or continuous administration of the drug to produce pleasure or to avoid discomfort’ (p. 723). Most people regard the latter as less important than the former. But, as we shall see, the reverse is true.

The evidence

Robbins and Everitt suggest that ‘drug dependence and addiction can be partly understood as gradual adaptations of the brain to chronic drug exposure’. But other psychological factors also influence drug-taking, from finding the drugs, to the motivation for using them, to being able to live without them.

For many years, heroin addiction has been considered as the prototype for all drug addictions. People who habitually take heroin (or other opiates) become physically dependent on the drug, that is, they show tolerance and withdrawal symptoms. **Tolerance** is the decreased sensitivity to a drug that comes from its continued use; the drug user must take larger and larger amounts of the drug in order for it to be effective. Once a person has taken an opiate regularly enough to develop tolerance, that person will suffer withdrawal symptoms if they stop taking the drug. **Withdrawal symptoms** are primarily the opposite of the effects of the drug itself. For example, heroin produces euphoria; withdrawal from it produces dysphoria – a feeling of anxious misery (euphoria and dysphoria mean ‘easy to bear’ and ‘hard to bear’, respectively). According to Freud, this was ‘agony beyond human power to bear’. Heroin produces constipation; withdrawal from it produces nausea, cramping and diarrhoea. Heroin produces relaxation; withdrawal from it produces agitation.

Most investigators believe that the withdrawal symptoms are produced by the body’s attempt to compensate for the unusual condition of heroin intoxication. That is, most systems of the body, including those controlled by the brain, are regulated so that they stay at an optimal value. When a drug artificially changes these systems for a prolonged time, home-

Controversies in Psychological Science – *Continued*

ostatic mechanisms begin to produce the opposite reaction, which partially compensates for the disturbance from the optimal value. These compensatory mechanisms account for the fact that more and more heroin must be taken in order to achieve the effects that were produced when the person first started taking the drug. They also account for the symptoms of withdrawal: when the person stops taking the drug, the compensatory mechanisms make themselves felt, unopposed by the action of the drug.

Heroin addiction has provided such a striking example of drug dependence that some authorities have concluded that 'real' addiction does not occur unless a drug causes tolerance and withdrawal. Withdrawal symptoms make it difficult for a person to stop taking heroin – they help keep the person hooked. But withdrawal symptoms do not explain why a person becomes a heroin addict in the first place; that fact is explained by the drug's reinforcing effect. Certainly, people do not start taking heroin so that they will become physically dependent on it and feel miserable when they go without it. Instead, they begin taking it because it makes them feel good.

Even though the withdrawal effects of heroin make it difficult to stop taking the drug, these effects alone are not sufficient to keep most people hooked (Baker *et al.*, 2006). In fact, when the cost of the habit gets too high, some addicts who stop taking heroin experience 'cold turkey'. Doing so is not as painful as most people believe; withdrawal symptoms have been described as similar to a bad case of influenza – unpleasant, but survivable. Mood declines – people feel unstable, stressed, anxious and depressed (Baker *et al.*, 2006). After a week or two, when their nervous systems adapt to the absence of the drug, these addicts recommence their habit, which now costs less to sustain. However, addicts do cite a fear of withdrawal symptoms as being one reason why they are motivated to continue taking drugs (the effects of withdrawal from a drug like ethanol, for example, include tremors and convulsions). The strength of withdrawal is not related to the strength of relapse. The reason why people take – and continue to take – drugs such as heroin is that the drugs give them a pleasurable 'rush'; in other words, the drugs have a reinforcing effect on their behaviour.

There are two other lines of evidence that contradict the assertion that drug addiction is caused by physical dependence. First, some potent drugs, including cocaine, do not produce physical dependence. That is, people who take the drug do not show tolerance; and if they stop, they do not show any withdrawal symptoms. As a result, experts believed for many years that cocaine was a relatively innocu-

ous drug, not in the same league as heroin. Obviously, they were wrong; cocaine is even more addictive than heroin. As a matter of fact, laboratory animals who can press a lever and give themselves injections of cocaine are more likely to die than are those who can give themselves injections of heroin. Secondly, some drugs produce physical dependence (tolerance and withdrawal symptoms) but are not abused (Jaffe, 1985).

The reason why they are not abused is that they do not have reinforcing effects on behaviour – they are just not any fun to take. People take drugs because they enjoy them. And the more they like them, the more excessive their drug-taking (Ahmed, 2005). Studies in rodents suggest that the greater the access to cocaine, the greater the rat's drug-seeking behaviour (Vanderschuren and Everitt, 2004). A three month exposure to a drug led to rats being unable *not* to seek drugs, even when they were punished for doing so (Deroche-Gamonet *et al.*, 2004). Rats exposed to heroin daily had lower and more stable levels of drug intake than those who were exposed to it for 24 hours (Kenny *et al.*, 2006). As the drug-taking increases, the excitability of the reward systems, reflected in brain activation and neurotransmitter release, decreases. Therefore, more of the drug is needed to resume this level of excitability (Kenny, 2007). Similarly, neuroimaging data from adults has shown that activation in the insula, prefrontal cortex and anterior cingulate cortex is associated with urges to take a drug, whether cigarettes, heroin, alcohol or cocaine (Naqvi and Bechara, 2008). Ultimately drugs 'work' by stimulating the release of dopamine from the brain stem tegmental area (Naqvi and Bechara, 2008).

A study by Kirby *et al.* (1999) tested a specific model of substance abuse which suggests that the value of a reward is affected by the length of time between the promise of that reward and actually obtaining it. For example, if a reward was promised a long time in the future, then its present value would be small. If a competing reward was made available sooner, this would be chosen over the other. This is called delay-discounting. This is relevant to drug use because the delay-discounting model of impulsive behaviour would suggest that impulsive individuals would choose a smaller, immediate reward rather than wait for a larger reward promised after a longer delay.

Kirby *et al.* put this hypothesis to the test in an experiment in which 56 heroin addicts and 60 drug-free controls had to make a choice between either receiving an \$11–80 reward available immediately, or receiving a larger reward (\$25–85) after a delay from one week to six months. There was a one in

Controversies in Psychological Science – *Continued*

six chance of winning the reward in each trial. The researchers found that heroin addicts were twice as likely as controls to discount delayed rewards in favour of immediate ones. They suggest that these findings are important for treatment interventions that focus on the consequences of drug abuse (such as going to jail, losing a family, failing to get a job, developing HIV) because such consequences may not be particularly salient to the addict. Programmes which provide rewards after short periods of abstinence, Kirby *et al.* argue, should be more effective in preventing drug use because the reward would be immediate and not delayed.

Conclusion

The most important lesson we can learn from the misguided distinction between ‘physiological’ and ‘psychological’ addiction is that we should never underestimate the importance of psychological factors. Given that behaviour is controlled by circuits of neurons in the brain, even psychological factors involve physiological mechanisms. People often pay more attention to physiological symptoms than psychological ones – they consider them more real. But behavioural research indicates that an exclusive preoccupation with physiology can hinder our understanding of the causes of addiction.

Stimulants

Several categories of drugs stimulate the central nervous system and thus activate behaviour. Because of the effects some of these drugs have on the neural circuits involved in reinforcement (reward), they tend to be abused. Two popular stimulant drugs, amphetamine and cocaine, have almost identical effects: they inhibit the reuptake of dopamine and thus strengthen the effectiveness of synapses that use this transmitter substance. As you will see in Chapter 13, reinforcing stimuli – such as food for a hungry animal, water for a thirsty one, or sexual contact for a sexually aroused one – exert their behavioural effects largely by increasing the activity of a circuit of dopamine-secreting neurons. Thus, amphetamine and cocaine mimic the effects of reinforcing stimuli. Free-base cocaine (crack) is particularly addictive. The drug has an immediate effect on the reuptake of dopamine and produces such a profound feeling of euphoria and pleasure that the person wants to repeat the experience again and again.

Cocaine and amphetamine, if taken in large enough doses for a few days, can produce the symptoms of paranoid schizophrenia – a serious mental disorder described in Chapter 18. Heavy users of these drugs suffer from hallucinations and their thoughts become confused and difficult to control. They may come to believe that they are being attacked or plotted against. In fact, an experienced clinician cannot distinguish the drug-induced symptoms from those that occur in people who really have the psychosis. This fact has suggested to some investigators that schizophrenia may be caused by overactivity of dopamine-secreting synapses.

Opiate drugs have both excitatory and inhibitory effects on behaviour. All of these effects occur because

these drugs mimic the effects of the body’s own opioid neuromodulators: they stimulate opioid receptors located on neurons in various parts of the brain. The inhibitory effects include analgesia (reduced sensitivity to pain), hypothermia (lowering of body temperature) and sedation. The pain reduction is accomplished by neurons in the midbrain, the hypothermia by neurons in the hypothalamus and the sedation by neurons in the medulla. A fatal overdose of an opiate kills its victim by inhibiting the activity of circuits of neurons in the medulla that control breathing, heart rate and blood pressure. But it is the excitatory effects of opiates that induce people to abuse them. Some opioid receptors are located on dopamine-secreting neurons involved in reinforcement (reward). When a person takes an opiate such as heroin, the activity of these neurons produces feelings of euphoria and pleasure, similar to those produced by cocaine or amphetamine. These excitatory effects, and not the inhibitory ones, are responsible for addiction.

Drugs and altered states of consciousness

Throughout history, people have enjoyed changing their consciousness now and then by taking drugs, fasting, meditating or chanting. Even children enjoy spinning around and making themselves dizzy – presumably for the same reasons. Chemicals found in several different plants produce profound changes in consciousness. Behaviourally, these changes are difficult to specify. Large doses of drugs such as marijuana or LSD tend to sedate laboratory animals, but the animals give no sign of having their consciousness altered. Only humans can describe the consciousness-altering effects of the drugs. In *Doors of*

Perception, Aldous Huxley described the intense vision he experienced on looking at a bowl of flowers. The experience was induced by a synthetic form of the drug mescaline (derived from cactus peyote), which has been used by shamans for centuries as religious communion.

[Plato] could never, poor fellow, have seen a bunch of flowers shining with their own inner light and all but quivering under the pressure of the significance with which they were charged; could never have perceived that what rose and iris and carnation so intensely signified was nothing more, and nothing less, than what they were – a transience that was yet eternal life, a perpetual perishing that was at the same time pure Being, a bundle of minute, unique particulars in which, by some unspeakable and yet self-evident paradox, was to be seen the divine source of all existence. I continued to look at the flowers, and in their living light I seemed to detect the qualitative equivalent of breathing – but of a breathing without returns to a starting point, with no recurrent ebbs but only a repeated flow from beauty to heightened beauty, from deeper to ever deeper meaning.

Source: Aldous Huxley (1954), *The Doors of Perception*.

More famously, Samuel Taylor Coleridge wrote *Kubla Khan* after a drug-taking session:

In the Summer of the year 1797, the Author . . . had retired to a lonely farmhouse between Porlock and Linton, on the Exmoor confines of Somerset and Devonshire. In consequence of a slight indisposition, an anodyne had been prescribed, from the effects of which he fell asleep in his chair at the moment he was reading. The Author continued for about three hours in a profound sleep, at least of the external senses, during which time he has the most vivid confidence, that he could not have composed less than from two hundred to three hundred lines. . . on awaking he appeared to himself to have a distinct recollection of the whole, and . . . instantly and eagerly wrote down the lines that are here preserved.

Source: Samuel Taylor Coleridge, prefatory note to *Kubla Khan* (1797).

Drugs can affect consciousness in several different ways. We have the clearest understanding of one category of drugs: those that affect synapses that use a transmitter substance called serotonin. Serotonin plays an important role in the control of dreaming. Normally, we dream only

when we are asleep, in a particular stage called REM sleep (because of the rapid eye movements that occur then). During the rest of the day, circuits of serotonin-secreting neurons inhibit the mechanisms responsible for dreaming, thus preventing them from becoming active. Drugs such as LSD, psilocybin and dimethyltryptamine (DMT) suppress the activity of serotonin-secreting neurons, permitting dream mechanisms to become active. As a result, hallucinations occur. These hallucinations are often interesting and even awe-inspiring, but sometimes produce intense fear and anxiety.

Not all hallucinogenic drugs interfere with serotonin-secreting synapses. Cocaine and amphetamine, which affect dopamine-secreting synapses, also produce hallucinations. However, the hallucinations produced by cocaine and amphetamine take some time to develop, and they are primarily auditory. LSD-induced hallucinations take place immediately and are primarily visual, as dreams are. The two types of hallucination undoubtedly occur for different reasons.

Aldous Huxley.

Source: Hulton Archive/Getty Images.

On the advice of the novelist Aldous Huxley, Timothy Leary, then a clinical psychologist at Harvard, took his first acid trip and reported its effect. He took lysergic acid (LSD), a powerful psychotropic drug derived from a fungus (ergot) and synthesised in the laboratory in 1930.

Source: Ben Martin/Time Life Pictures/Getty Images.

Tetrahydrocannabinol (THC), the active ingredient in marijuana, exerts its behavioural effects by stimulating THC receptors, specific neuromodulator receptors present in particular regions of the brain. THC produces analgesia and sedation, stimulates appetite, reduces nausea caused by drugs used to treat cancer, relieves asthma attacks, decreases pressure within the eyes in patients with glaucoma, and reduces the symptoms of certain motor disorders. On the other hand, THC interferes with concentration and memory, alters visual and auditory perception, and distorts perceptions of the passage of time (Howlett, 1990).

Drug classification

In the UK, controlled substances (drugs) are classified as either A, B or C. Class A drugs are those most likely to cause harm and include LSD, heroin and cocaine. Class B drugs are considered to be not as harmful and include amphetamines, Ritalin and cannabis. In the US, cannabis is deemed a Schedule 1 substance – it has the potential to be ‘abused’ and has no medical use. Class C drugs include ketamine, painkillers and various other drugs that require a prescription. Cannabis or marijuana is one of the most commonly used, if not the most commonly used prohibited drug in existence. According to one recent UK survey, marijuana was the most commonly experienced drug (87 per cent), followed by cocaine at 35 per cent (Observer Drugs, 2008). The 2006 *National Survey on Drug Use and Health* in the US estimated that 98 million Americans over 12 years of age had tried it at least once (the figure represents 40 per cent of the population). Between 71 and 77 per cent of US prisoners claimed to have used the drug at some point (Bureau of Justice Statistics, 2006). As the International Perspective below shows, it is also commonly used by 18–25-year-olds.

The psychology of cannabis use – An international perspective

Cannabis is a drug derived from the plant genus *Cannabis* and comprises around 400 compounds. The most potent of these is tetrahydrocannabinol (THC), one of the 60 cannabinoids the plant contains, and a typical joint will contain between 150 and 300 mg of THC. Surveys of UK universities show that around 50–60 per cent of respondents report having used cannabis (Ashton, 2001). A study of 1,261 Australian adolescents aged between 13 and 17 years found that a quarter of the sample reported having used cannabis and this use increased with age (Rey *et al.*, 2002). A glance at Figure 4.41 shows that people who are heavy users of cannabis also

report higher levels of depression than do light users (Rey *et al.*, 2002). While cannabis has been used recreationally for centuries to elevate mood, recent controversy has surrounded the use of cannabis to alleviate pain. One reason why the drug may be inappropriate is that it may have psychological consequences that could be either harmful or dangerous.

About 50 per cent of THC in a joint of cannabis is inhaled through smoke (the amount is less when taken orally). Because THC has a half-life of seven days, it can remain vital for up to 30 days which means that traces of cannabis can be detected in the body up to a month after inhalation/ingestion.

The psychology of cannabis use – *Continued*

Figure 4.41 The relationship between cannabis use and depression scores in over 4,000 Australian adolescents.

Source: Rey, J.M., Sawyer, M.G., Raphael, B., Patton, G.C. and Lynskey, M., Mental health of teenagers who use cannabis. *British Journal of Psychiatry*, 2002, 180, 216–21, reprinted by permission of the Royal College of Psychiatrists.

The behavioural effects of cannabis are varied. It can stimulate appetite, reduce anxiety and create psychedelic experiences. Doses of THC as low as 2.5 g in herbal cigarettes can produce a feeling of intoxication and a reduction in anxiety (Ashton, 2001). It can also produce panic attacks and paranoia. Its effects on psychomotor performance are similar to those of alcohol: behaviour becomes uncoordinated and reaction time slows. In many European countries, the second most common substance found in the bodies of drivers involved in fatal accidents or in drivers who drive poorly is cannabis. The majority of those who use cannabis show no evidence of excessive or illegal alcohol consumption. Similar performance decrements are seen in pilots (even pilots who are regular cannabis users) 24 hours after cannabis intake.

The association between cannabis use and the development of psychotic disorders, such as schizophrenia, is a controversial one. Many studies have reported that psychotic symptoms can occur but that these are short-lived; few studies have followed up such patients, however, to examine the long-term consequences of cannabis use. A study of 535 Danish patients who had been treated for cannabis-induced psychotic symptoms (Arendt *et al.*, 2005) found that 44 per cent of cases showed schizophrenia-type symptoms. Some 77

per cent of the sample reported new psychotic symptoms. Approximately 47 per cent of the sample received a diagnosis of cannabis-induced schizophrenia a year after seeking treatment for cannabis-related psychosis.

The authors caution, however, that there was a significant delay in the majority of patients in the development of schizophrenia-type symptoms. They also note that they were unable to control for any other type of substance use during the follow-up period. Between 40–51 per cent of patients with schizophrenia have used cannabis (Borsani *et al.*, 2002; Barnett *et al.*, 2007) and there appears to be an association between decreased grey matter and cannabis use in schizophrenia patients who are cannabis users and have had their first episode (Bangalore *et al.*, 2008). (In psychiatry, an episode is one serious experience or appearance of a disorder.)

Recent debate in some European countries has centred on the therapeutic effects of cannabis. Cannabis was a drug recommended for various ills as long as 5,000 years ago in China. A review by Robson (2001) describes how, historically, cannabis mixed with wine was recommended as a surgical analgesic. In nineteenth-century Britain, the use of cannabis for the alleviation of illness was common. Even Queen Victoria's physician lauded cannabis's ability to relieve physical ailments.

There is some evidence for cannabis's therapeutic effects. Patients with cancer frequently report a reduction in the feeling of nausea that is induced by chemotherapy (Robson, 2001). Questionnaire studies of British and American multiple sclerosis sufferers show that cannabis smokers report reduced muscle spasm, increased pain relief, improvement in balance and an improvement in memory. Since 2001, however, the US Congress has ruled that the drug has no medical value.

Cannabis use is legal in some European countries but in restricted contexts. Danish law states that cannabis is illegal but has a provision that condones possession or sale of up to 30 g of cannabis (MacCoun and Reuter, 2001). This level, set in 1976, was reduced to 5 g in 1985. Around 1,200 coffee shops sell cannabis in the Netherlands and operate according to strict guidelines (such as no advertising, no public disturbances, no sales to minors, and so on).

Because of cannabis's status as an illegal drug in some European countries, especially the United Kingdom, much debate has surrounded the legitimacy of this position, with a number of doctors and patients questioning the decision to restrict or prohibit its use.

Chapter review

The brain and its components

- The brain has two major functions: to control behaviour and to regulate the body's physiological processes.
- The central nervous system (CNS) consists of the spinal cord and the three major divisions of the brain: the brain stem, the cerebellum and the cerebral hemispheres. The cerebral cortex, which covers the cerebral hemispheres, is wrinkled by fissures and gyri.
- The brain communicates with the rest of the body through the peripheral nervous system, which includes the spinal nerves and cranial nerves.
- The basic element of the nervous system is the neuron. Neurons are assisted in their tasks by glia, which provide physical support, aid in the development of the nervous system, provide neurons with chemicals they need, remove unwanted chemicals, provide myelin sheaths for axons and protect neurons from infection.
- One neuron communicates with another (or with muscle or gland cells) by means of synapses. A synapse is the junction of the terminal button of the presynaptic neuron with the membrane of the postsynaptic neuron.
- Synaptic communication is chemical; when an action potential travels down an axon, it causes a transmitter substance to be released by the terminal buttons.
- An action potential consists of a brief change in the electrical charge of the axon, produced by a brief entry of positively charged sodium ions into the axon followed by a brief exit of positively charged potassium ions.
- Ions enter the axon through ion channels, and ion transporters eventually restore the proper concentrations of ions inside and outside the cell.
- Molecules of the transmitter substance released by terminal buttons either excite or inhibit the firing of the postsynaptic neuron. The combined effects of excitatory and inhibitory synapses on a particular neuron determine the rate of firing of that neuron.
- Neuromodulators resemble transmitter substances but travel further and are dispersed more widely. They are released by terminal buttons and modulate the activity of many neurons. The best-known neuromodulators are the opioids, which are released when an animal is engaged in essential, meaningful behaviour. The opiates, extracted from the sap of the opium poppy or produced in a laboratory, stimulate the brain's opioid receptors.

Techniques for studying the brain

- Various techniques are available for neuroscientists to investigate brain function. These include experimental lesion, observing the effects of natural or accidental brain damage, recording the electrical activity of the brain or observing its structure or metabolic activity.

- Neuropsychologists study the effects of brain damage on people's behaviour, correlating their behavioural deficits with the location of their lesions. The assessment of cognitive impairment after brain injury is called neuropsychological assessment.
- Neuropsychological rehabilitation refers to a programme of remediation that helps the patient regain some of the function lost through brain injury.
- Techniques used to measure activity of the peripheral nervous system or autonomic nervous system included galvanic skin response (GSR), electrocardiography (ECG) and electromyography (EMG).
- GSR is a measure of arousal indexed by electrodermal response; ECG is a measure of heart rate; EMG is a measure of muscle activity.
- Sophisticated methods of observing brain structure and activity in healthy individuals include computerised tomography (CT), positron emission tomography (PET), magnetic resonance imaging (MRI) and functional magnetic resonance imaging (fMRI).
- CT allows us to view the brain's structure; PET permits researchers to study the neural activity of specific regions of the living human brain. MRI is a measure of brain structure and provides clearer images of the brain's structure than does CT; fMRI is a measure of brain activity.
- Psychophysicists measure the brain's electrical activity using electroencephalography (EEG) and event-related potentials (ERP). Magnetoencephalography (MEG) records changes in magnetic fields generated by neurons.
- Repetitive transcranial magnetic stimulation (rTMS) involves passing a magnetic current over the head and exciting the cortex; this often results in temporary impairment of cognitive function or an alleviation of depressive symptoms.

Control of behaviour

- Anatomically, the cerebral cortex is divided into four lobes: frontal, parietal, occipital and temporal.
- Functionally, the cerebral cortex is organised into five major regions: the three regions of the primary sensory cortex (visual, auditory and somatosensory), the primary motor cortex and the association cortex.
- The association cortex consists of sensory regions that are responsible for perceiving and learning and motor regions that are responsible for planning and acting.
- Visual stimulation is transmitted from the eyes to the brain through the optic nerves, one of the pairs of cranial nerves. The information is sent to the primary visual cortex in the occipital lobe.
- The motor association cortex in the frontal lobe is responsible for planning activity; the primary motor cortex is responsible for initiating movement.

- Somatosensory information is transmitted from the skin to the spinal cord by means of a spinal nerve. It is then sent up through the spinal cord and is relayed to the primary somatosensory cortex.
- Lateralisation refers to whether a function is localised in the left or right hemisphere. The right and left hemispheres are involved with somewhat different functions: the left is superior at reading, speech production and speech comprehension; the right hemisphere is superior for visuospatial ability and recognition of emotion.
- The two cerebral hemispheres are connected by a large bundle of axons called the corpus callosum which allows the hemispheres to transfer information to one another.
- The frontal lobe is concerned with motor functions, planning strategies for action, working memory, emotion and problem-solving. A region of the left frontal cortex (Broca's area) is specialised for the control of speech.
- Somatosensory information is processed by the parietal lobe, visual information by the occipital and lower temporal lobes, and auditory information by the upper temporal lobe. Other functions of these lobes are related to these perceptual processes; for example, the parietal lobes are concerned with perception of space and knowledge about the body as well as mental arithmetic.

Control of internal functions and automatic behaviour

- The more primitive parts of the brain control homeostasis and species-typical behaviours. The brain stem, which consists of the medulla, the pons and the midbrain, contains neural circuits that control vital physiological functions and produce automatic movements such as those used in locomotion, fighting and sexual behaviour.
- The cerebellum assists the cerebral cortex in carrying out movements; it coordinates the control of muscles, resulting in smooth movements. It also regulates postural adjustments and appears to play some role in cognition and reading impairment.
- The thalamus participates in the control of movement and relays sensory information to the cerebral cortex.
- The hypothalamus receives sensory information from sense receptors elsewhere in the body and also contains its own specialised receptors, such as those used to monitor body temperature. It controls the pituitary gland, which, in turn, controls most of the endocrine glands of the body, and it also controls the internal organs through the autonomic nervous system.
- Hormones, secreted by endocrine glands, are chemicals that act on hormone receptors in target cells and produce physiological reactions in these cells. The hypothalamus can control homeostatic processes directly and automatically through its control of the pituitary gland and the autonomic nervous system, or it can cause neural circuits in the cerebral cortex to execute more complex, learned behaviour.
- The amygdala and the hippocampus are both located within the temporal lobe, specifically within the limbic system. The amygdala is involved in various emotional processes including fear conditioning.
- The hippocampus is involved in learning and memory; people with damage to this structure can recall old memories but are unable to learn anything new.

Drugs and behaviour

- Many chemicals found in nature have behavioural effects, and many more have been synthesised in the laboratory.
- Drugs can facilitate or interfere with synaptic activity. Facilitators include drugs that cause the release of a transmitter substance (such as the venom of the black widow spider); drugs that directly stimulate postsynaptic receptor molecules, thus duplicating the effects of the transmitter substance itself (such as nicotine); and drugs that inhibit the reuptake of a transmitter substance (such as amphetamine and cocaine).
- Drugs that interfere with synaptic activity include those that inhibit the release of a transmitter substance (such as botulinum toxin) and those that block receptor molecules (such as curare).
- There are several major categories of drugs that affect behaviour. Alcohol, barbiturates and tranquillisers depress the activity of the brain by stimulating various types of receptor molecule.
- Amphetamine and cocaine stimulate the brain primarily by retarding the reuptake of dopamine. The opiates duplicate the effects of the brain's opioids, decreasing sensitivity to pain and producing intensely enjoyable feelings of euphoria and pleasure. LSD, psilocybin and related drugs inhibit the activity of synapses that use serotonin.
- The hallucinogenic effects of these drugs may be related to dreaming, which is controlled by circuits of serotonin-secreting neurons.
- The physiological effects of marijuana are produced by a compound called THC which stimulates receptors that are normally activated by a natural neuromodulator called anandamide.
- Psychotherapeutic drugs include those that reduce the symptoms of schizophrenia and those that relieve depression. Anti-schizophrenic drugs block dopamine receptors, and antidepressant drugs generally facilitate the action of serotonin.
- Opiates produce tolerance and withdrawal symptoms, which make their habitual use increasingly expensive and make quitting more difficult.
- The primary reason for addiction is the reinforcing effect, not the unpleasant symptoms produced when an addict tries to quit. Tolerance appears to be produced by homeostatic mechanisms that counteract the effects of the drug.

Suggestions for further reading

Psychobiology and neuroscience – general reading

- Carlson, N.R. (2010) *Physiology of Behaviour* (10th edn). Boston: Allyn & Bacon.
- DeVries, A.C. and Nelson, R.J. (2009) *Current Directions in Biological Psychology*. Boston: Allyn & Bacon.
- Martin, G.N. (2003) *Essential Biological Psychology*. London: Arnold.
- Martin, G.N. (2006) *Human Neuropsychology* (2nd edn). Harlow: Pearson Education.
- Toates, F. (2006) *Biological Psychology* (2nd edn). Harlow: Pearson Education.
- Wickens, A. (2009) *Introduction to Biopsychology* (3rd edn). Harlow: Pearson Education.

These are good, comprehensive introductions to the physiology of behaviour, the relationship between human brain activity, structure and function, and general psychobiology.

The development of neuroscience

- Finger, S. (2000) *Minds behind the brain*. Oxford: Oxford University Press.
- Kandel, E.R. and Squire, L.R. (2000) Neuroscience: Breaking down scientific barriers to the study of brain and mind. *Science*, 290, 1113–20.

Two very good items on the history of neuroscience.

Localisation and lateralisation of function

- Cowey, A. (2001) Functional lateralization of the brain. *The Psychologist*, 14, 5, 250–54.
- Springer, S.P. and Deutsch, G. (2001) *Left Brain, Right Brain* (5th edn). New York: W.H. Freeman.
- Excellent accounts of lateralisation of function. Springer and Deutsch's book is probably the best book reviewing functional lateralisation.

Basic neuroanatomy and neurophysiology

- England, M.A. and Wakeley, J. (1991) *A Colour Atlas of the Brain and Spinal Cord*. Aylesbury: Wolfe.
- Kosslyn, S.M., Cacioppo, J.T., Davidson, R.J., Hugdahl, K., Lovallo, W.R., Spiegel, D. and Rose, R. (2002) Bridging psychology and biology. *American Psychologist*, 57, 5, 341–51.
- Swanson, L.W. (2002) *Brain Architecture: Understanding the basic plan*. Oxford: Oxford University Press.

A number of books cover the neuroanatomy and neurophysiology of the brain and the items listed here cover most of these two topics and do it well.

Methods

- Andreassi, J.L. (2001) *Psychophysiology* (4th edn). Hillsdale, NJ: Lawrence Erlbaum Associates.
- Beaulieu, A. (2002) A space for measuring mind and brain: Interdisciplinarity and digital tools in the development of brain mapping and functional imaging, 1980–1990. *Brain and Cognition*, 49, 13–33.
- Cabeza, R. and Nyberg, L. (1997) Imaging cognition: An empirical review of PET studies with normal subjects. *Journal of Cognitive Neuroscience*, 9, 1, 1–26.
- Cabeza, R. and Nyberg, L. (2000) Imaging cognition II: An empirical review of 275 PET and fMRI studies. *Journal of Cognitive Neuroscience*, 12, 1, 1–47.
- Grafton, S.T., Sinnott-Armstrong, W.P., Gazzaniga, S.I. and Gazzaniga, M.S. (2007) Brain scans go legal. *Scientific American Mind*, 17, 6, 30–37.
- Raichle, M.E. (2008) A brief history of human brain mapping. *Trends in Neurosciences*, 32, 2, 118–26.

Andreassi's book is the most well-known general introduction to psychophysiology. Raichle and Beaulieu's articles review the development of the techniques. The Cabeza and Nyberg articles review, and give a more critical account of, the contribution of PET and fMRI studies to neuropsychology.

Drugs and behaviour

- Baker, T.B., Japuntich, S.J., Hogle, J.M., McCarthy, D.E. and Curtin, J.J. (2006) Pharmacologic and behavioural withdrawal from addictive drugs. *Current Directions in Psychological Science*, 15, 5, 232–36.
- Crombag, H.S. and Robinson, T.E. (2004) Drugs, environment, brain and behavior. *Current Directions in Psychological Science*, 13, 3, 107–11.
- Grilly, D.M. (2006) *Drugs and Human Behaviour* (5th edn). Boston: Allyn & Bacon.
- Hobson, J.A. (2005) *The Dream Drugstore: Chemically altered states of consciousness*. Cambridge, MA: MIT Press.
- Julien, R.M.A. (2007) *A Primer of Drug Action* (11th edn). San Francisco: W.H. Freeman.
- Naqvi, N.H. and Bechara, A. (2008) The hidden island of addiction: the insula. *Trends in Neurosciences*, 32, 1, 56–67.
- Parrott, A., Morinian, A., Moss, M. and Scholey, A. (2003) *Understanding Drugs and Behaviour*. Chichester: Wiley.
- Robinson, T.E. and Berridge, K.C. (2003) Addiction. *Annual Review of Psychology*, 54, 25–54.

Julien's book is probably the best introductory book on drugs and the biochemistry of drug use available. Parrott et al.'s book focuses not only on the psychopharmacology of drug use – from tobacco to ecstasy – but on the health and social consequences of drug use. The other items give very good overviews of drugs and addiction.

Sensation

You really can smell fear, say scientists

James Randerson, Science correspondent

The smell of fear, one of the most terrible clichés of pulp fiction, is actually founded in fact, scientists claim today.

People can unconsciously detect whether someone is stressed or scared by smelling a chemical pheromone released into their sweat, according to researchers who have investigated the underarm secretions of petrified skydivers.

The team found that the smell of fear triggered a heightened response in brain regions associated with fear when inhaled by volunteers in a brain scanner. The research suggests that, like many animal species, humans can detect and subconsciously respond to pheromones released by other people.

WHAT YOU SHOULD BE ABLE TO DO AFTER READING CHAPTER 5

- Be aware of the difference between sensation and perception.
- Describe the processes involved in sensation, such as transduction and sensory coding.
- Describe each of the sense organs and how they function.
- Think of reasons why such senses have evolved.

QUESTIONS TO THINK ABOUT

- How many senses do we have?
- Why did the senses evolve?
- Are some senses more important to us than others?
- Which sense do we use least (or think we do) and why?
- Do the different senses function along similar lines, using similar mechanisms?
- Is the importance of a sense reflected in the amount of brain capacity needed to support it?
- Why are some animals more reliant on some senses than others?
- Are there some stimuli that we sense, even though we are not consciously aware of sensing them?
- How can we tell the difference between the sight (and sound) of a bird and a plane, or between the smell of chocolate and gas?

Explore the accompanying videos, simulations, and animations on MyPsychLab. This chapter includes activities on: Normal vision, nearsightedness, farsightedness • Perceiving sound • The olfactory system • Manipulating your sense of smell • Check your understanding and prepare for your exams using the multiple choice, short answer and essay practice tests also available.

Sensation and behaviour

Our senses are the means by which we experience the world; everything we learn is detected by sense organs and transmitted to our brains by sensory nerves. Without sensory input, a human brain would be utterly useless; it would learn nothing, think no thoughts, have no experiences and control no behaviours.

Vision, to most people, is the most important sense modality. Through it we recognise family and friends, see their facial expressions and gestures, learn to read, perceive objects that are beyond our reach, and find our way around our environment. It provides us with information about the size, shape, colour and movement of objects nearby and at a distance. Through vision, we receive some of our most powerful aesthetic experiences, in the form of art, a sexual partner and other beautiful images.

The other senses also contribute to the richness of experience. Because of the role that speech plays in human culture, audition is important for social behaviour and communication. Audition and vision provide information about distant events, as does the sense of smell, which can tell us about sources of aromatic molecules before we can see or hear that source. The other senses deal with immediate and proximal events such as the taste of our favourite food or the touch of someone we love. The body senses are closely tied to our own movements. When we feel an object, the experience is active, not passive; we move our hands over it to determine its shape, texture and temperature. And information from specialised organs in the inner ear and from receptors in the muscles and joints is generated by our own movements. This information helps us to maintain our balance as we engage in our everyday activities.

Sensory processing

Experience is traditionally divided into two classes: sensation and perception. Most psychologists define **sensation** as the detection of simple properties of stimuli, such as brightness, colour, warmth and sweetness. **Perception** is the detection of objects (both animate and inanimate), their locations, their movements and their backgrounds. According to these definitions, seeing the colour red is a sensation, but seeing a red apple is a perception. Similarly, seeing a movement is a sensation, but seeing a cricket ball coming towards us and realising that we will have to move to the left to catch it is a perception. Psychologists used to believe that perceptions depended heavily on learning whereas pure sensations involved

innate, 'prewired' physiological mechanisms. However, neither behavioural nor physiological research has been able to establish a clear boundary between 'simple' sensations and 'complex' perceptions. Research indicates that experience is essential to the development of some of the most elementary features of sensory systems (Blakemore and Mitchell, 1973). This is called 'functional validation' – the notion whereby the nervous system needs to be stimulated during development in order for it to develop properly.

According to tradition, we have five senses: vision (seeing), audition (hearing), gustation (tasting), olfaction (smelling) and somatosensation (touching). In fact, we have several more. The somatosensory system, for example, includes separate components that are able to detect touch, warmth, coolness, vibration, physical damage (pain), head tilt, head movement, limb movement, muscular contraction and various events occurring within our bodies (Kandel *et al.*, 1995). Whether we choose to call each of these components 'senses' is a matter of terminology.

Transduction

Sense organs detect the presence of environmental stimuli provided by light, sound, odour, taste or mechanical contact. This information is transmitted to the brain through neural impulses – action potentials carried by the axons in sensory nerves. The task of the sense organs is to transmit signals to the brain that are coded in such a way as to faithfully represent the events that have occurred in the environment. The task of the brain is to analyse this information and reconstruct what has occurred.

Transduction (literally, 'leading across') is the process by which the sense organs convert energy from environmental events into neural activity. Each sense organ responds to a particular form of energy given off by an environmental stimulus and translates that energy into neural firing to which the brain can respond. The means of transduction are as diverse as the kinds of stimuli we can perceive. In most senses, specialised neurons called receptor cells release chemical transmitter substances that stimulate other neurons, thus altering the rate of firing of their axons. In the somatosenses ('body senses'), dendrites of neurons respond directly to physical stimuli without the intervention of specialised **receptor cells**. However, some of these neurons do have specialised endings that enable them to respond to particular kinds of sensory information. Table 5.1 summarises the types of transduction accomplished by our sense organs.

Sensory coding

As you saw in Chapter 4, nerves are bundles of axons which can do no more than transmit action potentials. These action potentials are fixed in size and duration; they

Table 5.1 The types of transduction accomplished by the sense organs

Location of sense organ	Environmental stimuli	Energy transduced
Eye	Light	Radiant energy
Ear	Sound	Mechanical energy
Vestibular system	Tilt and rotation of head	Mechanical energy
Tongue	Taste	Recognition of molecular shape
Nose	Odour	Recognition of molecular shape
Skin, internal organs	Touch	Mechanical energy
	Temperature	Thermal energy
	Vibration	Mechanical energy
	Pain	Chemical reaction
Muscle	Stretch	Mechanical energy

cannot be altered. Thus, different stimuli cannot be translated into different types of action potential. Yet we can detect an enormous number of different stimuli with each of our sense organs. For example, we are capable of discriminating among approximately 7.5 million different colours. We can also recognise touches to different parts of the body, and we can further discriminate the degree of pressure involved and the sharpness or bluntness, softness or hardness, and the temperature of the object touching us. We can detect over 10,000 different odours. If action potentials cannot be altered, how do the sense organs tell the brain that a red apple or a yellow lemon has been seen or that the right hand is holding a small, cold object or a large, warm one? The answer is that the information from the sense organs must be coded in the activity of axons carrying information from the sense organs to the brain.

A code is a system of symbols or signals representing information. Spoken English, written French, semaphore signals, magnetic fields on a recording tape, and the electrical zeros and ones in the memory of a computer are all examples of codes. As long as we know the rules of a code, we can convert a message from one medium to another without losing any information. Although we do not know the precise rules by which the sensory systems transmit information to the brain, we do know that they take two general forms: anatomical coding and temporal coding.

Anatomical coding

Since the early 1800s, when Johannes Müller formulated his doctrine of specific nerve energies (discussed in Chapter 1), we have known that the brain learns what is happening through the activity of specific sets of neurons. Sensory organs located in different places in the body send their information to the brain through different nerves. Because the brain has no direct information about the physical energy impinging on a given sense organ, it uses **anatomical coding** to interpret

the location and type of sensory stimulus according to which incoming nerve fibres are active. For example, if you rub your eyes, you will mechanically stimulate the light-sensitive receptors located there. This stimulation produces action potentials in the axons of the nerves that connect the eyes with the brain (the optic nerves). The visual system of the brain has no way of knowing that the light-sensitive receptors of the eyes have been activated by an unnatural stimulus. As a result, the brain acts as if the neural activity in the optic nerves was produced by light – so you see stars and flashes. Experiments performed during surgery have shown that artificial stimulation of the nerves that convey taste produces a sensation of taste, electrical stimulation of the auditory nerve produces a sensation of a buzzing noise, and so forth (Calvin and Ojemann, 1994).

Forms of anatomical coding distinguish not only between the sense modalities themselves, but also between stimuli of the same sense modality. Sensory coding for the body surface is anatomical: different nerve fibres serve different parts of the skin. Thus, we can easily discriminate between a touch on the arm and a touch on the knee. As you saw in Chapter 4, the primary somatosensory cortex contains a neural map of the skin. Receptors in the skin in different parts of the body send information to different parts of the primary somatosensory cortex. Similarly, the primary visual cortex maintains a map of the visual field.

Temporal coding

Temporal coding is the coding of information in terms of time. The simplest form of temporal code is rate. By firing at a faster or slower rate according to the intensity of a stimulus, an axon can communicate quantitative information to the brain. For example, a light touch to the skin can be encoded by a low rate of firing, and a more forceful touch by a high rate. Thus, the firing of a particular set of neurons (an anatomical code) tells where the body is being touched; the rate at which these neu-

rons fire (a temporal code) tells how intense that touch is. As far as we know, all sensory systems use rate of firing to encode the intensity of stimulation.

Psychophysics

Psychophysics is the systematic study of the relation between the physical characteristics of stimuli and the sensations they produce (the ‘physics of the mind’). To study perceptual phenomena, scientists had to find reliable ways to measure people’s sensations. Two of these methods are the just-noticeable difference and the procedures of signal detection theory.

The principle of the just-noticeable difference

Ernst Weber (1795–1878), a German anatomist and physiologist, investigated the ability of humans to discriminate between various stimuli. He measured the **just-noticeable difference (jnd)** – the smallest change in the magnitude of a stimulus that a person can detect. He discovered a principle that held true for all sensory systems: the jnd is directly related to the magnitude of that stimulus. For example, when he presented subjects with two metal objects and asked them to say whether they differed in weight, the subjects reported that the two weights felt the same unless they differed by a factor of 1 in 40. That is, a person could just barely distinguish a 40 g weight from a 41 g weight, an 80 g weight from an 82 g weight, or a 400 g weight from a 410 g weight. Psychologically, the difference between a 40 g weight and a 41 g weight is equivalent to the difference between an 80 g weight and an 82 g weight: 1 jnd. Different senses had different ratios. For example, the ratio for detecting differences in the brightness of white light is approximately 1 in 60. These ratios are called **Weber fractions**.

Gustav Fechner (1801–87), another German physiologist, used Weber’s concept of the just-noticeable difference to measure people’s sensations. Assuming that the jnd was the basic unit of a sensory experience, he measured the absolute magnitude of a sensation in jnds. Imagine that we want to measure the strength of a person’s sensation of light of a particular intensity. We seat the subject in a darkened room facing two discs of frosted glass, each having a light bulb behind it; the brightness of the light bulb is adjustable. One of the discs serves as the sample stimulus, the other as the comparison stimulus, as seen in Figure 5.1.

We start with the sample stimulus and the comparison stimulus turned off completely and increase the brightness of the comparison stimulus until our subject can just

Figure 5.1 The method for determining a just-noticeable difference.

detect a difference. That value is 1 jnd. Then we set the sample stimulus to that intensity (1 jnd) and again increase the brightness of the comparison stimulus just until our subject can again tell them apart. The new value of the comparison stimulus is 2 jnds. We continue making these measurements until our stimuli are as bright as we can make them or until they become uncomfortably bright for our subject. Finally, we construct a graph indicating the strength of a sensation of brightness (in jnds) in relation to the intensity of a stimulus. See Figure 5.2.

Signal detection theory

Psychophysical methods rely heavily on the concept of a **threshold**, the line between not

Figure 5.2 A hypothetical range of perceived brightness (in jnds) as a function of intensity.

perceiving and perceiving. The just-noticeable difference can also be called a **difference threshold**, the minimum detectable difference between two stimuli. An **absolute threshold** is the minimum value of a stimulus that can be detected, that is, discriminated from no stimulus at all. Thus, the first comparison in the experiment just described – using a dark disc as the sample stimulus – measured an absolute threshold. The subsequent comparisons measured difference thresholds.

Even early psychophysicists realised that a threshold was not an absolutely fixed value. When an experimenter flashes a very dim light, a subject may report seeing it on some trials but not on others. By convention, the threshold is the point at which a subject detects the stimulus 50 per cent of the time. This definition is necessary because of the inherent variability of the activity in the nervous system. Even when they are not being stimulated, neurons are never absolutely still; they continue to fire. If a very weak stimulus occurs when neurons in the visual system happen to be quiet, the brain is likely to detect it. But if the neurons happen to be firing, the effects of the stimulus are likely to be lost in the ‘noise’. Work such as that involved in air traffic control illustrates this point, as seen in Figure 5.3. The worker must select only the most relevant information from a background of competing information.

Figure 5.3 According to signal detection theory, we must discriminate between the signal, conveying information, and noise, contributed by background stimuli and random activity of our own nervous systems.

Source: J. Silver/SuperStock.

An alternative method of measuring a person’s sensitivity to changes in physical stimuli takes account of random changes in the nervous system (Green and Swets, 1974). According to **signal detection theory**, every stimulus event requires discrimination between signal (stimulus) and noise (consisting of both background stimuli and random activity of the nervous system).

An example of this might involve an individual seated in a quiet room, facing a small warning light. The experimenter informs the individual that when the light flashes, he or she hears a faint tone one second later. The person’s task is to say yes or no after each flash of the warning light, according to whether or not they hear the tone. At first, the task is easy: some flashes are followed by an easily heard tone; others are followed by silence. As the experiment progresses, however, the tone gets fainter and fainter, until it is so soft that the individual has doubts about how to respond. The light flashes but did the individual really hear a tone or was it just imagined?

Response bias – which, as you read about in Chapter 2, is the tendency to say yes or no when unsure of detecting a stimulus and can have a considerable effect on signal detection. According to the terminology of signal detection theory, hits are saying ‘yes’ when the stimulus is presented; misses are saying ‘no’ when it is presented; correct rejections are saying ‘no’ when the stimulus is not presented; and false alarms are saying ‘yes’ when the stimulus is not presented. Hits and correct rejections are correct responses; misses and false alarms are incorrect responses. Figure 5.4 shows the relationship between these responses. If a person wants to ensure that they are correct when they say yes (because they would feel foolish saying they have

		Judgement	
		‘Yes’	‘No’
Event	Light <i>did</i> flash	Hit	Miss
	Light <i>did not</i> flash	False alarm	Correct rejection

Figure 5.4 Four possibilities in judging the presence or absence of a stimulus.

heard something that is not there), the response bias is to err in favour of making hits and avoiding false alarms, even at the risk of making misses. Alternatively, a response bias might be to err in favour of detecting all stimuli, even at the risk of making false alarms.

This response bias can seriously affect an investigator's estimate of the threshold of detection. A conservative person will appear to have a higher threshold than will someone who does not want to let a tone go by without saying yes. Therefore, signal detection theorists have developed a method of assessing people's sensitivity, regardless of their initial response bias. They deliberately manipulate the response biases and observe the results of these manipulations on the people's judgements.

Imagine, for example, that you are a participant in an experiment and the experimenter promises you a sum of money every time you make a hit (correctly report hearing a tone), with no penalty for false alarms. You would undoubtedly tend to say yes on every trial, even if you were not sure you had heard the tone; after all, you have nothing to lose and everything to gain. In contrast, imagine that the experimenter announced that she would fine you the same amount of money every time you made a false alarm and would give you nothing for making hits. You would undoubtedly say no every time, because you would have everything to lose and nothing to gain: you would be extremely conservative in your judgements.

Now consider your response bias under a number of intermediate conditions. If you receive money for every hit but are also fined half that amount for every miss, you will say yes whenever you are reasonably sure you heard the tone. If you receive a sum of money for every hit but are fined twice as much for each false alarm, you will be more conservative. But if you are sure you heard the tone, you will say yes.

The graph in Figure 5.5 is a **receiver operating characteristic (ROC) curve**, named for its original use in research at the Bell Laboratories to measure the intelligibility of speech transmitted through a telephone system. The curve shows performance when the sound is difficult to detect. If the sound were louder, so that you rarely doubted whether you heard it, you would make almost every possible hit and very few false alarms. The few misses you made would be under the low pay-off condition, when you wanted to be absolutely certain you heard the tone. The few false alarms would occur when guessing did not matter because the fine for being wrong was low or non-existent. The difference between the two curves seen in Figure 5.6 demonstrates that the louder tone is easier to detect. Detectability is measured by the relative distances of the curves from a 45-degree line.

The signal detection method is the best way to determine an individual's sensitivity to the occurrence of a particular stimulus. Note that the concept of threshold is

not used. Instead, a stimulus is more or less detectable. The person decides whether a stimulus occurred, and the consequences of making hits or false alarms can bias this decision: for example, missing the sound of an alarm clock may be more important than missing a telephone

Figure 5.5 A receiver operating characteristic (ROC) curve. The percentage of hits and false alarms in judging the presence of a stimulus under several pay-off conditions.

Figure 5.6 Two ROC curves, obtained by presenting a more discriminable stimulus (orange curve) and a less discriminable stimulus (red curve).

call. Signal detection theory emphasises that sensory experience involves factors other than the activity of the sensory systems, such as motivation and prior experience. Sensitivity to a signal can be influenced by these factors. The fact that you know that you will either be rewarded or financially penalised for making false alarms will influence the care with which you make decisions.

You can see signal detection theory applied in a number of important ways. For example, a radiologist who takes an X-ray has to discriminate between shadows on an X-ray image that indicate disease – the signal – and those that just show differences in the anatomy of the patient – the noise (Parasuraman, 1985). Response bias can occur if the radiologist knows whether the patient has a history of disease or not. The likelihood of detecting a tumour increases or decreases, respectively.

There is a quasi-experiment reported in the literature of factory workers complaining about the weight of large boxes that they had to shift. Carrying these heavy boxes made their backs ache. All the boxes were black. The supervisor, for reasons that you can imagine, decided to replace the black boxes with lighter-coloured ones. When the workers returned to the factory after the weekend and had to move the new boxes, they remarked on how much lighter they were than the black boxes even though the new boxes weighed the same as the old boxes. Why do you think this was?

Vision

The visual system allows us to do many activities that we take for granted: in a quick glance we can recognise what there is to see – people, objects and landscapes – in depth and full colour. Because of the dominance of visual information in our lives, it is perhaps not surprising that vision is our dominant sense.

Light

The eye is sensitive to light. Light consists of radiant energy similar to radio waves. As the radiant energy is transmitted from its source, it oscillates. For example, the antenna that broadcasts the programmes of your favourite FM station may transmit radio waves that oscillate at 88.5 MHz (megahertz, or million times per second). Because radiant energy travels at 297,600 km/s, the waves transmitted by this antenna are approximately 3.3 m apart (297,600 km divided by 88.5 million equals approximately 3.3 m). Thus, the **wavelength** of the signal from the station – the distance between the waves of radiant energy – is 3.3 m (see Figure 5.7).

Figure 5.7 Wavelength versus vibration. Because the speed of light is constant, faster vibrations produce shorter wavelengths.

The wavelength of visible light is much shorter, ranging from 380 to 760 nanometres (a nanometre, nm, is one-billionth of a metre). When viewed by a human eye, different wavelengths of visible light have different colours: for instance, 380 nm light looks violet and 760 nm light looks red.

All other radiant energy is invisible to our eyes. Ultraviolet radiation, X-rays and gamma rays have shorter wavelengths than visible light has, whereas infrared radiation, radar and radio waves have longer wavelengths. The entire range of wavelengths is known as the electromagnetic spectrum; the part our eyes can detect – the part we see as light – is referred to as the visible spectrum, as seen in Figure 5.8.

The definition of the visible spectrum is based on the human visual system. Some other species of animals would define the visible spectrum differently. Bees, for example, can see ultraviolet radiation that is invisible to us. Some plants have taken advantage of this fact and produce flowers that contain dyes that reflect ultraviolet radiation, presenting patterns that attract bees to them. Some snakes (notably, pit vipers such as the rattlesnake) have special organs that detect infrared radiation. This ability enables them to find their prey in the dark by detecting the heat emitted by small mammals in the form of infrared radiation.

The eye and its functions

The eyes are important and delicate sense organs – and they are well protected. Each eye is housed in a bony socket and can be covered by the eyelid to keep out dust and dirt. The eyelids are edged by

Figure 5.8 The electromagnetic spectrum.

eyelashes, which help keep foreign matter from falling into the open eye. The eyebrows prevent sweat on the forehead from dripping into the eyes. Reflex mechanisms provide additional protection: the sudden approach of an object towards the face or a touch on the surface of the eye causes automatic eyelid closure and withdrawal of the head.

Figure 5.9 shows a cross-section of a human eye. The transparent **cornea** forms a bulge at the front of the eye and admits light. The rest of the eye is coated by a tough white membrane called the **sclera** (from the Greek *skleros*, ‘hard’). The **iris** consists of two bands of muscle that control the amount of light admitted into the eye. The brain controls these muscles and thus regulates the size of the pupil, constricting it in bright light and dilating it in dim light. The space immediately behind the cornea is filled with aqueous humour, which simply means ‘watery fluid’. This fluid is constantly produced by tissue behind the cornea that filters the fluid from the blood. In place of blood vessels, the aqueous humour nourishes the

cornea and other portions of the front of the eye; this fluid must circulate and be renewed. If aqueous humour is produced too quickly or if the passage that returns it to the blood becomes blocked, the pressure within the eye can increase and cause damage to vision – a disorder known as glaucoma. Because of its transparency, the cornea must be nourished in this unusual manner. Our vision would be less clear if we had a set of blood vessels across the front of our eyes.

The curvature of the cornea and of the **lens**, which lies immediately behind the iris, causes images to be focused on the inner surface of the back of the eye. Although this image is upside-down and reversed from left to right, the brain interprets this information appropriately. The shape of the cornea is fixed, but the lens is flexible; a special set of muscles can alter its shape so that the eye can obtain focused images of either nearby or distant objects. This change in the shape of the lens to adjust for distance is called **accommodation**.

Normally, the length of the eye matches the refractive power of the cornea and the lens so that the image of the visual scene is sharply focused on the retina. However, for some people these two factors are not matched, and the image on the retina is therefore out of focus. There is a problem with sensing objects at various distances: some have difficulty in focusing on objects in the distance; others have difficulty in focusing on near objects. These people need an extra lens in front of their eyes (in the form of spectacles or contact lenses) to correct the discrepancy and bring the image into focus. People whose eyes are too long (front to back) are said to be near-sighted; they need a concave lens to correct the focus. The image on the right of Figure 5.10 shows what a near-sighted person would see.

People whose eyes are too short are said to be farsighted; they need a convex lens. As people get older, not only does the cornea of the eye begin to yellow and the sensitivity of the rods to decline (Sturr *et al.*, 1997), but the lenses of their

Figure 5.9 A cross-section of the human eye.

Figure 5.10 To a nearsighted person, distant objects are blurry and out of focus.

Source: Image 312427-003 Richard Elliot/Stone/Getty.

eyes also become less flexible and it becomes difficult for them to focus on objects close to them. These people need reading glasses with convex lenses (or varifocals, if they already wear glasses) (see Figure 5.11).

The **retina**, which lines the inner surface of the back of the eye, performs the sensory functions of the eye. Embedded in the retina are over 130 million **photorecep-**

tors – specialised neurons that transduce light into neural activity. The information from the photoreceptors is transmitted to neurons that send axons towards one point at the back of the eye – the **optic disc**. All axons leave the eye at this point and join the optic nerve, which travels to the brain (see Figure 5.12).

Figure 5.11 Lenses used to correct nearsightedness and farsightedness.

Figure 5.12 A view of the back of the eye. The photograph shows the retina, the optic disc and blood vessels.

Source: Courtesy of Douglas G. Mollerstuen, New England Medical Center.

Because there are no photoreceptors directly in front of the optic disc, this portion of the retina is blind. If you have not located your own blind spot, try the demonstration shown in Figure 5.13.

Before the seventeenth century, scientists thought that the lens sensed the presence of light. Johannes Kepler (1571–1630), the astronomer who discovered the true shape of the planets' orbits around the sun, is credited with the suggestion that the retina, not the lens, contained the receptive tissue of the eye. It remained for Christoph Scheiner (another German astronomer) to demonstrate in 1625 that the lens is simply a focusing device. Scheiner obtained an ox's eye from a slaughter-

+

Figure 5.13 A test for the blind spot. With the left eye closed, look at the + with your right eye and move the page back and forth, towards and away from yourself. At about 20 cm, the coloured circle disappears from your vision because its image falls on your blind spot.

house. After carefully peeling the sclera away from the back of the eye, he was able to see an upside-down image of the world through the thin, translucent membrane that remained. As an astronomer, he was familiar with the fact that convex glass lenses could cast images, so he recognised the function of the lens of the eye.

Figure 5.14 shows a cross-section of the retina. The retina has three principal layers. Light passes successively through the ganglion cell layer (front), the bipolar cell layer (middle) and the photoreceptor layer (back). Early anatomists were surprised to find the photoreceptors in the deepest layer of the retina. As you might expect, the cells that are located above the photoreceptors are transparent.

Photoreceptors respond to light and pass the information on by means of a transmitter substance to the bipolar cells, the neurons with which they form synapses. **Bipolar cells** transmit this information to the **ganglion cells**, neurons whose axons travel across the retina and through the optic nerves. Thus, visual information passes through a three-cell chain to the brain: photoreceptor–bipolar; cell–ganglion; and cell–brain.

A single photoreceptor responds only to light that reaches its immediate vicinity, but a ganglion cell can receive information from many different photoreceptors. The retina also contains neurons that interconnect both adjacent photoreceptors and adjacent ganglion cells. The existence of this neural circuitry indicates that some kinds of information processing are performed in the retina.

The human retina contains two general types of photoreceptors: 125 million rods and 6 million cones, so called because of their shapes. **Rods** function mainly in dim light; they are very sensitive to light. **Cones** function when the level of illumination is bright enough to see things clearly. They are also responsible for colour vision. The **fovea**, a small pit in the back of the retina approximately 1 mm in diameter, contains only cones and is responsible for our most detailed vision. When we look at a point in our visual field, we move our eyes so that the image of that point falls directly on the cone-packed fovea.

Farther away from the fovea, the number of cones decreases and the number of rods increases. Up to 100 rods may converge on a single ganglion cell. A ganglion cell that receives information from so many rods is sensitive to very low levels of light. Rods are therefore responsible for our sensitivity to very dim light, but they provide poor acuity.

Transduction of light by photoreceptors

Although light-sensitive sensory organs have evolved independently in a wide variety of animals – from insects to fish to mammals – the chemistry is in essence the same in all species: a molecule derived from vitamin A is the central ingredient in the transduction of the energy of light into neural activity (carrots are said to be good for vision because they contain a substance that the body easily converts to vitamin A). In the absence of light, this molecule is attached to another molecule, a protein. The two molecules together form a **photopigment**. The photoreceptors of the human eye contain four kinds of photopigment (one for rods and three for cones), but their basic mechanism is the same. When a photon (a particle of light) strikes a photopigment, the photopigment splits apart into its two constituent molecules. This event starts the process of transduction. The splitting of the photopigment causes a series of chemical reactions that stimulate the photoreceptor and cause it to send a message to the bipolar cell with which it forms a synapse. The bipolar cell sends a message to the ganglion cell, which then sends one on to the brain, as seen in Figure 5.15.

Intact photopigments have a characteristic colour. **Rhodopsin**, the photopigment of rods, is pink (*rhodon* means ‘rose’ in Greek). However, once the photopigments are split apart by the action of light, they lose their colour – they become bleached. Franz Boll discovered this phenomenon in 1876 when he removed an eye from an animal and pointed it towards a window that opened out onto a brightly lit scene. He then examined the retina under dim light and found that the image of the scene was still there. The retina was pink where little light had fallen and pale where the image had been bright. It was Boll’s discovery that led investigators to suspect that a chemical reaction was responsible for the transduction of light into neural activity.

Figure 5.15 Transduction of light into neural activity. A photon strikes a photoreceptor and causes the photopigment to split apart. This event initiates the transmission of information to the brain.

After light has caused a molecule of photopigment to split and become bleached, energy from the photoreceptor’s metabolism causes the two molecules to recombine. The photopigment is then ready to be bleached by light again. Each photoreceptor contains many thousands of molecules of photopigment. The number of intact, unbleached molecules of photopigment in a given cell depends on the relative rates at which they are being split by light and being put back together by the cell’s energy. The brighter the light, the more bleached photopigment there is.

Adaptation to light and dark

Think, for a moment, about how difficult it can be to find a seat in a darkened cinema. Another example: if you have just come in from the bright sun, your eyes do not respond well to the low level of illumination. However, after a few minutes, you can see rather well – your eyes have adapted to the dark. This phenomenon is called **dark adaptation**.

In order for light to be detected, photons must split molecules of rhodopsin or one of the other photopigments. When high levels of illumination strike the retina, the rate of regeneration of rhodopsin falls behind the rate of the bleaching process. With only a small percentage of the rhodopsin molecules intact, the rods are not very sensitive to light. If you enter a dark room after being in a brightly lit room or in sunlight, there are too few intact rhodopsin molecules for your eyes to respond immediately to dim light. The probability that a photon will strike an intact molecule of rhodopsin is very low. However, after a while, the regeneration of rhodopsin overcomes the bleaching effects of the light energy. The rods become full of unbleached rhodopsin, and a photon passing through a rod is likely to find a target. The eye has become dark adapted.

Eye movements

Our eyes are never completely at rest, even when our gaze is fixed on a particular place called the **fixation point**. Our eyes make fast, aimless, jittering movements, similar to the fine tremors our hands and fingers make when we try to keep them still. They also make occasional slow movements away from the target they are fixed on, which are terminated by quick movements that bring the image of the fixation point back to the fovea.

Although the small, jerky movements that the eyes make when at rest are random, they appear to serve a useful function. Riggs *et al.* (1953) devised a way to project stabilised images on the retina – images that remain in the same location on the retina. They mounted a small mirror in a contact lens worn by the participant and bounced a beam of light off it. They then projected the image onto a white screen in front of the participant, bounced it off several more mirrors, and finally directed it towards the participant's eye, as illustrated by Figure 5.16.

The path of the light was arranged so that the image on the screen moved in perfect synchrony with the eye movements. If the eye moved, so did the image; thus, the image that the experimenters projected always fell on precisely the same part of the retina despite the subject's eye

Figure 5.16 A procedure for stabilising an image on the retina.
Source: Riggs, L.A., Ratliff, F., Cornsweet, J.C. and Cornsweet, T.N., *Journal of the Optical Society of America*, 1953, 43, 495–501.

movements. Under these conditions, details of visual stimuli began to disappear. At first, the image was clear, but then a ‘fog’ drifted over the subject’s field of view, obscuring the image. After a while, some images could not be seen at all. All of this occurred within seconds.

These results suggest that elements of the visual system are not responsive to an unchanging stimulus. The photoreceptors or the ganglion cells, or perhaps both, apparently cease to respond to a constant stimulus. The small, involuntary movements of our eyes keep the image moving and thus keep the visual system responsive to the details of the scene before us. Without these involuntary movements, our vision would become blurry soon after we fixed our gaze on a single point and our eyes became still.

The eyes also make three types of ‘purposive’ movement: conjugate movements, saccadic movements and pursuit movements. **Conjugate movements** are cooperative movements that keep both eyes fixed on the same target, or, more precisely, that keep the image of the target object on corresponding parts of the two retinas. If you hold up a finger in front of your face, look at it, and then bring your finger closer to your face, your eyes will make conjugate movements towards your nose. If you then look at an object on the other side of the room, your eyes will rotate outward, and you will see two separate blurry images of your finger. As you will learn in Chapter 6, conjugate eye movements assist in the perception of distance.

When you scan the scene in front of you, your gaze travels from point to point as you examine important or interesting features. As you do so, your eyes make jerky **saccadic movements** – you shift your gaze abruptly from one point to another. For example, when you read a line in this book, your eyes stop several times, moving quickly between each stop. You cannot consciously control the speed of movement between stops; during each saccade the eyes move as fast as they can.

Much of the time, the scene in front of us contains moving objects: objects blown by the wind, cars, aeroplanes, animals, other people. When we concentrate on one of these objects, we fix our gaze on it and track its movements with our eyes. These tracking movements, which follow the object we are watching, are called **pursuit movements**.

Colour vision

Light consists of radiant energy having wavelengths between 380 and 760 nm. Light of different wavelengths gives rise to sensations of different colours. How can we tell the difference between different wavelengths of light?

Experiments have shown that there are three types of cone in the human eye, each containing a different type of photopigment. Each type of photopigment is most sensitive to light of a particular wavelength. That is, light of a particular wavelength most readily causes a particular photo-

pigment to split. Thus, different types of cone are stimulated by different wavelengths of light. Information from the three types of cone enables us to perceive colours.

Wavelength is related to colour, but the terms are not synonymous. For example, the spectral colours (the colours we see in a rainbow, which contains the entire spectrum of visible radiant energy) do not include all the colours that we can see, such as brown, pink, and the metallic colours silver and gold. The fact that not all colours are found in the spectrum means that differences in wavelength alone do not account for the differences in the colours we can perceive.

The dimensions of colour

Most colours can be described in terms of three physical dimensions: wavelength, intensity and purity. Three perceptual dimensions – hue, brightness and saturation – corresponding to these physical dimensions describe what we see. The **hue** of most colours is determined by wavelength; for example, light having a wavelength of 540 nm is perceived as green. A colour's **brightness** is determined by the intensity, or amount of energy, of the light that is being perceived, all other factors being equal. A colour of maximum brightness dazzles us with a lot of light. A colour of minimum brightness is simply black. The third perceptual dimension of colour, **saturation**, is roughly equivalent to purity. A fully saturated colour consists of light of only one wavelength, for example pure red or pure blue. Desaturated colours look pastel or washed out. See Table 5.2 for a summary of the dimensions of colour.

Saturation is probably the most difficult dimension of colour to understand. White light consists of a mixture of all wavelengths of light. Although its components consist of light of all possible hues, we perceive it as being colourless. White light is completely desaturated; no single wavelength is dominant. If we begin with light of a single wavelength (a pure, completely saturated colour) and then mix in some white light, the result will be a less

saturated colour. For example, when white light is added to red light (700 nm), the result is pink light. The dominant wavelength of 700 nm gives the colour a reddish hue, but the addition of white light to the mixture decreases the colour's saturation. In other words, pink is a less saturated version of red. Figure 5.17 illustrates how a colour having a particular dominant wavelength (hue) can vary in its brightness and saturation.

Colour mixing

Vision is a synthetic sensory modality. It synthesises (puts together) rather than analyses (takes apart). When two wavelengths of light are present, we see an intermediate colour rather than the two components. In contrast, the auditory system is analytical. If a high note and a low note are played together on a piano, we hear both notes instead of a single, intermediate tone. The addition of two or more lights of different wavelengths is called **colour mixing**. Colour mixing is an additive process and is very different from paint mixing. So are its results. If we pass a beam of white light through a prism, we break it into the spectrum of the different wavelengths it contains. If we recombine these colours by passing them through another prism, we obtain white light again (see Figure 5.18).

Colour mixing must not be confused with pigment mixing – what we do when we mix paints. An object has a particular colour because it contains pigments that absorb some wavelengths of light (converting them into heat) and reflect other wavelengths. For example, the chlorophyll found in the leaves of plants absorbs less green light than light of other wavelengths. When a leaf is illuminated by white light, it reflects a high proportion of green light and appears green to us.

Table 5.2 Physical and perceptual dimensions of colour

Perceptual dimension	Physical dimension	Physical characteristics
Hue	Wavelength	Frequency of oscillation of light radiation
Brightness	Intensity	Amount of energy of light radiation
Saturation	Purity	Intensity of dominant wavelength relative to total radiant energy

Figure 5.17 Hue, brightness and saturation. The colours shown have the same dominant wavelength (hue) but different saturation and brightness.

Figure 5.18 Colour mixing. White light can be split into a spectrum of colours with a prism and recombined through another prism.

When we mix paints, we are subtracting colours, not adding them. Mixing two paints yields a darker result. For example, adding blue paint to yellow paint yields green paint, which certainly looks darker than yellow. But mixing two beams of light of different wavelengths always yields a brighter colour. For example, when red and green light are shone together on a piece of white paper, we see yellow. In fact, we cannot tell a pure yellow light from a synthesised one made of the proper intensities of red and green light. To our eyes, both yellows appear identical.

To reconstitute white light, we do not even have to recombine all the wavelengths in the spectrum. If we shine a blue light, a green light and a red light together on a sheet of white paper and properly adjust their intensities, the place where all three beams overlap will look perfectly white. A colour television or a computer display screen uses this system. When white appears on the screen, it actually consists of tiny dots of red, blue and green light (see Figure 5.19).

Colour-coding in the retina

In 1802, Thomas Young, a British physicist and physician, noted that the human visual system can synthesise any colour from various amounts of almost any set of three

colours of different wavelengths. Young proposed a **trichromatic theory** ('three colour' theory) of colour vision. He hypothesised that the eye contains three types of colour receptor, each sensitive to a different hue, and that the brain synthesises colours by combining the information received by each type of receptor. He suggested that these receptors were sensitive to three of the colours that people perceive as 'pure': blue, green and red. Young's suggestion was incorporated into a more elaborate theory of colour vision by Hermann von Helmholtz. (We'll return to Young in the section on creativity in Chapter 11.)

Experiments in recent years have shown that the cones in the human eye do contain three types of photopigment, each of which preferentially absorbs light of a particular wavelength: 420, 530 and 560 nm. Although these wavelengths actually correspond to blue-violet, green and yellow-green, most investigators refer to these receptors as blue, green and red cones. To simplify the discussion here, we will assume that the three types of cone respond to these three pure hues. Red and green cones are present in about equal proportions. There are far fewer blue cones.

Several scientists after Young and Helmholtz devised theories that took account of the fact that people also perceive yellow as a psychologically pure hue. Late in the nineteenth century, Ewald Hering, a German physiologist,

Figure 5.19 Additive colour mixing and paint mixing. When blue, red and green light of the proper intensity are all shone together, the result is white light. When red, blue and yellow paints are mixed together, the result is a dark grey.

noted that the four primary hues appeared to belong to pairs of opposing colours: red/green and yellow/blue. We can imagine a bluish green or a yellowish green, or a bluish red or a yellowish red. However, we cannot imagine a greenish red or a yellowish blue. Hering originally suggested that we cannot imagine these blends because there are two types of photoreceptor, one kind responding to green and red and the other kind responding to yellow and blue.

Hering's hypothesis about the nature of photoreceptors was wrong, but his principle describes the characteristics of the information the retinal ganglion cells send to the brain. Two types of ganglion cell encode colour vision: red/green cells and yellow/blue cells. Both types of ganglion cell fire at a steady rate when they are not stimulated. If a spot of red light shines on the retina, exci-

tation of the red cones causes the red/green ganglion cells to begin to fire at a high rate.

Conversely, if a spot of green light shines on the retina, excitation of the green cones causes the red/green ganglion cells to begin to fire at a slow rate. Thus, the brain learns about the presence of red or green light by the increased or decreased rate of firing of axons attached to red/green ganglion cells. Similarly, yellow/blue ganglion cells are excited by yellow light and inhibited by blue light. Because red and green light, and yellow and blue light, have opposite effects on the rate of axon firing, this coding scheme is called an **opponent process**.

Figure 5.20 provides a schematic explanation of the opponent-process coding that takes place in the retina. Stimulation of a red cone by red light excites the red/green ganglion cell, whereas stimulation of a green

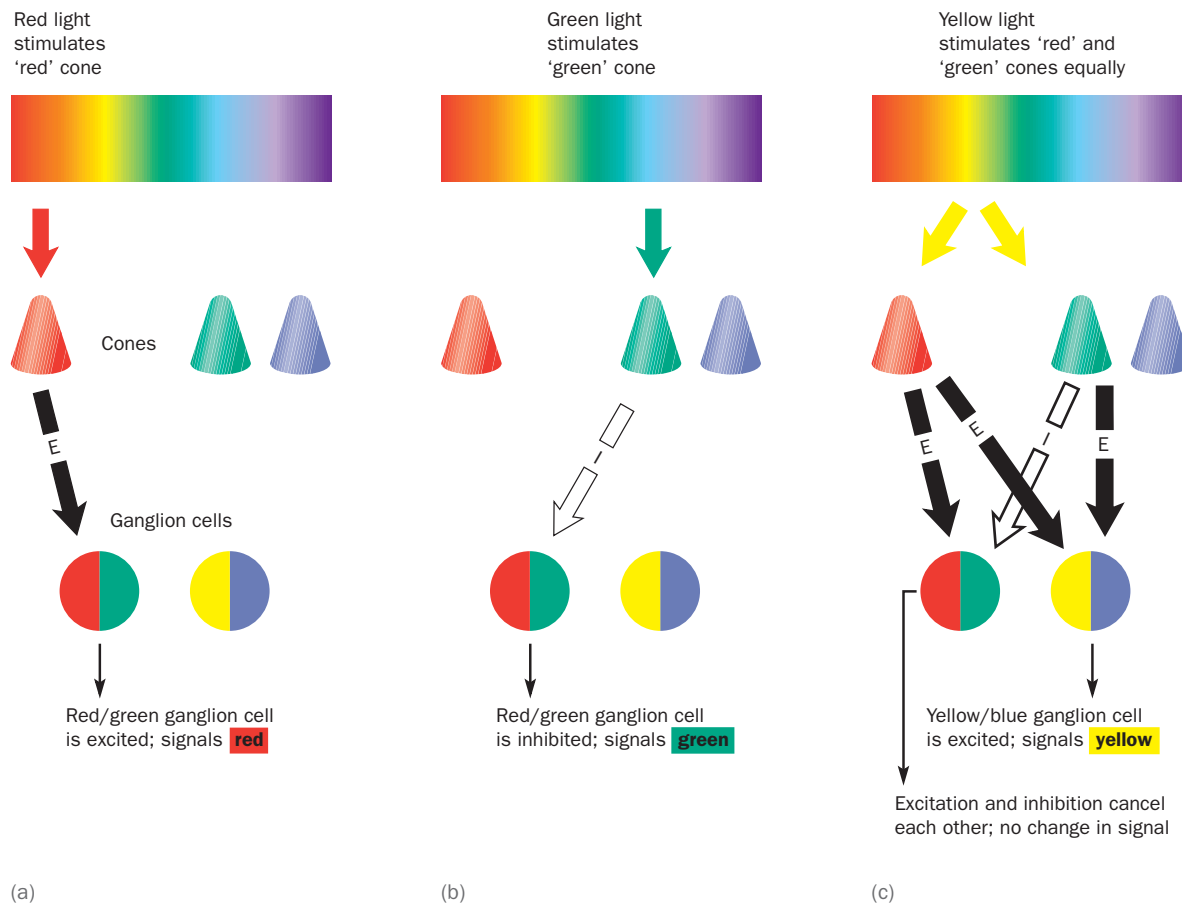

Figure 5.20 Colour coding in the retina. **(a)** Red light stimulating a 'red' cone, which causes excitation of a red/green ganglion cell. **(b)** Green light stimulating a 'green' cone, which causes inhibition of a red/green ganglion cell. **(c)** Yellow light stimulating 'red' and 'green' cones equally. The stimulation of 'red' and 'green' cones causes excitation of a yellow/blue ganglion cell. The arrows labelled E and I represent neural circuitry within the retina that translates excitation of a cone into excitation or inhibition of a ganglion cell, respectively. For clarity, only some of the circuits are shown.

cone by green light inhibits the red/green ganglion cell (Figure 5.20 (a) and (b)). If the photoreceptors are stimulated by yellow light, both the red and green cones are stimulated equally. Because of the neural circuitry between the photoreceptors and the ganglion cells, the result is that the yellow/blue ganglion cell is excited, signalling yellow (Figure 5.20 (c)).

The retina contains red/green and yellow/blue ganglion cells because of the nature of the connections between the cones, bipolar cells and ganglion cells. The brain detects various colours by comparing the rates of firing of the axons in the optic nerve that signal red or green and yellow or blue. Now you can see why we cannot perceive a reddish green or a bluish yellow: an axon that signals red or green (or yellow or blue) can either increase or decrease its rate of firing. It cannot do both at the same time. A reddish green would have to be signalled by a ganglion cell firing slowly and rapidly at the same time, which is impossible.

Negative after-images

Figure 5.21 demonstrates an interesting property of the visual system: the formation of a **negative after-image**. Stare at the cross in the centre of the image on the left for approximately 30 seconds. Then quickly look at the cross in the centre of the white rectangle to the right. You will have a fleeting experience of seeing the red and green colours of a radish – colours that are complementary, or opposite, to the ones on the left. Complementary items go together to make up a whole. In this context, complementary colours are those that make white (or shades of grey) when added together.

The most important cause of negative after-images is adaptation in the rate of firing of retinal ganglion cells. When ganglion cells are excited or inhibited for a prolonged period of time, they later show a rebound effect,

firing faster or slower than normal. For example, the green of the radish in Figure 5.21 inhibits some red/green ganglion cells. When this region of the retina is then stimulated with the neutral-coloured light reflected off the white rectangle, the red/green ganglion cells – no longer inhibited by the green light – fire faster than normal. Thus, we see a red after-image of the radish.

Defects in colour vision

Approximately one in 12 men has some form of defective colour vision. These defects are sometimes called colour-blindness, but this term should probably be reserved for the very few people who cannot see any colour at all. Men are affected more than women because many of the genes for producing photopigments are located on the X chromosome. Because males have only one X chromosome (females have two), a defective gene there will always be expressed.

There are many different types of defective colour vision. Some individuals are missing a photopigment and are called dichromats (and the condition is called **dichromacy**). These people use two primary colours for matching and confuse various colours, as you will see below. Other individuals, called anomalous trichromats (the condition is called **anomalous trichromacy**), have an altered – not missing – photopigment. These people account for the majority of men with colour defects although they probably do not realise they have a deficit because they may only show a slight loss of sensitivity for the reds, greens and blues, but generally good colour discrimination. Extreme cases, however, will show greater loss of sensitivity and poorer colour discrimination. In rare cases, some people may express more than three photopigments and should, theoretically, have an added

Figure 5.21 A negative after-image. Stare for approximately 30 seconds at the cross in the centre of the left figure; then quickly transfer your gaze to the cross in the centre of the right figure. You will see colours that are complementary to the originals.

Psychology in action – Red light = danger?

According to some anthropologists, the colour red is seen as a sign of dominance in non-human species. Of course, what applies in the animal kingdom does not necessarily apply to the human kingdom. A study from researchers at the University of Durham, UK, however, suggests that it might.

In a novel study, the researchers examined the success and failure of sportsmen and women who wore red or blue costumes (Hill and Barton, 2005). In the 2004 Olympic Games, contestants in the combat sports, boxing, tae kwon do, Greco-Roman wrestling and freestyle wrestling, were randomly given either red or blue costumes to wear. When Hill and Barton (2005) analysed the win rate of contestants, those in red costumes won more fights than those in blue costumes.

They then further extended this research by examining the win rate of players in the Euro 2004 international football competition. The performance of five teams that wore red was compared with the performance of the same teams when they wore a different colour. Again, the study's finding was novel: the team won more often when wearing red shirts.

According to the authors, 'given the ubiquity of aggressive competition throughout human societies and history, our results suggest that the evolutionary psychology of colour is likely to be a fertile field for further investigation'.

The effect of the colour red even seems to extend to cognitive test performance. Researchers exposed students to either the colour red, green or black before giving them a test. Participants who were exposed to red – even if participants were not consciously aware of it – performed less well on a test than did those who were not (Elliot *et al.*, 2007). The effect was found even when a number was written in red ink at the top of a sheet of paper. When participants' brain activation was examined, there was greater activation in the right side of the frontal lobe when seeing the colour red (a theory, described in Chapter 13, argues that the left and right front parts of the brain mediate different kinds of emotional experiences, positive and negative respectively).

But some psychologists have questioned this influence of red, especially that seen in the sport studies. For example, it could be argued that the colour itself did not influence the chances of winning but that fact that red was more highly visible

in the sports studied (Rowe *et al.*, 2005). Some have also questioned the bias of the referee. The colour might influence the perception of performance, regardless of actual performance.

In an ingenious test of this hypothesis, Hagemann *et al.*, (2008) asked 42 experience tae kwon do referees to watch a videotape of five different sparring competitions. The competitors's heads and trunk were covered in red or blue material. When asked to award points to these competitors, the red ones were given 13 per cent more points (as previous research would predict). Then, and this is the ingenious twist, the experimenters electronically switched the colours of the competitors – the actual competitors remained the same, as did their performance, but the colour they wore changed. When this happened, the points awarded to the red competitors increased. Those who had been given the points in the previous study (and were now dressed in blue) were awarded fewer. These results, according to the authors, suggest 'need a change to the rules (i.e., to forbid red sports attire) and support referees by providing electronic-decision making only'.

Does the colour of a team's kit influence their success?

Source: Chris Coleman/Manchester United

dimension to their colour vision. A study of women with a phenotype expressing four photopigments found that this was the case: these people perceived more chromatic appearances than did male or female trichromats (Jameson *et al.*, 2001).

Two of the three colour defects described below involve the red/green system. People with these defects confuse red and green. Their primary colour sensations

are yellow and blue; red and green both look yellowish. Figure 5.22 shows one of the figures from a commonly used test for defective colour vision. A person who confuses red and green will not be able to see the '5'.

The most serious defect, called **protanopia** (literally, 'first-colour defect'), appears to result from a lack of the photopigment for red cones. The fact that people with protanopia have relatively normal acuity suggests that

Figure 5.22 A figure commonly used to test for defective colour vision. People with red/green colour blindness will fail to see the 5.

Source: Courtesy of American Optical Corporation.

they have red cones but that these cones are filled with green photopigment (Boynton, 1979). If red cones were missing, almost half of the cones would be gone from the retina, and vision would be less acute. To a protanope, red looks much darker than green, and reds and oranges generally appear very dark because the red end of the spectrum cannot be seen. Around 1 per cent of men suffer from this defect.

The second form of red/green defect, called **deutanopia** ('second-colour defect'), appears to result from the opposite kind of substitution: green cones are filled with red photopigment. Around 8 per cent of European men and 0.5 per cent of European women have the inherited colour defect, Daltonism (protanopia and deutanopia) (Fletcher and Voke, 1985) and there is evidence of other culture-related differences in colour vision impairment although whether such differences are due to cultural or physiological differences is unclear (Davies *et al.*, 1998). The topic of colour perception and the use of colour terms across cultures is discussed in more detail in the next chapter.

The third form of colour defect, called **tritanopia** ('third-colour defect'), involves the blue cones and is much rarer: it affects fewer than 1 in 10,000 people. Tritanopes see the world in greens and reds; to them, a clear blue sky is a bright green, and yellow looks pink. The faulty gene that causes tritanopia is not carried on a sex chromosome, therefore it is equally common in males and females. This defect appears to involve loss of blue cones, but because there are far fewer of these than of red and green cones to begin with, investigators have not yet determined whether the cones are missing or are filled with one of the other photopigments.

Synaesthesia

There are some individuals who claim to be able to sense colours when hearing words (and there are others who claim that tastes elicit sensations of shapes). This phenomenon is called **synaesthesia** (from the Greek *syn*, meaning 'union' and *aisthesis* meaning 'sensation'): a sensation in one modality produces an inexorable sensation in another (Harrison and Baron-Cohen, 1996). It affects about 1 in 100,000 and cases of 'coloured hearing' were reported as early as the nineteenth century (Galton, 1883). One very famous composer, Liszt, claimed synaesthetic ability, see Figure 5.23.

The phenomenon seems to be reliable. Baron-Cohen *et al.* (1987) investigated the synaesthetic ability of a 78-year-old woman (EP) who claimed to see colours when she heard words. Her responses were 100 per cent consistent at 10 weeks whereas an IQ-matched control was only 17 per cent consistent at two weeks. Another example, recently reported in the literature, is that of a 20-year old undergraduate who consistently experienced tastes when hearing words (Gendle, 2007). Beeli *et al.* (2005) report the case of a right-handed musician (ES) who, when she hears a musical interval, reports a taste sensation on her tongue that is always associated with that

Figure 5.23 Some people claim to 'see' colours when they hear specific musical notes. The composer Liszt was one such person.

Source: Brash, S., Maranto, G., Murphy, W. and Walker, B. (1990) *How Things Work: The brain*. Virginia: Time-Life Books. © 1990 Time-Life Books.

specific interval. (The types of taste sensations evoked by the notes can be seen in Table 5.3).

Baron-Cohen *et al.* (1993) studied nine individuals who claimed to sense colours when hearing speech. The participants were tested at two points, one year apart. The researchers found that identical responses were reported in 92.3 per cent of cases over one year. For a control group, the response rate was 37.6 per cent after only one week. Some colours were specifically elicited by vowels. For example, the same colours were consistently associated with 'i', 'o' and 'u' (88.9 per cent of the time).

One hypothesis suggests that **synaesthetes** show a breakdown in modularity, that is, there are links between the colour and language regions that have either disappeared or never even existed in non-synaesthetes. In synaesthetes, however, these links are intact. Alternatively, non-synaesthetes can inhibit the activity of these modules but this inhibition is dysfunctional in synaesthetes. Paulesu *et al.* (1996) used PET technology to study six synaesthete women who were asked to indicate which colours they sensed when hearing words and tones. The experimenters found that synaesthesia was elicited by words but not by tones. While both synaesthetes and controls activated the perisylvian regions of the brain, the synaesthetes showed activation of other visual association areas including the posterior inferior temporal cortex and the junction between the parietal and occipital cortex. No activation was observed in the major visual areas such as the primary visual cortex (V1) suggesting that it is possible to experience conscious visual perception without activating V1. This lack of V1 activation suggests to the researchers that synaesthesia involves an interaction between the areas of the brain responsible for higher visual function and the areas responsible for aspects of language processing.

Table 5.3 The taste sensations in ES triggered by different notes

Tone interval	Taste experienced
Minor second	Sour
Major second	Bitter
Minor third	Salty
Major third	Sweet
Fourth	(Mown grass)
Tritone	(Disgust)
Fifth	Pure water
Minor sixth	Cream
Major sixth	Low-fat cream
Minor seventh	Bitter
Major seventh	Sour
Octave	No taste

Synaesthesia highlights one of the problems of studying sensation. The problem is as old as psychology and philosophy: how do we really know that the person is experiencing what they say they are experiencing? Baron-Cohen's studies suggest two ways of circumventing this problem: (1) look for consistency of responses in an experimental group over time and compare these with control responses, and (2) compare brain activation in these two groups, working under the assumption that synaesthesia activates different areas of the brain when compared with a resting state and with a non-synaesthete control group.

Audition

Vision involves the perception of objects in three dimensions, at a variety of distances, and with a multitude of colours and textures. These complex stimuli may occur at a single point in time or over an extended period. They may also involve an unchanging scene or a rapidly changing one. The other senses analyse much simpler stimuli (such as an odour or a taste) or depend on time and stimulus change for the development of a complex perception. For example, to perceive a solid object in three dimensions by means of touch, we must manipulate it – turn it over in our hands or move our hands over its surface. The stimulus must change over time for a fully-fledged perception of form to emerge. The same is true for audition: we hear nothing meaningful in an instant.

Most people consider the sense of hearing second in importance only to vision. In some ways it is more important. A blind person can converse and communicate with other people almost as well as a sighted person. Deafness is much more likely to produce social isolation. A deaf person cannot easily join in the conversation of a group of people who do not know sign language. Although our eyes can transmit much more information to the brain, our ears are used for some of our most important forms of social communication.

Sound

Sound consists of pressure changes in air. As an object vibrates, it causes the air around it to move. The surface of a vibrating object moves back and forth. As the surface moves towards you, it compresses molecules of air; as it moves away, it pulls the molecules of air farther apart. These successive waves of compression and 'rarefaction' flow away from the surface as sound. As a pressure wave arrives at your ear, it pushes your eardrum inward. The following wave of negative pressure (when the molecules are pulled farther apart) sucks your eardrum outward.

Figure 5.24 The physical and perceptual dimensions of sound waves.

Sound waves are measured in frequency units of cycles per second called **hertz (Hz)**. The human ear perceives vibrations between approximately 30 Hz and 20,000 Hz. Sound waves can vary in intensity and frequency. These variations produce corresponding changes in sensations of loudness and pitch. Consider a loudspeaker. Alternations in the electrical current transmitted from an amplifier cause the loudspeaker cone to move back and forth. If the cone begins vibrating more rapidly, the pitch of the sound increases. If the vibrations become more intense (that is, if the cone moves in and out over a greater distance), the loudness of the sound increases. A third perceptual dimension, timbre, corresponds to the complexity of the sound vibration. See Figure 5.24.

The ear and its functions

When people refer to the ear, they usually mean what anatomists call the *pinna* – the flesh-covered cartilage attached to the side of the head (*pinna* means ‘wing’ in Latin). But the pinna performs only a small role in audition: it helps us to determine the direction of sound. The real business of hearing is done in the inner ear (see Figure 5.25).

The eardrum is a thin, flexible membrane that vibrates back and forth in response to sound waves. It passes these vibrations, via the bones of the middle ear, to the inner ear, a 2 cm cavity which separates the outer and middle ear. The eardrum is attached to the first of three middle ear bones called the **ossicles** (literally, ‘little bones’). The three ossicles are known as the malleus, incus and stapes (from Latin: hammer, anvil and stirrup) because of their shapes. These bones act together, in lever fashion, to transmit the vibrations of the eardrum to the fluid-filled structure of the inner ear that contains the receptive organ.

The part of the ear that contains the receptive organ of hearing is called the **cochlea** (*kokblos* means ‘snail’, which also describes its shape). Uncoiled, this would reach 35 mm and is 2 mm in diameter (Goldstein, 2007). It is filled with

liquid and a bony chamber attached to the cochlea (the vestibule) contains two openings, the oval window and the round window. The last of the three ossicles (the stapes) presses against a membrane behind an opening in the bone surrounding the cochlea called the **oval window**, thus transmitting sound waves into the liquid inside the cochlea, where it can reach the receptive organ of hearing. The cochlea is divided along its length into three cavities by the **basilar membrane** and Reissner’s membrane. The auditory receptor cells sit on the surface of the basilar membrane. As the footplate of the stapes presses back and forth against the membrane behind the oval window, pressure changes in the fluid above the basilar membrane cause the basilar membrane to vibrate up and down. Because the basilar membrane varies in width and flexibility along its length, different frequencies of sound cause different parts of the basilar membrane to vibrate. High-frequency sounds cause the end near the oval window to vibrate, medium-frequency sounds cause the middle to vibrate, and low-frequency sounds cause the tip to vibrate. Figure 5.26 shows a schematic drawing and the corresponding photographic image of the cochlea.

Figure 5.25 Anatomy of the auditory system.

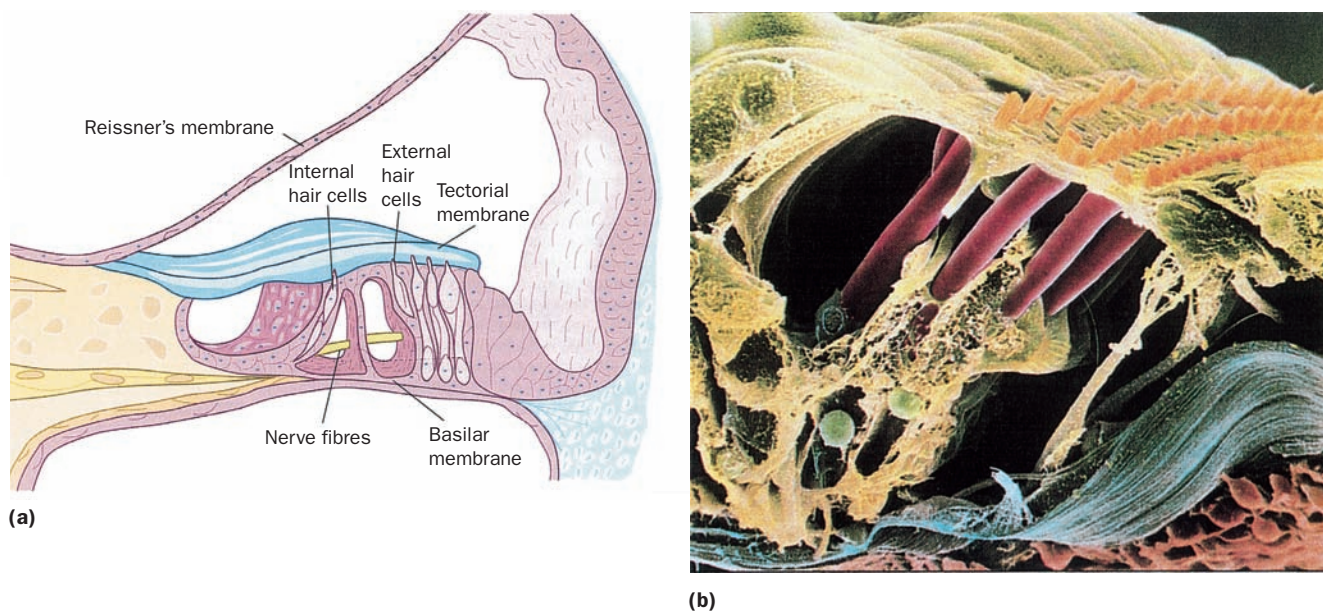

Figure 5.26 (a) A schematic image of the cochlea. (b) A photographic image of the cochlea.

Source: Beatty, J., *Principles of Behavioral Neuroscience*. Madison: Wm C. Brown Communications, Inc. Reprinted with permission.

In order for the basilar membrane to vibrate freely, the fluid in the lower chamber of the cochlea must have somewhere to go. Free space is provided by the **round window**. When the basilar membrane flexes down, the displacement of the fluid causes the membrane behind the round window to bulge out. In turn, when the basilar membrane flexes up, the membrane behind the round window bulges in.

Some people suffer from a middle ear disease that causes bone to grow over the round window. Because their basilar membrane cannot easily flex back and forth, these people have a severe hearing loss. However, their hearing can be restored by a surgical procedure called fenestration ('window making') in which a tiny hole is drilled in the bone where the round window should be.

Sounds are detected by special neurons known as **auditory hair cells**, located on the basilar membrane. Auditory hair cells transduce mechanical energy caused by the flexing of the basilar membrane into neural activity. These cells possess hair-like protrusions called **cilia** ('eyelashes'). The ends of the cilia are embedded in a fairly rigid shelf (the **tectorial membrane**) that hangs over the basilar membrane like a balcony. When sound vibrations cause the basilar membrane to flex back and forth, the cilia are stretched. This pull on the cilia is translated into neural activity (see Figure 5.27). The threshold for hearing in humans is 100 trillionth of a metre – we can detect a sound that is as little in strength as 100 picometres. See Figure 5.28, which compares the movement of a hair cell with the equivalent necessary to move 10 mm of the Eiffel Tower.

When a mechanical force is exerted on the cilia of the auditory hair cells, the electrical charge across their membrane is altered. The change in the electrical charge causes a transmitter substance to be released at a synapse between the auditory hair cell and the dendrite of a neuron of the auditory nerve. The release of the transmitter substance excites the neuron, which transmits messages through the auditory nerve to the brain.

Detecting and localising sounds in the environment

As we saw, sounds can differ in loudness, pitch and timbre. They also have sources; they come from particular locations. How does the ear distinguish these characteristics? The ear's ability to distinguish sounds by their timbre depends on its ability to distinguish loudness and pitch. Some common auditory stimuli and their loudness levels are presented in Figure 5.29.

Loudness and pitch

Scientists have long debated how the auditory system represents pitch on the auditory nerve. Some think that pitch is represented by axons firing in synchrony with the vibrations of the basilar membrane. However, axons cannot fire rapidly enough to represent the high pitches that we can hear. A good, young ear can distinguish frequencies of more than 20,000 Hz, but axons cannot fire more than 1,000 times per second. Therefore, high-frequency sounds, at least, must be encoded in some other way.

Figure 5.27 The transduction of sound vibrations in the auditory system.

As we saw, sounds of different frequency cause different parts of the basilar membrane to vibrate. Thus, sounds of different frequencies stimulate different groups of auditory hair cells located along the basilar membrane. So, the brain can be informed of the pitch of a sound by the activity of different sets of axons from the auditory nerve. When low-frequency sound waves reach the ear, the top of the basilar membrane vibrates, and auditory hair cells located in this region are activated. In contrast, high-frequency sounds activate auditory hair cells located at the base of the basilar membrane, near the oval window. Therefore, the brain can tell the frequency from the set of axons which is firing.

Two kinds of evidence indicate that pitch is detected in this way. First, direct observation of the basilar membrane has shown that the region of maximum vibration depends on the frequency of the stimulating tone (von

Békésy, 1960). Van Békésy's place theory of hearing argued that the frequency of a sound is indicated by the place along the organ of Corti where the firing of nerves is strongest. The vibration of the basilar membrane is a little like the snapping of a whip, creating a travelling wave. When electrodes are placed along the cochlea, a map of frequencies can be plotted out along the cochlea (this is called a tonotopic map). Frequencies are higher at the base and lower at the apex of the cochlea.

Secondly, experiments have found that damage to specific regions of the basilar membrane causes loss of the ability to perceive specific frequencies. The discovery that some antibiotics damage hearing (for example, deafness is one of the possible side effects of an antibiotic used to treat tuberculosis) has helped auditory researchers to investigate the anatomical coding of pitch. Stebbins *et al.* (1969) administered an antibiotic to different groups of

animals for varying times. Next, they tested the animals' ability to perceive tones of different frequencies. Afterwards, they removed the animals' cochleas and examined them. They found that the longer the animals

were exposed to the antibiotic, the more of their hair cells were killed. Damage started at the end of the basilar membrane nearest the oval window and progressed towards the other end. The experimenters compared the various groups of animals and found that the hearing loss was proportional to the amount of damage to the hair cells. The loss began with the highest frequencies and progressed towards the lower frequencies.

Thus, the hair cells nearest the oval window are responsible for detecting high-pitched sounds.

Although different frequencies cause different regions of the basilar membrane to vibrate and therefore different axons from the auditory nerve to fire, there is also evidence that pitch information can be encoded in a different way. The basilar membrane vibrates in synchrony with the sound waves. Neurons that are stimulated by hair cells located there are able to fire in synchrony with these vibrations, thus firing at the same frequency as the sound. The brain times the intervals between these responses and thus detects the pitch. This process is an example of temporal coding.

One piece of evidence that low frequencies are detected in this way comes from an experiment performed many years ago by Miller and Taylor (1948). These investigators used white noise as a stimulus. White noise consists of a random mixture of all the perceptible frequencies of sound – it sounds like the 'sssh' heard when an FM radio is tuned between stations. White noise stimulates all regions of the basilar membrane because it contains all frequencies of sound.

Miller and Taylor presented participants with white noise that passed through a hole in a rotating disc. By spinning the disc at various speeds, the investigators could divide the noise into extremely brief pulses, which could be presented at various rates. Thus, a 'pitch' was artificially created by setting the pulse rate of the white noise. When the frequency of the pulsation was less than 250 Hz, the participants could accurately identify its pitch. However,

Figure 5.28 Comparison of the movement of the cilia of a hair cell with the Eiffel Tower.

above 250 Hz, the perception of pitch disappeared. Because the white noise stimulated all parts of the basilar membrane, the sounds must have been detected by neurons that fired in synchrony with the pulsations.

What about loudness? The axons of the cochlear nerve appear to inform the brain of the loudness of a stimulus by altering their rate of firing. More intense vibrations stimulate the auditory hair cells more intensely. This stimulation causes them to release more transmitter substance, which results in a higher rate of firing by the axons in the auditory nerve. The code is therefore similar to that used in other senses.

However, there is a problem. If they fire more frequently with sound intensity, why does that not signal a higher pitch according to the temporal code described above? Obviously, they cannot signal both loudness and pitch by the same means. The answer is that loudness is signalled by the number of auditory hair cells that are active at a given time. A louder sound excites a larger number of hair cells.

Timbre

You can easily distinguish between the sounds of a violin and a clarinet, even if they are playing tones of the same pitch and loudness. So, clearly, pitch and loudness are not the only characteristics of a sound. Sounds can vary greatly in complexity. They can start suddenly or gradually increase in loudness, be short or long, and seem thin and reedy or full and vibrant. The enormous variety of sounds that we can distinguish is in large part owing to an important characteristic of sound called timbre.

The combining, or synthesis, of two or more simple tones, each consisting of a single frequency, can produce a complex tone. For example, an electronic synthesiser produces a mixture of sounds of different frequencies, each of which can be varied in amplitude (intensity). Thus, it can synthesise the complex sounds of a clarinet or violin or can assemble completely new sounds not produced by any other source. Conversely, complex sounds that have a regular sequence of waves can be reduced by means of analysis into several simple tones.

We can tell a clarinet from another instrument because each instrument produces sounds consisting of a unique set of simple tones called **overtones**. Their frequencies are multiples of the **fundamental frequency**, or the basic pitch of the sound. **Timbre** is the distinctive combination of overtones with the fundamental frequency. The fundamental frequency causes one part of the basilar membrane to vibrate, while each of the overtones causes another portion to vibrate. During a complex sound many different portions of the basilar membrane are vibrating simultaneously. Thus, the ear

analyses a complex sound. Information about the fundamental frequency and each of the overtones is sent to the brain through the auditory nerve, and the person hears a complex tone having a particular timbre. When you consider that we can listen to an orchestra and identify several instruments playing simultaneously, you can appreciate the complexity of the analysis performed by the auditory system.

Locating the source of a sound

When we hear an unexpected sound, we usually turn our heads quickly to face its source. Even newborn infants can make this response with reasonably good accuracy. And once our faces are oriented towards the source of the sound, we can detect changes in its location of as little as 1 degree. To do so, we make use of two qualities of sound: relative loudness and difference in arrival time.

Relative loudness is the most effective means of perceiving the side from which a high-frequency sound comes. Low-frequency sounds can bend around a solid object but high-frequency sounds bounce off. Thus, objects, such as the human head, cast an ‘acoustic shadow’ (at least for high-frequency sounds), rather as opaque objects cast a shadow in the sunlight. The head reflects high-frequency sounds so that they are made louder to the ear nearer the source of the sound and less loud at the more distant ear which is in the acoustic shadow cast by the head. Thus, if a source on your right produces a high-frequency sound, your right ear will receive more intense stimulation than your left ear will. The brain uses this difference to calculate the location of the source of the sound.

The second method involves detecting differences in the arrival time of sound pressure waves at each eardrum. This method works best for frequencies below approximately 1,500 Hz. A 1,000 Hz tone produces pressure waves approximately 0.3 m apart. Because the distance between a person’s eardrums is about half that, a source of 1,000 Hz sound located to one side of the head will cause one eardrum to be pushed in while the other eardrum is being pulled out. In contrast, if the source of the sound is directly in front of the listener, both eardrums will move in synchrony.

Researchers have found that when the source of a sound is located to the side of the head, axons in the right and left auditory nerves will fire at different times. The brain is able to detect this disparity, which causes the sound to be perceived as being off to one side. In fact, the brain can detect differences in firing times of a fraction of a millisecond (ms, one-thousandth of a second). The easiest stimuli to locate are those that produce brief clicks, which cause brief bursts of neural activity. Apparently, it

is easiest for the brain to compare the arrival times of single bursts of incoming information.

Each of these cues, the difference in the loudness and the difference in the timing across the ears, allows one to discriminate between left and right. However, humans are also able to tell whether sounds come from in front or behind, above or below. This information cannot be encoded by differences across the ears. This is where the role of the pinna (mentioned above) comes to the fore. The pinna has a very distinctive shape and for humans its usefulness is far from obvious from its appearance – contrast the obvious funnel shape of a horse's ears which has plainly evolved to gather sound from a particular direction. The various ridges and folds of the human ear cause sound to interact with the surface in a process called acoustic interference. The result is that the timbre of the sound changes according to the sound direction. The importance of the pinna's corrugations in sound localisation can be demonstrated by filling up the folds with plastic material and showing that localisation becomes much poorer.

The interaction between audition and vision

The brain can also be 'persuaded' to believe that sounds can enhance the perception of visual stimuli. How senses interact is important because in real life we usually do not experience stimuli in only one sensory modality. In one study, eight observers watched a single flash, which was accompanied by multiple auditory beeps, spaced 57 ms apart (Shams *et al.*, 2000). In this condition, observers reported having seen several flashes and not the one actually presented. Multiple flashes were consistently seen when multiple beeps were presented. When beeps were presented over 70 ms apart, however, the illusion was diminished and observers reported seeing single flashes. When a single beep was presented with multiple flashes, observers correctly reported seeing multiple flashes. The

study highlights how manipulable our senses can be: in this case, simply increasing the number of presentations of stimuli in one modality (vision) while presenting single instances of a stimulus in another modality (audition) made people believe they had been presented with more stimuli in the second of these senses than they had.

A similar study explored the phenomenon whereby the introduction of a sound at the point when two identical visual targets pass 'through' each other leads people to report that they thought the two stimuli collided (Watanabe and Shimojo, 2001). Without the sound, people reported that the stimuli just seemed to stream through each other. Watanabe and Shimojo found that this collision effect could be weakened under certain conditions. For example, when identical auditory stimuli were presented 300 ms before and after the visual targets passed through each other, the collision effect did not occur. However, when the preceding and following sounds were different from the target sound, the collision effect remained. The context and the salience of the target sound, therefore, was important to preserving the effect.

The effect may exist because when two real objects collide they usually make a transient sound. The inclusion of the target noise in these experiments seemed to provide the 'missing' sound that you would expect to hear when two objects collided. But if a target noise is preceded or followed by a similar noise, it will be difficult for the viewer/listener to draw a cause-and-effect relationship between the contact of the two images and the simultaneous noise because the simultaneous noise is the same as that which preceded and followed the collision.

Audition and the temporal cortex

The cortical areas which mediate our perception of sound are located in the temporal cortex. One of the key features of the visual system is that it is organised hierarchically at the neural level. That is, sensory input is broken down and

Cutting edge – Hearing voices

We know that when we hear our own voice on some recording device, it sounds different. We also seem to orient towards our own name, more than that of others – the cocktail party effect described later in Chapter 9.

A group of researchers at the Institute for the Study of Child Development in New Jersey has recently reported that the brain regions activated when we hear our own name are different to those activated when we hear the names of others (Carmody and Lewis, 2006). They scanned four right-handed

young men, using fMRI, and found that areas of the left hemisphere – middle frontal cortex and middle and superior temporal cortex – were more active when the men heard their own names than others.

The researchers note that these regions are also those which become active when people make judgements about themselves or their personal qualities, suggesting that they have a role in mediating our perception of ourselves and of stimuli personally relevant to us as individuals.

then put together to form complex stimuli in various regions of the brain. This means that different regions of neurons are responsible for processing different types of visual stimuli. A similar phenomenon has also been demonstrated for the auditory sense: tones, non-speech stimuli, meaningless speech sounds and other types of auditory stimuli have been found to generate specific areas of the cortex (as well as areas they seem to have in common).

For example, a recent study investigated whether certain types of stimuli activated ‘core’ auditory areas or a ‘belt’ region outside this core area (Wessinger *et al.*, 2001). In an fMRI study, Wessinger *et al.*, presented pure tones and complex auditory stimuli to 12 healthy, right-handed men and women. They found that pure tones activated a core area – areas that surrounded Heschl’s gyrus – but more complex stimuli activated areas outside this core (the pure tones did not). The authors propose that this hierarchical system of sound analysis participates in the early processing of many sounds including those for speech.

Perry *et al.* (1999) found greater right-sided activation in the temporal cortex (the primary auditory cortex) when people sang than when they passively listened to singing. This region may be responsible for the processing of complex pitches. In an ingenious experiment, Halpern and Zatorre (1999) asked people to imagine the rest of a musical excerpt (the theme to the television series *Dallas*) after being cued with the first few notes. Blood flow was measured while participants imagined the piece of music. In the recruiting session, and prior to the scanning, the tune was played in order to familiarise participants with it. During scanning, the first five notes were played and participants were asked to imagine the rest of the sequence. When people imagined the rest of the tune, the right auditory association cortex and supplementary motor area were activated, suggesting that these regions are recruited in the imagination of meaningful complex auditory stimuli. Pantev *et al.* (1998) also found that musical training increased activation in those parts of the cortex involved in musical processing. In piano players who had played from age 12 to 28 years there was 25 per cent more activation in this region than there was in non-players.

The current view of the auditory cortex’s contribution to sound processing, therefore, sees it as a region that is made up of a core (comprising the auditory cortex and nearby areas) and a parabelt (Tramo, 2001; Zattore *et al.*, 2002), both of which contribute the hierarchical processing of sound. The core area extracts and analyses information about the pitch of tones (Zattore *et al.*, 2002). The belt and the parabelt in the right hemisphere appear to be areas which detect changes in the duration of notes and in the patterns of music; the parabelt in both hemispheres may be involved in grouping sounds by metre (Tramo, 2001). An area beyond the auditory

cortex, the frontal cortex, may be involved in organising sounds in time and keeping them ‘in mind’.

The where and what aspects of hearing have been likened to those for sight. That is, there are two streams in the brain that allow us to locate a sound and another to identify it (Kaas and Hackett, 1999). The what, or ventral, stream is found anterior to the core of the belt and extends to the prefrontal cortex. The where, or dorsal, stream is found in posterior areas and extends to the parietal lobe. See Figure 5.30. Neurons in the anterior belt area fire more actively when responding to the pattern of sounds but weakly when trying to locate them. This neurophysiological finding is supported by research on a double dissociation in two patients with brain injury. Patient ES, for example, can recognise sounds but the ability to localise is poor (Clarke *et al.*, 2002), whereas another patient is poor at recognising but good at localising sound. Figure 5.31 shows their responses and the brain regions damaged.

Given what you now know about the auditory system, how would you describe the physiological basis of listening to a favourite piece of music, from initial sensation to recognition?

Deafness

Deafness profoundly affects a person’s ability to communicate with others but hearing difficulties disappear in the company of other deaf people because they can sign read; it is only in the company of people who have normal hearing that deafness hinders a person’s ability to communicate (Sachs, 1989). People who are postlingually deaf – people who become deaf late in life, after they have learned oral and written language – are unlikely to

learn sign language. (In this context, lingual, from the word for 'tongue', refers to the acquisition of spoken language.) Some prelingually deaf people – people who are born deaf or who become deaf during infancy – never learn sign language, primarily because they are 'mainstreamed' in community schools or attend a school for the deaf that teaches oral communication.

A recent technological development, the cochlear implant, is an electronic device surgically implanted in the inner ear that can enable deaf people to hear. Over 120,000 people had received such implants (Moore and Shannon, 2009) and the procedure is very successful (Krueger *et al.*, 2008). It is most useful for two groups: people who become deaf in adulthood and very young children who can produce speech more easily if the implant occurs before the age of five (Tye-Murray *et al.*, 1995). Putting a cochlear implant in a young child means that the child's early education will be committed to the oralist approach. Many deaf people, however, resent the implication that deafness is something that needs to be repaired, seeing themselves as different but not at all defec-

tive. In very rare cases, individuals who have damage to the auditory cortex and should, therefore, be 'cortically' deaf, appear to show evidence of hearing.

If you had a child who was born deaf, would you send your child to a school that taught sign language or to one that emphasised speaking and lip-reading? Why? Now imagine that you are deaf (or, if you are deaf, that you are hearing). Would your answer change?

Gustation

We have two senses specialised for detecting chemicals in our environment: taste and smell. Together, they are referred to as the **chemosenses** and the process by which they sense chemicals is called **chemosensation**. Taste, or **gustation**, is the simplest of the sense modalities. We can perceive four, possibly five, qualities of taste: sourness, sweetness, saltiness, bitterness and umami (which produces a savoury sensation, like monosodium glutamate). Taste is not the same as flavour; the flavour of a food includes its odour, texture, temperature, shape as well as its taste: these are called head factors. You have probably noticed that the flavours of foods are diminished when you have a head cold. This loss of flavour occurs not because your taste buds are ineffective (you can actually tell whether a food is sweet or salty) but because congestion with mucus makes it difficult for odour-laden air to reach your sense of smell receptors. Without their characteristic odours to serve as cues, onions taste much like apples (although apples do not make your eyes water).

Taste receptors and the sensory pathway

The purpose of the sense of taste appears to be to provide guidance or warning to the gastrointestinal system: it will reject tastes it does not like and will accept those it does. This benefits us by allowing us to avoid ingesting potentially harmful substances (most poisons, for example, tend to be very bitter).

Our ability to taste depends on the tongue, mouth and the receptors in them. The tongue has a corrugated appearance, being marked by creases and bumps. The bumps are called **papillae** (from the Latin, meaning 'nipple'). Each papilla contains a number of taste buds (in some cases as many as 200) (see Figure 5.32(a) and (b) for an illustration).

A **taste bud** is a small organ that contains a number of receptor cells, each of which is shaped rather like a segment of an orange. The cells have hairlike projections

Figure 5.32 (a) The taste buds

called microvilli that protrude through the pore of the taste bud into the saliva that coats the tongue and fills the trenches of the papillae. Molecules of chemicals dissolved in the saliva stimulate the receptor cells, probably by interacting with special receptors on the microvilli that are similar to the postsynaptic receptors found on other neurons. The receptor cells form synapses with dendrites of neurons that send axons to the brain through three different cranial nerves, the vagus, cranial and facial nerves. Information is sent from the nerves to the medulla, then the thalamus and then the cortex, as Figure 5.33 shows.

Taste and the cortex

There also appear to be primary and secondary taste cortices in the brain, as Figure 5.34 illustrates (Rolls and Baylis, 1994). The primary taste (gustatory) area is found

Figure 5.34 The brain seems to have two taste areas – a primary and a secondary – located near the frontal lobe.

near the front of the brain in regions called the insula or frontal operculum and further back in part of the parietal cortex; the location of the secondary taste cortex is not as well documented but appears to be principally in the orbitofrontal cortex. This is where flavour is thought to be processed (see page 560 in Chapter 13 on flavour).

Other brain structures, such as the amygdala, contain cells that are responsive to taste and these cells may be partly responsible for determining the hedonic quality of taste – whether the food is palatable. The amygdala forms part of an area which Small *et al.* (1997) describe as the anteromedial temporal lobe (AMTL). Patients who have had this removed or damaged report increased sensitivity to bitter tastes and an elevated ability to recognise, but not detect, citric acid. Small *et al.* (2001a) have proposed that this region may play an important role in perceiving the intensity of tastes, especially aversive taste. One reason for the increase in intensity, may be that the damage to the AMTL disinhibited cells in the cortex that are sensitive to taste concentration or palatability.

In a recent experiment, participants who were hungry or sated were asked to taste sucrose, caffeine, saccharine and citric acid (Haase *et al.*, 2009). Hungry people activated different brain regions from those activated in satisfied ones. (Specifically, the insula, thalamus and substantia nigra). The sated participants showed less activation in the hippocampus and an area near the pre-frontal lobe.

The four or more qualities of taste

The surface of the tongue was once thought to be differentially sensitive to taste. The tip was considered most sensitive to sweet and salty substances; the sides to sour substances; and the back of the tongue, the back of the throat, and the soft palate overhanging the back of the tongue to bitter substances, as Figure 5.35 illustrates.

Figure 5.35 It is commonly thought that different parts of the tongue allow the experience of different tastes; the figure seen here, and in many other textbooks, is inaccurate.

Source: Whitfield, P. and Stoddart, M., *Pathways of Perception*. New York: Torstar Books.

This description, however, is largely mythical: the tongue is not this taste-specific and more than one region can detect the same sensation. There is also evidence that there may exist a fifth taste sensation, umami first reported at the beginning of the 20th century. This is difficult to describe accurately but appears to reflect the sensation we get when ingesting monosodium glutamate or very savoury foods (such as Chinese meals).

The physical properties of the molecules that we taste determine the nature of the taste sensations. Different molecules stimulate different types of receptor. For example, all substances that taste salty ionise (break into charged particles) when they dissolve. The most important salty substance is table salt – sodium chloride (NaCl). Other chlorides, such as lithium or potassium chloride, and some other salts, such as bromides or sulphates, are also salty in taste, but none tastes quite as salty as sodium chloride. This finding suggests that the specific function of salt-tasting receptors is to identify sodium chloride. Sodium plays a unique role in the regulation of our body fluid. If the body's store of sodium falls, we cannot retain water and our blood volume will fall. The result can be heart failure. Loss of sodium stimulates a strong craving for the salty taste of sodium chloride.

Both bitter and sweet substances seem to consist of large, non-ionising molecules. Scientists cannot predict, merely on the basis of shape, whether a molecule will taste bitter or sweet (or neither). Some molecules (such as saccharin) stimulate both sweet and bitter receptors; they taste sweet at the front of the tongue and bitter at the back of the palate and throat. Most likely, the function of the bitterness receptor is to avoid ingesting poisons. Many plants produce alkaloids that serve to protect them against being eaten by insects or browsing animals. Some of these alkaloids are poisonous to humans, and most of them taste bitter. In contrast, the sweetness receptor enables us to recognise the sugar content of fruits and other nutritive plant foods. When sweet-loving animals

gather and eat fruit, they tend to disperse the seeds and help propagate the plant; thus, the presence of sugar in the fruit is to the plant's advantage as well.

Most sour tastes are produced by acids, in particular, by the hydrogen ion (H⁺) contained in acid solutions. The sourness receptor probably serves as a warning device against substances that have undergone bacterial decomposition, most of which become acidic.

People who have suffered head injury or experienced certain types of medical treatment, such as radiotherapy, sometimes experience disorders of taste. These can vary from complete loss of taste (ageusia), decreased sensitivity (hypogeusia) and distorted taste sensations, especially those for meats, eggs, fruits, coffee and carbonated drinks (dysgeusia). Patients with these symptoms, however, are rare; only around 1 per cent of patients are ageusic, for example. A common complaint among those who suffer from one of these disorders is the lack of enjoyment of food and a loss of appetite.

The development of taste preference

Newborns seem to respond in a characteristic way to some tastes, especially if these tastes are strong. When babies are given a sweet stimulus to ingest, they typically lick their lips, suck and look relaxed; when given bitter substances, the corners of their mouths depress, they tighten their eyes, flatten their tongues and shake their heads. Many adults who experience unfamiliar, strong bitter tastes do the same. Sour substances tend to elicit similar responses to those elicited by bitter ones but in a more diminished way.

The development of taste preference appears to be highly malleable. For example, if a newborn is given sweetened water at 6 months of age, it will prefer sweetened water a year later; those fed normally will not show this preference for sweetened water. A similar finding is found when the newborn's diet contains additional salt

(Beauchamp and Moran, 1982; Harris and Booth, 1987). This learned response is also illustrated by adults' food preferences. Our liking for foods such as lima beans, coffee, whisky and chillies, for example, grows from late childhood; children tend to find these foods too bitter (or hot in the case of chillies) to ingest.

Olfaction

The sense of smell – **olfaction** – is one of the most interesting and puzzling of the sense modalities. It is unlike other sense modalities in two important ways. First, it is the only sense whose receptors are directly exposed to the environment. Secondly, people have difficulty identifying even familiar odours (Engen, 1987) although they can describe their properties very well (such as how nice smelling they are or what they remind them of). Odours have a powerful ability to evoke memories and feelings, even many years after an event, although they do not appear to be more effective than stimuli in other sensory modalities at doing this (Herz and Cupchik, 1992; Herz and Engen, 1996). At some time in their lives, most people encounter an odour that they recognise as having some childhood association, even though they cannot identify it. One of the most widely quoted examples is the experience of the French novelist Marcel Proust, whose mammoth series of autobiographical adventures, *À la recherche du temps perdu* (*Remembrance of Things Past*), was provoked by the odour of a madeleine cake dipped in tea which transported him back to his childhood. It is also a sense which we think we can do without; if asked which of the senses is least important to us or which we would be willing to relinquish if we had to, people usually nominate the sense of smell (Martin *et al.*, 2001).

Olfaction, like audition, seems to be an analytical sense modality. That is, when humans sniff air that contains a mixture of familiar odours, we usually identify the individual components. The molecules do not blend together and produce a single odour in the same way that lights of different wavelengths produce a single colour.

Other animals, such as dogs, have more sensitive olfactory systems than humans do because they have a great many more olfactory receptors (described below). The difference in sensitivity between our olfactory system and those of other mammals may be that other mammals put their noses where odours are the strongest – just above ground level. Even a bloodhound's nose would not be very useful if it were located five feet above the ground, as ours is. You can see how effective a hound's olfactory system is at tracking other animals from Figure 5.36. However, we should not underrate our own. We can

smell some substances at lower concentrations than can the most sensitive instruments (the human nose is actually more sensitive than a smoke detector) and a recent study has found that we can follow a 10 cm trail of chocolate essential oil in an open grass field while wearing a blind-fold (Porter *et al.*, 2007). This study also found that both nostrils were better than one at the task but, more specifically, that the velocity of air into the right nostril was 0.45 ms and in the left 0.3 ms. This gives a spatial reach of 1.5–2 cm in the left nostril and 1–1.5 cm in the right. There is also evidence of circadian asymmetry in sniffing. The velocity of inhalation is greater in one nostril than the other and the side changes throughout the day (Sobel *et al.*, 1999).

Odours interact with other senses in very peculiar ways. Djordjevic *et al.* (2004) asked participants to smell or imagine smelling the odours of either strawberry or ham as they took part in a taste detection task – the participants had to indicate at which point they detected the sweet taste of sucrose. People detected the taste of sucrose better when they smelled or imagined smelling strawberry than when they smelled/imagined smelling ham. The imagery of pleasant and unpleasant scents activates similar brain areas to those activated during the actual inhalation of those odours (Bensafi *et al.*, 2007). People exposed to a pleasant odour they were not consciously aware of, have been found to rate photographs of neutral faces as more likeable (Li *et al.*, 2007). The Cutting Edge section gives a more startling illustration.

Odours play an important role in the lives of most mammals. Although we do not make use of olfaction in identifying one another, we do use it to avoid some dangers, such as food that has spoiled, or gas. In fact, the odour of rotting meat will trigger withdrawal – a useful response if some of the rotten meat has been swallowed. Other animals recognise friends and enemies by means of

smell and use odours to attract mates and repel rivals. And the reproductive behaviour of laboratory mammals – and even the menstrual cycles of women – may be influenced by the odours emitted by other animals of the same species, a controversial topic taken up in the Controversies in Psychological Science section on p.200.

Cutting edge – Cheese, body odour and the orbitofrontal cortex

Our sense of smell is one of the most manipulable. People can be convinced that a neutral odour has a scent and, when told that an odour has a particular quality, judge that odour accordingly (regardless of whether it has that quality). Researchers at Oxford University presented the odour of isovaleric acid (which has a cheesy odour) to 12 healthy young men and told them it was either ‘body odour’ or ‘cheddar cheese’ (de Araujo *et al.*, 2005). Participant’s ratings of the odours’ pleasantness under each label condition, and their brain activation, was measured.

The odour was rated as significantly more unpleasant when labelled body odour than cheese, and activation in the anterior cingulate cortex and medial orbitofrontal cortex was greater when participants smelled clean air and the odour labelled cheese than body odour.

The experiment demonstrates neatly how semantic information can influence hedonic judgement.

Odour perception – An international perspective

Perfumery is a universal art and few of us have not received or bought a gift of scent or cologne, but do all cultures and nations respond to the same smells in the same way? As you might expect, the answer is no. In general, there are cross-cultural similarities in people’s responses to odour: there is a universal correlation between odour familiarity and pleasantness, for example. The more familiar a person thinks an odour is, the more likeable it is judged. A study of Japanese and German participants found that the number of memories evoked by pleasant and unpleasant odours was similar (Schleidt *et al.*, 1988). But different cultures do rate the pleasantness of some odours differently.

In one study, Haller *et al.* (1999) found that exposure to vanilla in childhood affected a German participant’s food preferences later in life (Germans, at one time, received bottled milk flavoured with vanilla). When German participants were asked to rate ketchup or ketchup scented with vanilla, those who had been bottle-fed preferred the vanilla ketchup, compared with those who were breast-fed.

More directly, Doty *et al.* (1985) compared the ability of American Korean, Caucasian, African American and Japanese participants to identify odours on a brief scratch and sniff test called the University of Pennsylvania Smell Identification Test (the UPSIT). The Koreans were better at identification than

were the Caucasians and African Americans; the last two groups were better than the Japanese, probably because the US-validated odours were more familiar to the Westerners than to the Japanese. A study of odour detection thresholds (the lowest concentration at which a person can detect an odour) reported lower detection thresholds for Japanese ink and aniseed (Hübener *et al.*, in press).

Cultures also differ in the way they classify odour. For example, when Japanese and Sherpa people were asked to classify 20 artificial scents into perceptually similar categories, there was agreement on most but the Japanese classified some odours as ‘fishy’: Sherpa are not used to eating fish but the Japanese are famously fish-friendly (Ueno, 1993). Americans and French people are more likely to describe fruit odorants as sweets or flowers and flower odorants as cleaning products than are Vietnamese raters (Chrea *et al.*, 2004).

One comprehensive study asked a sample of Japanese and German participants to rate the pleasantness and ‘edibility’ of three classes of odours which the authors described as ‘European’, ‘Japanese’ and ‘International’ (Ayabe-Kanamura *et al.*, 1998). Table 5.4 shows examples of each. Of the European odours, the Japanese sample rated the odours of church incense, anise and almond as less pleasant than did the

Odour perception – Continued

Table 5.4 The odorants used in Ayabe-Kanamura *et al.* (1998), together with participants' descriptions of them

Odorants	Descriptors
<i>Japanese</i>	
Dried bonito flakes	dried fish
Soy sauce	soy sauce, soy
Roasted tea	Japanese tea
Dried fermented soybeans	fermented soybeans
India ink	India ink
Japanese cypress wood flakes	wood, furniture
<i>International</i>	
Ground coffee	coffee
Grated dark chocolate	chocolate, cacao
Chopped, roasted peanuts	peanuts
Lowenbrau	beer
Vick's Vaporub	ointment with menthol
Angel	perfume
<i>European</i>	
Marzipan	almond, marzipan
Blue cheese	cheese
Pernod	anise
Italian salami	salami
Sawdust of pinewood	wood, furniture
Catholic church incense	incense

Germans, but rated the odour of cheese and pinewood as more pleasant. Of the international odours, the German sample rated perfume to be more pleasant and the odours of beer and peanuts to be less pleasant than did the Japanese. When asked whether the substance represented by an odour was edible, the Japanese rated the Japanese food odours to be more edible than did the Germans; the Germans found anise and almond to be more edible. The odours of cheese and peanuts were rated as more edible by the Japanese than the Germans.

A coda, however. The sense of smell is notoriously duplicitous and deceitful – think of trying to put a name to a familiar or unfamiliar odour. It is difficult and is summed up by the term 'tip-of-the-nose' phenomenon. In the study above, 25 per cent of the Japanese sample thought that India ink represented an edible substance; 40 per cent of Germans thought that Vick's Vaporub did.

Anatomy of the olfactory system

Figure 5.37 shows the anatomy of the olfactory system. The receptor cells for the olfactory system lie in the **olfactory mucosa**, one-inch square patches of mucous membrane located on the roof of the nasal sinuses, just under the base of the brain. The receptor cells have cilia that are embedded in the olfactory mucosa. They also have axons that pass through small holes in the bone above the olfactory mucosa and form synapses with neurons in the olfactory bulbs. The **olfactory bulbs** are stalk-like structures located at the base of the brain that contain neural circuits that perform the first analysis of olfactory information. There is evidence that the cortex also processes aspects of olfactory sensation and perception (Lorig, 1989; Small *et al.*, 1997; Martin, 1998).

For example, Martin (1998) recorded EEG from healthy individuals while they were exposed to a series of synthetic and real food odours. The odours included chocolate, spearmint, baked beans, strawberry, coffee and rotting

pork. The odours of spearmint and chocolate (but primarily chocolate) were associated with significant reductions in one type of brain activity, theta (which we will consider at greater length in Chapter 9). Increases in this EEG waveband are thought to be associated with increased attention; it is plausible that the change in response to chocolate may reflect this pleasant odour's ability to distract a person's attention and make them feel relaxed.

In a novel neuroimaging experiment, Small *et al.* (1997) compared neural activation while people smelled substances, tasted them or did both (that is, perceived flavour). In some conditions, the odours and the tastes did not match. Using soy sauce, water, coffee, grapefruit and strawberry as stimuli, the experimenters found that when the odours and tastes were presented simultaneously, there was a decrease in activation at the primary taste cortex and the primary and secondary olfactory cortex. When tastes and smells did not match, increases in the amygdala were found, suggesting a role for the amygdala in the processing of novel or unpleasant stimuli. (We return to this role of the amygdala in emotion in Chapter 13.)

Figure 5.37 The olfactory system.

The interaction between odour molecule and receptor appears to be similar to that of transmitter substance and postsynaptic receptor on a neuron. That is, when a molecule of an odorous substance fits a receptor molecule located on the cilia of a receptor cell, the cell becomes excited. This excitation is passed on to the brain by the axon of the receptor cell. Thus, similar mechanisms may detect the stimuli for taste and olfaction. However, the

mechanism for olfactory reception continues to be one of science's mysteries.

Unlike information from all other sensory modalities, olfactory information is not sent to the thalamus and then relayed to a specialised region of the cerebral cortex. Instead, olfactory information is sent directly to several regions of the limbic system, in particular to the amygdala and to the limbic cortex of the frontal lobe.

Controversies in Psychological Science – Do human pheromones exist?

The issue

Some species in the animal kingdom have a terrifically efficient sense of smell. Dogs have a remarkable ability to detect and discriminate between odours, hence their use in drug-sniffing operations. The odour of vaginal copulins can arouse male monkeys. Scents which produce stereotypical responses in a receiving organism without the scent being overtly detected are called **pheromones**. A well-known example is **androstenone** (its full, chemical name is 5-alpha-16-androst-16-en-3-one), a steroid developed in the testes of pigs which has a musk-like odour and is secreted in the saliva of male pigs during mating.

The unusual feature of androstenone is that it can induce a sow to adopt the mating position when it is sprayed on her. Farmers and vets can even buy the chemical in aerosol form, Boarmate, so that the sow can be prepared for mating (Figure 5.38). (In fact, truffle hunters use sows to detect the delicacy because it contains androstenone.) Pigs are not the only

species to secrete androstenone. It is also present in men's sweat glands and in the urine of men and women, although at stronger concentrations in men (Brooksbank *et al.*, 1974).

Does a human pheromone exist?

The evidence

One of the earliest studies of the pheromone effect in humans was conducted by Martha McClintock in the 1970s (McClintock, 1971). She found that 17–22-year-old women students who lived and slept in the same halls of residence reported menstrual synchrony. That is, their menstrual cycles began on or about the same time. The effect was unrelated to food intake, lifestyle pattern or stress. The result is difficult to explain because no mechanism that we know of can account for the finding. McClintock suggested that the mechanism might be pheromonal or mediated by an awareness of another's menstrual cycle. To explain the result, replications would be needed. If the effect was pheromonal then a controlled

Controversies in Psychological Science – *Continued*

experiment in which menstrual cycles were deliberately manipulated would show this. This is what Russell *et al.* (1980) did.

They applied the sweaty secretions of a woman who had a history of 28-day cycles and experience of ‘driving’ (that is influencing) other women’s cycles, on the upper lips of 5 women, 3 times a week for 4 months. Six individuals wore odourless alcohol (the control group). The mean difference in cycle onset for the experimental group was 3–9 days before the experiment; 3–4 days during driving. Controls’ figures were 8 days and 9.2 days, respectively. A significant difference, therefore, was found between the experimental group’s cycle onset and that of controls. However, there were some important limitations to the study. The experiment was not single- or double-blind, which means (as you will recall from Chapter 2) that the experimenters knew which participant was in each condition and each participant knew the purpose of the experiment. The woman who provided the samples was also one of the experimenters.

A similar experiment found that women reported shorter menstrual cycles when compounds from the follicular (late) stage of another woman’s cycle were placed on the upper lip; longer cycles were reported when receiving ovulatory compounds (Stern and McClintock, 1998). A group from the

Monell Chemical Senses Center and Chicago University also found that chemical substances collected from lactating women increased the ‘sexual motivation’ of other women (such as sexual desire and fantasy) (Spencer *et al.*, 2004). Women with partners experienced more sexual desire whereas women without partners experienced more sexual fantasies. Does this suggest that ‘pheromones’ can modulate ovulation? Or are the effects limited to healthy young women? Would the same effect occur in women on various types of oral contraceptive? And are there alternative explanations, other than pheromonal ones, for the results?

Questions such as these crop up quite often in pheromone research in humans. They become even more pertinent when examining the results of studies investigating the effect of ‘pheromones’ on sexual attractiveness. The majority of experiments, for example, have tended to expose subjects to volatile chemicals in contexts which are not generally appropriate. For example, participants have rated imaginary verbal descriptions of people (Filsinger *et al.*, 1984), pictures and slides of buildings, people and animals (Kirk-Smith and Booth, 1977; Kirk-Smith *et al.*, 1978) or have indicated the number of sexual partners they have recently had (Filsinger and Monte, 1986). They have worn masks impregnated with an odour (Cowley *et al.*, 1980), a necklace impregnated with the odour (Cowley and Brooksbank, 1991), worn the odour on the top lip (Benton, 1982), sat on a chair impregnated with the odour (Kirk-Smith and Booth, 1980; Pause, 2004), or used a doctored changing room cubicle (Gustavson *et al.*, 1987). A recent study has even found that the presence of androstadienone increased the perception of pain (Villemure and Bushnell, 2007). As you can see, none of these conditions reflects the behaviour and contexts normally seen when physical attraction might occur.

In the most ecologically valid experiment, Black and Biron (1982) required participants to interact with a confederate of the opposite sex who wore either androstenone or a control odour. The participant was later asked to rate the confederate for attractiveness. The experimenters found no effect of these chemicals on the rated attractiveness of the confederate.

Another investigation examined the effect of male and female fragrances on women’s genital arousal during the follicular and periovulatory stages as participants watched a hardcore video or sexually fantasised (Graham *et al.*, 2000). During the follicular stage only, genital arousal was greater during exposure to male fragrance when women were fantasising. One study found that exposure to 4, 16-androstadien-3-one made women feel more focused – although leaving other mood-related states unaffected (Lundstrom *et al.*, 2003) while another found that fertile women were more sensitive to the odour of this chemical than the odour of rose, whereas the opposite was true of women using oral contraceptives (Lundstrom *et al.*, 2006a).

Controversies in Psychological Science – Continued

When brain electrical activity in relation to this odour was measured in women, the brain responded more quickly to it than it did to control odours (Lundstrom *et al.*, 2006b). There may be reasons for this beyond pheromonal ones: androstenone can be perceived as unpleasant (smelling like a gents' lavatory) by some people and as a 'chemical' smell in those who can detect it but are not repulsed by it. Both reactions could have made the brain respond to this odour more quickly.

Curiously, homosexual men, like heterosexual women, show increased activation in the hypothalamus when smelling 4, 16-androstadien-3-one (Savic *et al.*, 2005). Common odours were found to activate similar areas in homosexual men and heterosexual men and women, suggesting that the response to the chemical can depend on sexual orientation more than sex.

In a related study in which the body odour preferences of homosexual and heterosexual men and women was measured, researchers found that heterosexual men and women and lesbians preferred the body odour of homosexual men to

gay men; gay men preferred the body odour of gay men (Martins *et al.*, 2005). None of the participants knew the sex or sexual orientation of the person who donated the body odour. All participants over 25, apart from gay men, preferred the body odour of lesbians to that of gay men. Gay men preferred the body odour of heterosexual women to that of heterosexual men. The results suggest that attraction to body odour can be sex- and sexual orientation- specific.

Conclusion

There is some evidence that the organ in the brain responsible for detecting and acting on pheromones (the vomeronasal organ) may be absent in humans (Moran *et al.*, 1995). If this organ is important for sensing pheromones then humans will have difficulty sensing pheromones. Meanwhile, however, the evidence suggests that if you want to attract a member of the opposite sex, a bottle of good perfume or cologne would be a better option than would exposing your armpits, or investing in a can of Boarmate.

The dimensions of odour

Although we know that there are at least four qualities of taste and that a colour can be specified by hue, brightness and saturation, the several attempts at classifying odour have not been particularly successful. It seems to be a slippery sense to make sense of. One of the most famous systems, Henning's odour prism (1916), seen in Figure 5.39, plotted different categories of odour qualities at six corners of a prism.

Recent research in molecular biology suggests that the olfactory system uses up to 1,000 different receptor molecules, located in the membrane of the receptor cells, to detect different categories of odours (Jones and Reed, 1989; Buck and Axel, 1991; Axel, 1995). Linda Buck and Michael Axel won the Nobel Prize in 2004 for their discovery – that a family of genes was responsible for coding olfactory receptors. There are around 1000 different receptors in mice and around 350 in humans (Buck, 2004). Presumably, the presence of molecules of a substance with a particular odour produces a particular pattern of activity in the olfactory system. That is, the molecules will strongly stimulate some receptors, weakly stimulate others, and stimulate still others not at all. This pattern of stimulation is transmitted to the brain, where it is recognised as belonging to a particular odour. Malnic *et al.* (1999) found that some odorants generated weak firing at some receptors and strong firing at others, as the large and

Figure 5.39 The odour prism proposed by Henning (1916).

small dots show in Figure 5.40 (a) and (b). It may be that different odorants are coded by different combinations of receptors so that one receptor could respond to more than one odorant. Researchers do not yet know exactly

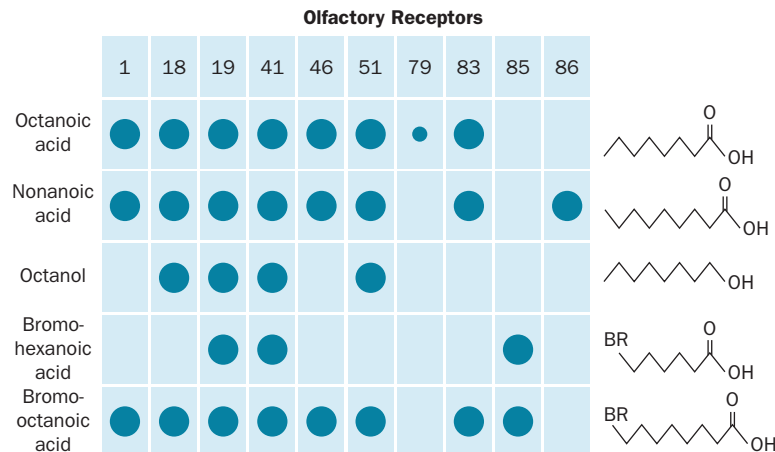

Figure 5.40 (a) Recognition profiles for some odorants. Large dots indicate that the odorant causes a high firing rate for the receptor listed along the top; small dots indicate lower firing rates for the receptor. The structure of the compounds are shown on the right.

which molecules stimulate which receptors; nor do they know how the information from individual olfactory receptor cells is put together.

Sex differences

Research suggests that women are, on average, better at identifying, recognising and detecting odours than are men (Doty *et al.*, 1985) and give more positive and less negative hedonic emotional responses to some odours (Seubert *et al.*, 2008). This sex difference may have important implications for any study of the neural basis of olfactory processing. If individual differences exist at the behavioural level (for example, detecting, recognising, identifying), then neural activation may be different in men and women when they both smell the same odours. To test this hypothesis, Yousem and his colleagues carried

out an fMRI study of the brain activation of eight right-handed men and eight right-handed women as they smelled pleasant, neutral and unpleasant odours (Yousem *et al.*, 1999). Activation was greater in women, especially in the left and right frontal and perisylvian regions.

The somatosenses

The body senses, or **somatosenses**, include our ability to respond to touch, vibration, pain, warmth, coolness, limb position, muscle length and stretch, tilt of the head and changes in the speed of head rotation. The number of sense modalities represented in this list depends on one's definition of a sense modality. However, it does not really matter whether we say that we respond to warmth and coolness by means of one sense modality or two different ones; the important thing is to understand how our bodies are able to detect changes in temperature.

Many experiences require simultaneous stimulation of several different sense modalities. For example, taste and odour alone do not determine the flavour of spicy food; mild (or sometimes not-so-mild) stimulation of pain detectors in the mouth and throat gives Mexican food its special characteristic. Sensations such as tickle and itch are apparently mixtures of varying amounts of touch and pain. Similarly, our perception of the texture and three-dimensional shape of an object that we touch involves cooperation among our senses of pressure, muscle and joint sensitivity, and motor control (to manipulate the object). If we handle an object and find that it moves smoothly in our hand, we conclude that it is slippery. If,

after handling this object, our fingers subsequently slide across each other without much resistance, we perceive a feeling of oiliness. If we sense vibrations when we move our fingers over an object, it is rough. And so on. If you close your eyes as you manipulate some soft and hard, warm and cold, and smooth and rough objects, you can make yourself aware of the separate sensations that interact and give rise to a complex perception.

The skin senses

The entire surface of the human body is innervated (supplied with nerve fibres) by the dendrites of neurons that transmit somatosensory information to the brain. Cranial nerves convey information from the face and front portion of the head (including the teeth and the inside of the mouth and throat); spinal nerves convey information from the rest of the body's surface. All somatosensory information is detected by the dendrites of neurons; the system uses no separate receptor cells. However, some of these dendrites have specialised endings that modify the way they transduce energy into neural activity.

Figure 5.41 shows the sensory receptors found in hairy skin and in smooth, hairless skin (such as skin on the palms of the hands or the soles of the feet). The most common type of skin sensory receptor is the free nerve ending, which resembles the fine roots of a plant. **Free nerve endings** infiltrate the middle layers of both smooth and hairy skin and surround the hair follicles in hairy skin. If you bend a single hair on your forearm, you will see how sensitive the free nerve endings are.

The largest of the special receptive endings, called the Pacinian corpuscle, is visible to the naked eye. **Pacinian corpuscles** are very sensitive to touch. When they are moved, their axons fire a brief burst of impulses. Pacinian

corpuscles are thought to be the receptors that inform us about vibration. Other specialised receptors detect other sensory qualities, including warmth, coolness and pain.

Temperature

There is general agreement that different sensory endings produce the sensations of warmth and coolness. Detectors for coolness appear to be located closer to the surface of the skin. If you suddenly place your foot under a stream of rather hot water, you may feel a brief sensation of cold just before you perceive that the water is really hot. This sensation probably results from short-lived stimulation of the coolness detectors located in the upper layers of the skin.

Our temperature detectors respond best to changes in temperature. Within reasonable limits, the air temperature of our environment comes to feel 'normal'. Temporary changes in temperature are perceived as warmth or coolness. Thus, our temperature detectors adapt to the temperature of our environment. This adaptation can be easily demonstrated. If you place one hand in a pail of hot water and the other in a pail of cold water, the intensity of the sensations of heat and cold will decrease after a few minutes. If you then plunge both hands into a bucket of water that is at room temperature, it will feel hot to the cold-adapted hand and cold to the hot-adapted hand. It is mainly the change in temperature that is signalled to the brain. Of course, there are limits to the process of adaptation. Extreme heat or cold will continue to feel hot or cold, however long we experience it.

Pressure

Sensory psychologists speak of touch and pressure as two separate senses. They define touch as the sensation of very light contact of an object with the skin and pressure as the sensation produced by more forceful contact. Sensations of pressure occur only when the skin is actually moving, which means that the pressure detectors respond only while they are being bent. Just how the motion stimulates the neurons is not known. If you rest your forearm on a table and place a small weight on your skin, you will feel the pressure at first, but eventually you will feel nothing at all, if you keep your arm still. You fail to feel the pressure not because your brain 'ignores' incoming stimulation but because your sensory endings actually cease sending impulses to your brain. Studies that have measured the very slow, very minute movements of a weight sinking down into the skin have shown that sensations of pressure cease when the movements stop. With the addition of another weight on top of the first one, movement and sensations of pressure begin again (Nafe and Wagoner, 1941). A person will feel a

Figure 5.41 Sensory receptors in hairy skin (left) and in hairless skin (right).

very heavy weight indefinitely, but the sensation is probably one of pain rather than pressure. In terms of the perception of a person's touch, we judge others' skin to be more pleasant than our own and their forearms as smoother, softer and less sticky (Guest *et al.*, 2009).

Sensitivity to subtle differences in touch and pressure varies widely across the surface of the body. The most sensitive regions are the lips and the fingertips. The most common measure of the tactile discrimination of a region of skin is the **two-point discrimination threshold**. To determine this measure, an experimenter touches a person with one or both legs of a pair of dividers and asks the person to say whether the sensation is coming from one or two points. The further apart the legs of the dividers must be before the person reports feeling two separate sensations, the lower the sensitivity of that region of skin, as seen in Figure 5.42.

Studies have also shown that the brain regions responsible for somatosensation may also be involved in the imagination of somatosensation. Data from neuroimaging studies of visual imagery and the imagination of movement, show that similar brain regions are activated during the actual perception of visual stimuli/the execution of an action and during the imagination of these visual stimuli/imagining making movements. You will find more on this phenomenon in the next chapter.

Pain

Pain is a complex sensation involving not only intense sensory stimulation but also an emotional component. That is, a given sensory input to the brain might be interpreted as pain in one situation and as pleasure in another. For example, when people are sexually aroused, they become less sensitive to many forms of pain and may even find such intense stimulation pleasurable.

Physiological evidence suggests that the sensation of pain is quite different from the emotional reaction to pain. Opiates such as morphine diminish the sensation of

pain by stimulating opioid receptors on neurons in the brain; these neurons block the transmission of pain information to the brain. In contrast, some tranquillisers (such as Valium) depress neural systems that are responsible for the emotional reaction to pain but do not diminish the intensity of the sensation. Thus, people who have received a drug like Valium will report that they feel the pain just as much as they did before but that it does not bother them much.

Many noxious stimuli elicit two kinds of pain: an immediate sharp, or 'bright', pain followed by a deep, dull, sometimes throbbing, pain. Some stimuli elicit only one of these two kinds of pain. For example, a pinprick will produce only the superficial 'bright' pain, whereas a hard blow from a blunt object to a large muscle will produce only the deep, dull pain. Different sets of axons mediate these two types of pain. Pain – or the fear of pain – is one of the most effective motivators of human behaviour. However, it also serves us well in the normal course of living. As unpleasant as pain is, we would have difficulty surviving without it. For example, pain tells us if we have sprained an ankle, broken a bone or have an inflamed appendix.

Neuroimaging studies have highlighted how the control of pain is related to different degrees of brain activation. Controlling this activation may reduce pain. For example, Koyama *et al.* (2005) administered thermal pain to 10 healthy volunteers as fMRI measured brain activation. As the pain became more intense, so did activation in the thalamus, prefrontal cortex and anterior cingulate cortex, areas of the brain known to respond to pain. When participants were told that they could expect a reduction in pain, however, there was a decrease in activation in these areas as well as a decrease in self-reported pain.

Taking this finding a step further, deCharms *et al.* (2005) speculated on what might happen if activity in the anterior cingulate cortex (ACC) could be manipulated. If it could be reduced, would participants experience less pain? Hypnosis, for example, has been associated with reduced pain and, in turn, less activation in the ACC. The researchers studied 36 healthy volunteers, some of whom undertook a training course in increasing/decreasing brain activation and pain. These included instructions either to pay attention to the pain or to direct attention away from it; to perceive the stimulus as tissue-damaging, or as a neutral sensory stimulus; to perceive the stimulus as being either very or not very intense; and to control the experience or to be controlled by it. The pain stimulus was heat.

When participants used these instructions to increase or decrease activation in the ACC, the perception of pain changed: those who were instructed to increase ACC activation, experienced more pain. When patients experiencing pain were given the same instructions, decreases in self-reported pain were found after training.

Figure 5.42 The method for determining the two-point discrimination threshold.

The results suggest that when healthy people exposed to pain, and patients experiencing pain, follow instructions designed to reduce activation in a part of the brain known to respond during painful experiences, then such experiences are reduced.

Phantom limbs

A particularly interesting form of pain sensation occurs after a limb has been amputated. After their limbs are gone, up to 70 per cent of amputees report that they feel as though their missing limbs still exist, and that they often hurt. This phenomenon is referred to as the **phantom limb** (Melzak, 1992). People who have phantom limbs report that the limbs feel very real, and they often say that if they try to reach out with their missing limbs, it feels as if they were responding. Sometimes, they perceive the limbs as sticking out, and they may feel compelled to avoid knocking them against the side of a door frame or sleeping in a position that would make the limbs come between them and the mattress. People have reported all sorts of sensations in phantom limbs, including pain, pressure, warmth, cold, wetness, itching, sweatiness and prickliness.

The classic explanation for phantom limbs has been activity of the sensory axons belonging to the amputated limbs. Presumably, this activity is interpreted by the nervous system as coming from the missing limbs. When nerves are cut and connections cannot be re-established between the proximal and distal portions, the cut ends of the proximal portions form nodules known as neuromas. The treatment for phantom pain has been to cut the nerves above these neuromas, to cut the bundles of nerve fibres that bring the information from these nerves into the spinal cord, or to make lesions in somatosensory pathways in the spinal cord, thalamus or cerebral cortex. Sometimes these procedures work for a while, but, unfortunately, the pain often returns.

Melzak (1992) suggests that the phantom limb sensation is inherent in the organisation of the parietal cortex. The parietal cortex is involved in our awareness of our own bodies. Indeed, people who have sensory neglect, caused by lesions of the right parietal lobe, have been known to push their own legs out of bed, believing that they actually belong to someone else. Melzak reports that some people who were born with missing limbs nevertheless experience phantom limb sensations, which would suggest that our brains are genetically programmed to provide sensations for all four limbs even if we do not have them.

The internal senses

Sensory endings located in our internal organs, bones and joints, and muscles convey painful, neutral, and in some cases pleasurable sensory information. For example, the

internal senses convey the pain of arthritis, the perception of the location of our limbs, and the pleasure of a warm drink descending to our stomachs.

Muscles contain special sensory endings. One class of receptors, located at the junction between muscles and the tendons that connect them to the bones, provides information about the amount of force the muscle is exerting. These receptors protect the body by inhibiting muscular contractions when they become too forceful. During competition, some weightlifters have received injections of a local anaesthetic near the tendons of some muscles to eliminate this protective mechanism. As a result, they are able to lift even heavier weights. Unfortunately, if they use this tactic, some tendons may snap or some bones may break.

Another set of stretch detectors consists of spindle-shaped receptors distributed throughout the muscle. These receptors, appropriately called **muscle spindles**, inform the brain about changes in muscle length. People are not conscious of the specific information provided by the muscle spindles, but the brain uses the information from these receptors and from joint receptors to keep track of the location of parts of the body and to control muscular contractions.

Together these sensations are called **proprioception** – our sense of bodily position and movement – and the receptors for this sense, as the examples above show, are found in the joints of skeletons and skeletal muscles. Receptors at joints are called mechanoreceptors and these are essential for allowing us to sense the angle of a joint. There are four types of mechanoreceptors, most of which have specific functions such as responding to rapid movement of limbs or maintaining the position of limbs and so on. However, as studies of limb amputation and even hip replacements show, these receptors may take some time to adapt to changing bodily structure or function. People who have had hip replacement surgery, for example, can sense limb position, but they do not sense it very well.

Unlike somatosensation, proprioceptive information seems to recruit different cortical regions so that data about tactile sensation are sent to specific areas of the somatosensory cortex and data from muscle afferents and from joints are sent to different ones. More complex proprioception and tactile sensation most probably involves posterior regions of the parietal lobes.

The vestibular senses

What we call our ‘sense of balance’ involves several senses, not just one. If we stand on one foot and then close our eyes, we immediately realise how important a role vision plays in balance. The **vestibular apparatus** of the inner ear provides only part of the sensory input that helps us remain upright.

The three **semicircular canals**, located in the inner ear and oriented at right angles to one another, detect changes in rotation of the head in any direction (see Figure 5.43). These canals contain a liquid. Rotation of the head makes the liquid flow, stimulating the receptor cells located in the canals.

Another set of inner ear organs, the **vestibular sacs**, contain crystals of calcium carbonate that are embedded in a gelatin-like substance attached to receptive hair cells. In one sac, the receptive tissue is on the wall; in the other, it is on the floor. When the head tilts, the weight of the calcium carbonate crystals shifts, producing different forces on the cilia of the hair cells. These forces change the activity of the hair cells, and the information is transmitted to the brain.

The vestibular sacs are very useful in maintaining an upright head position. They also participate in a reflex that enables us to see clearly even when the head is being jarred. When we walk, our eyes are jostled back and forth. The jarring of the head stimulates the vestibular sacs to cause reflex

Figure 5.43 The three semicircular canals and two vestibular sacs located in the inner ear.

movements of the eyes that partially compensate for the head movements. People who lack this reflex because of localised brain damage must stop walking in order to see things clearly, for example to read a street sign.

Chapter review

Sensory processing

- We experience the world through our senses. Our knowledge of the world stems from the accumulation of sensory experience and subsequent learning.
- All sensory experiences are the result of energy from events that is transduced into activity of receptors, which are specialised neurons. Transduction causes changes in the activity of axons of sensory nerves, and these changes in activity inform the sensory mechanisms of the brain about the environmental event. The information received from the receptors is transmitted to the brain by means of two coding schemes: anatomical coding and temporal coding.
- In nineteenth-century Germany, Weber devised the concept of the just-noticeable difference (jnd), and Fechner used the jnd to measure the magnitude of sensations.
- The methods of psychophysics apply to all sensory modalities, including sight, smell, taste, hearing and touch.

Vision

- The cornea and lens of the eyes cast an image of the scene on the retina, which contains photoreceptors: rods and cones. Cones gather visual information under illuminated conditions; rods work only when the light is very dim.
- The energy from the light that reaches cones is transduced into neural activity when photons strike molecules of photopigment, splitting them into their two constituents. This

event causes the cones to send information through the bipolar cells to the ganglion cells. The axons of the ganglion cells travel through the optic nerves and form synapses with neurons in the brain.

- Vision requires the behaviour of looking, which consists of moving our eyes and head. Small, involuntary movements keep an image moving across the photoreceptors, thus preventing them from adapting to a constant stimulus.
- Saccadic eye movements are rapid ocular movements that are conjugate in nature; each eye is fixed on the same point.
- The focus of the lenses of the eyes is adjusted when looking from near to distant objects (and vice versa).
- When an image of the visual scene is cast upon the retina, each part of the image has a different colour, which can be specified in terms of its hue (dominant wavelength), brightness (intensity) and saturation (purity).
- Information about colour is encoded trichromatically by your cones; the red, green and blue cones respond in proportion to the amount of the appropriate wavelength contained in the light striking them. This information is transformed into an opponent-process coding, signalled by the firing rates of red/green and yellow/blue ganglion cells, and is transmitted to the brain.
- There are many different types of defective colour vision. Individuals missing a photopigment are called dichromats (and the condition is called dichromacy) and use two primary colours for matching and confuse various colours; anomalous

trichromats (the condition is called anomalous trichromacy) have an altered – not missing – photopigment, and comprise the majority of men with colour defects; protanopia, the most serious condition, appears to result from a lack of the photopigment for red cones: red looks much darker than green, and reds and oranges generally appear very dark.

- Synaesthesia refers to the phenomenon whereby a stimulus in one modality evokes a sensation in another.

Audition

- The physical dimensions of sound – amplitude, frequency and complexity – can be translated into the perceptual dimensions of loudness, pitch and timbre for sounds ranging from 30 Hz to 20,000 Hz.
- Sound pressure waves put the process in motion by setting up vibrations in the eardrum, which are passed on to the ossicles. Vibrations of the stirrup against the membrane behind the oval window create pressure changes in the fluid within the cochlea that cause the basilar membrane to flex back and forth. This vibration causes the auditory hair cells on the basilar membrane to move relative to the tectorial membrane. The resulting pull on the cilia of the hair cells stimulates them to secrete a transmitter substance that excites neurons of the auditory nerve. This process informs the brain of the presence of a sound.
- Two different methods of detection enable the brain to recognise the pitch of a sound. Different high-frequency and medium-frequency sounds are perceived when different parts of the basilar membrane vibrate in response to these frequencies. Low-frequency vibrations are detected when the tip of the basilar membrane vibrates in synchrony with the sound, which causes some axons in the auditory nerve to fire at the same frequency.
- Low-frequency sounds are located by differences in the arrival time of the sound waves in each ear. High-frequency sounds are located by differences in intensity caused by the ‘sound shadow’ cast by the head.
- The auditory system will analyse sounds of complex timbre into their constituent frequencies, each of which causes a particular part of the basilar membrane to vibrate. All these functions proceed automatically.
- The temporal lobe contains the primary auditory cortex and is active during the comprehension of the phonological aspects of language tasks, and when listening to music.

Gustation and olfaction

- Gustation and olfaction refer to the senses of taste and smell, respectively, and are called chemical senses. Both are served by cells having receptors that respond selectively to various kinds of molecule.
- We can perceive sweet, salty, sour or bitter tastes and a fifth, umami (which delivers a savoury sensation). To most organisms, sweet and moderately salty substances taste pleasant, whereas sour or bitter substances taste unpleasant.
- Sweetness and saltiness receptors permit us to detect nutritious foods and sodium chloride. Sourness and bitterness receptors help us avoid substances that might be poisonous.
- Olfactory information combines with information about taste to provide us with the flavour of a food present in our mouths. We can distinguish countless different odours and can recognise smells encountered in childhood. Women tend to be better detectors of odours than men.
- Unlike visual stimuli, odours do not easily blend. The detection of different odours appears to be accomplished by up to 1,000 different receptor molecules located in the membrane of the olfactory receptor cells.
- Pheromones are chemicals produced by the body which generate a stereotypical behavioural or physiological response without necessarily being detected. The evidence for human pheromones is weak, probably because humans lack the vomeronasal organ necessary to respond to such stimuli.

The somatosenses

- The somatosenses gather several different kinds of information from different parts of the body.
- The skin senses of temperature, touch and pressure, vibration and pain inform us about the nature of objects that come in contact with our skin.
- Pacinian corpuscles in fingers can detect vibration caused by movement which helps us to determine the texture of surfaces.
- Temperature receptors detect hot and cold; free nerve endings can give rise to sensations of pain.
- Sensory receptors in muscles and joints inform the brain of the movement and location of arms and legs. This is called proprioception.
- The vestibular senses help an organism to keep balance.

Suggestions for further reading

Sensation – general reading

- Coren, S., Ward, L.M. and Enns, J.T. (2003) *Sensation and perception* (6th edn). Chichester: Wiley.
- Goldstein, E.B. (2004) *Blackwell Handbook of Sensation and Perception*. Oxford: Blackwell.

- Goldstein, E.B. (2007) *Sensation and Perception*. (7th edn). California: Thompson.
- Levine, M.W. and Shefner, J.M. (2000) *Fundamentals of Sensation and Perception*. Oxford: Oxford University Press.
- Schiffman, H.R. (2000) *Sensation and Perception: An integrated approach* (5th edn). Chichester: Wiley.

Scientific American, 2006, 16, 3.

Some excellent texts on sensation – and the Goldstein (2007) book is one of the very best on the subject. The special issue of the magazine focuses on the senses and includes excellent articles on the relationship between vision and consciousness, visual microchips, music and the brain, phantom limbs, how the blind draw, the chemistry of smell, and making sense of taste.

Vision

Bruce, V., Green, P. and Georgeson, M. (2003) *Visual Perception: Physiology, psychology and ecology* (4th edn). Hove: Psychology Press.

Gregory, R.L. (1998) *Eye and Brain: The psychology of seeing* (5th edn). New York: Oxford University Press.

Zeki, S. (1993) *A Vision of the Brain*. Oxford: Blackwell Scientific.

These three texts provide an excellent introduction to visual perception. Bruce et al.'s book is a good, solid undergraduate textbook covering most aspects of vision. Gregory's and Zeki's books provide a neurophysiological account of vision: these are exemplary texts of their kind and you should try to consult these.

Audition

King, A.J. and Nelken, I. (2009) Unravelling the principles of auditory cortical processing. *Nature Neuroscience*, 12, 698–701

Moore, D.R. and Shannon, R.V. (2009) Beyond cochlear implants. *Nature Neuroscience*, 12, 6, 686–691

Schnupp, J.W.H. and Carr, C.E. (2009) On hearing with more than one ear. *Nature Neuroscience*, 12, 692–697.

Yost, W.A. (1994) *Fundamentals of Hearing: An introduction* (3rd edn). San Diego: Academic Press.

Zatorre, R.J., Berlin, P. and Penhune, V.B. (2002) Structure and function of auditory cortex: Music and speech. *Trends in Cognitive Sciences*, 6, 1, 37–46.

There are many excellent books on hearing. These two are recommended for their thoroughness and accuracy. The Zatorre et al. article is a good review of the role of the cortex in the processing of sound.

Sensory interaction

Kayser, C. (2007) Listening with your eyes. *Scientific American Mind*, 18, 2, 24–29.

A nice article on the interaction between audition and vision.

Somatosensation

Romo, R. and Salinas, E. (2001) Touch and go: Decision-making mechanisms in somatosensation. *Annual Review of Neuroscience*, 24, 107–37.

Dobbs, D. (2007) The pain gate. *Scientific American Mind*, 18, 2, 48–55.

A detailed but informative review of somatosensation and a provocative article on how a rare disorder can shed some light on how we experience pain.

Olfaction and gustation

Doty, R.L. (2003) *Handbook of Olfaction and Gustation* (2nd edn). New York: Dekker.

Martin, G.N. (2004) A neuro-anatomy of flavour. *Petits Propos Culinaires*, 76, 58–82.

Smith, D.V. and Margolskee, R.F. (2001) Making sense of taste. *Scientific American Mind*, March, 26–33.

Doty's edited book covers a broad range of topics related to olfaction and gustation, with a particularly good introductory chapter. The article by Smith and Margolskee provides a very good review of our current understanding of the sense of taste. Martin's article is a good review of the neuro-anatomy of smell and taste.

Perception

In 1988, police raided the home of Cherry Groce, searching for her son, Michael, who was suspected of a robbery at a building society. A police officer shot Mrs Groce in the raid and the incident attracted considerable publicity. Subsequently, the son was apprehended and prosecuted for the robbery, a prosecution based entirely on the evidence of a CCTV (closed circuit television) image which showed a young black man, alleged to be Groce. One witness for the prosecution claimed that he was able to prove that the identities matched by comparing the precise numbers of pixels (the elements which make up a picture) separating key features of the face.

Now this was impressive technical stuff for a jury, until the defence called an expert in facial movement. Alf Linney, a medical physicist from University College London, pointed out that if any of his students had committed such elementary mistakes in face comparison and measurement (not correcting for viewpoint and resolution), they would certainly fail.

Michael Groce was acquitted.

Explore the accompanying videos, simulations, and animations on MyPsychLab. This chapter includes activities on: Facial perception • Recognising the sex of a face • Cues to depth • The phi phenomenon • Check your understanding and prepare for your exams using the multiple choice, short answer and essay practice tests also available.

WHAT YOU SHOULD BE ABLE TO DO AFTER READING CHAPTER 6

- Define perception.
- Describe and understand how form, motion and space might be perceived.
- Describe the way in which the brain processes different types of visual information.
- Describe and understand the way in which we recognise faces and other types of stimuli.
- Understand the consequences of brain damage on visual perception and be aware of how these might help us to understand how the brain normally perceives.

QUESTIONS TO THINK ABOUT

- How do we assemble sensory cues from the environment and turn them into something meaningful?
- What is it about a face that makes it recognisable?
- How can we perceive a moving object as moving?
- How can we tell a moving car from a moving bus or train?
- Damage to which parts of the brain do you think would impair perception?
- Does the brain process different types of perception – form, space, motion, colour – differently?
- Are there stimulus-specific brain regions, ones that respond to specific classes of stimuli but not to others?

The nature of perception

Take a look around you – around the room or out the window. What do you see as you and your eyes move around? Shapes? Figures? Background? Shadows? Areas of light and dark? Your knowledge of the objects you see and their relative location is extensive, and you have a good idea of what they will feel like, even if you have not touched them. If the lighting suddenly changes (if lamps are turned on or off or if a cloud passes in front of the sun), the amount of light reflected by the objects in the scene changes too, but your perception of the objects remains the same – you see them as having the same shape, colour and texture as before. Similarly, you do not perceive an object as increasing in size as you approach it, even though the image it casts upon your retina does get larger. Form, movement and space are the essential elements of perception.

The brain receives fragments of information from approximately 1 million axons in each of the optic nerves. It combines and organises these fragments into the perception of a scene – objects having different forms, colours and textures, residing at different locations in three-dimensional space. Even when our bodies or our eyes move, exposing the photoreceptors to entirely new patterns of visual information, our perception of the scene before us does not change. We see a stable world, not a moving one, because the brain keeps track of our own movements and those of our eyes and compensates for the constantly changing patterns of neural firing that these movements cause.

Definition of perception

Perception is the process by which we recognise what is represented by the information provided by our sense organs. This process gives unity and coherence to this input. Perception is a rapid, automatic, unconscious process; it is not a deliberate one in which we puzzle out the meaning of what we see. We do not first see an object and then perceive it; we simply perceive the object. Occasionally we do see something ambiguous and must reflect about what it might be or gather further evidence to determine what it is, but this situation is more problem-solving than perception. If we look at a scene carefully, we can describe the elementary sensations that are present, but we do not become aware of the elements before we perceive the objects and the background of which they are a part. Our awareness of the process of visual perception comes only after it is com-

plete; we are presented with a finished product, not the details of the process.

The distinction between sensation and perception is not easy to make; in some respects, the distinction is arbitrary. Probably because of the importance we give to vision and because of the richness of the information provided by our visual system, psychologists make a more explicit distinction between visual sensation and perception than they do for any other sensory system.

Perception of form

When we look at the world, we do not see patches of colours and shades of brightness. We see things – cars, streets, people, books, trees, dogs, chairs, walls, flowers, clouds, televisions. We see where each object is located, how large it is, and whether it is moving. We recognise familiar objects and also recognise when we see something we have never seen before. The visual system is able to perceive shapes, determine distances and detect movements; it tells us what something is, where it is located, and what it is doing.

Figure and ground

Most of what we see can be classified as either object or background. Objects are things having particular shapes and particular locations in space. Backgrounds are in essence formless and serve mostly to help us judge the location of objects we see in front of them. Psychologists use the terms **figure** and **ground** to label an object and its background, respectively. The classification of an item as a figure or as a part of the background is not an intrinsic property of the item. Rather, it depends on the behaviour of the observer. If you are watching some birds fly overhead, they are figures and the blue sky and the clouds behind them are part of the background. If, instead, you are watching the clouds move, then the birds become background. If you are looking at a picture hanging on a wall, it is an object. Sometimes, we receive ambiguous clues about what is object and what is background. For example, do you think that Figure 6.1 illustrates two faces or a wine goblet?

What are the characteristics of the complex patterns of light – varying in brightness, saturation and hue – that give rise to perceptions of figures, of things? One of the most important aspects of form perception is the existence of a boundary. If the visual field contains a sharp and distinct change in brightness, colour or texture, we

Figure 6.1 A drawing in which figure and ground can be reversed. You can see either two faces against a white background or a goblet against a dark background.

perceive an edge. If this edge forms a continuous boundary, we will probably perceive the space enclosed by the boundary as a figure, as Figure 6.2 illustrates.

Organisation of elements: the principles of Gestalt

Most figures are defined by a boundary. But the presence of a boundary is not necessary for the perception of form. Figure 6.3 shows that when small elements are arranged in groups, we tend to perceive them as larger figures. Figure 6.4 demonstrates illusory contours – lines that do not exist.

Figure 6.3 Grouping. We tend to perceive a group of smaller elements as a larger figure.

In this figure, the orientation of the pie-shaped objects and the three 45-degree segments makes us perceive two triangles, one on top of the other. The one that looks like it is superimposed on the three black circles even appears to be brighter than the background.

As you saw in Chapter 1, in the early twentieth century, a group of psychologists, Max Wertheimer (1880–1943), Wolfgang Kohler (1887–1967) and Kurt Koffka (1886–1941), devised a theory of perception called **Gestalt psychology**. *Gestalt* is

Figure 6.4 Illusory contours. Even when boundaries are not present, we can be fooled into seeing them. The triangle with its point down looks brighter than the surrounding area.

Figure 6.2 Form perception and boundaries. We immediately perceive even an unfamiliar figure when its outline is closed.

the German word for 'form'. They maintained that the task of perception was to recognise objects in the environment according to the organisation of their elements. They argued that in perception the whole is more than the sum of its parts. Because of the characteristics of the visual system of the brain, visual perception cannot be understood simply by analysing the scene into its elements. Instead, what we see depends on the relations of these elements to one another (Wertheimer, 1912).

Elements of a visual scene can combine in various ways to produce different forms. Gestalt psychologists have observed that several principles of grouping can predict the combination of these elements. The fact that our visual system groups and combines elements is useful because we can then perceive forms even if they are fuzzy and incomplete. The real world presents us with objects partly obscured by other objects and with backgrounds that are the same colour as parts of the objects in front of them. The laws of grouping discovered by Gestalt psychologists describe the ability to distinguish a figure from its background.

The **adjacency/proximity principle** states that elements that are closest together will be perceived as belonging together (Wertheimer, 1912). Figure 6.5 demonstrates this principle. The pattern on the left looks like five vertical columns because the dots are closer to their neighbours above and below them than to those located to the right and to the left. The pattern on the right looks like five horizontal rows.

The **similarity principle** states that elements that look similar will be perceived as part of the same form. You can easily see the diamond inside the square in Figure 6.6.

Good continuation is another Gestalt principle and refers to predictability or simplicity. For example, in Figure 6.7 it is simpler to perceive the line as following a smooth course than as suddenly making a sharp bend.

Often, one object partially hides another, but an incomplete image is perceived. The **law of closure** states that our visual system often supplies missing information and 'closes' the outline of an incomplete figure. For example, Figure 6.8 looks a bit like a triangle, but if you

Figure 6.5 The Gestalt principle of proximity. Different spacing of the dots produces five vertical or five horizontal lines.

Figure 6.6 The Gestalt principle of similarity. Similar elements are perceived as belonging to the same form.

place a pencil on the page so that it covers the gaps, the figure undeniably looks like a triangle.

The final Gestalt principle of organisation relies on movement. The **principle of common fate** states that elements that move in the same direction will be perceived as belonging together and forming a figure. In the forest, an animal is camouflaged if its surface is covered with the same elements found in the background – spots of brown, tan and green – because its boundary is obscured. There is no basis for grouping the elements on the animal. As long as the animal is stationary, it remains well hidden. However, once it moves, the elements on its surface will move together, and the animal's form will quickly be perceived.

Figure 6.7 The Gestalt principle of good continuation. It is easier to perceive a smooth continuation than an abrupt shift.

Figure 6.8 The Gestalt principle of closure. We tend to supply missing information to close a figure and separate it from its background. Lay a pencil across the gaps and see how strong the perception of a complete triangle becomes.

Models of pattern perception

Templates and prototypes

One explanation for our ability to recognise shapes of objects is that as we gain experience looking at things, we acquire templates, which are special kinds of visual memories stored by the visual system. A **template** is a type of pattern used to manufacture a series of objects (Selfridge and Neisser, 1960). When a particular pattern of visual stimulation is encountered, the visual system searches through its set of templates and compares each of them with the pattern provided by the stimulus. If it finds a match, it knows that the pattern is a familiar one. Connections between the appropriate template and memories in other parts of the brain could provide the name of the object and other information about it, such as its function, when it was seen before, and so forth.

The template model of pattern recognition has the virtue of simplicity. However, it is unlikely that it could actually work because the visual system would have to store an unreasonably large number of templates. Despite the fact that you may look at your hand and watch your fingers wiggling about, you continue to recognise the pattern as belonging to your hand. How many different templates would your visual memory have to contain just to recognise a hand? Figure 6.9 illustrates this problem using the letter A.

A more flexible model of pattern perception suggests that patterns of visual stimulation are compared with prototypes rather than templates. **Prototypes** (Greek for ‘original model’) are idealised patterns of a particular shape; they resemble templates but are used in a much more flexible way. The visual system does not look for exact matches between the pattern being perceived and the memories of shapes of objects but accepts a degree of disparity; for instance, it accepts the various patterns produced when we look at a particular object from different viewpoints.

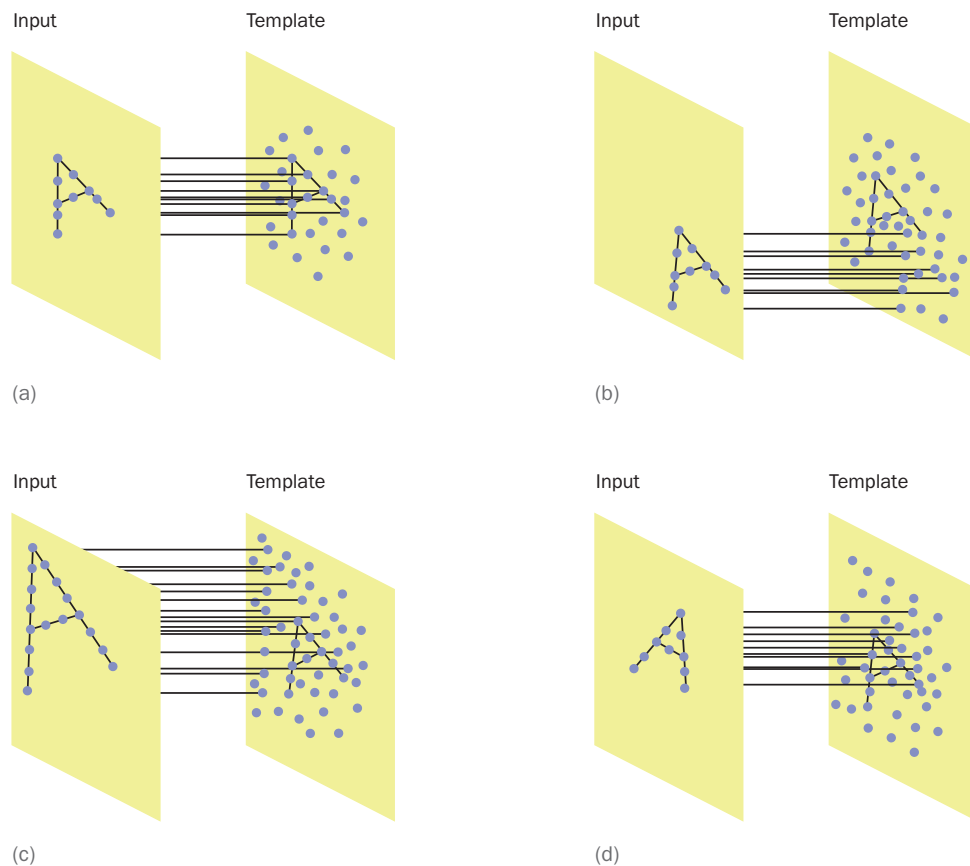

Figure 6.9 These four figures illustrate how template matching can fail. The position of the input may change **(b)**, its size may change **(c)** or its orientation may change **(d)**.

Source: Neisser, U., *Cognitive Psychology*. New York: Appleton-Century-Crofts, 1967. Reprinted with permission.

Most psychologists believe that pattern recognition by the visual system does involve prototypes, at least in some form. For example, you can probably identify maple trees, fir trees and palm trees when you see them. In nature, each tree looks different from all the others, but maples resemble other maples more than they resemble firs, and so on. A reasonable assumption is that your visual system has memories of the prototypical visual patterns that represent these objects. Recognising particular types of tree, then, is a matter of finding the best fit between stimulus and prototype.

The visual system of the brain may indeed contain generic prototypes that help us recognise objects we have never seen before: coffee cups, maple trees, human faces. But we do more than recognise categories of objects; we can recognise particular coffee cups, maple trees or human faces. In fact, we can learn to recognise enormous numbers of objects. Think of how many different people you can recognise by sight, how many buildings in your town you can recognise, how many pieces of furniture in your house and in your friends' houses you are familiar with – the list will be very long. Standing (1973) showed people 10,000 colour slides and found that they could recognise most of them weeks later, even though they had seen them just once.

Feature detection models

Some psychologists suggest that the visual system encodes images of familiar patterns in terms of **distinctive features** – collections of important physical features that specify particular items (Selfridge, 1959). We are better at distinguishing some stimuli from others. We are better at searching for the letter A among a series of Bs than we are searching for the letter B among a series of As; we are better at finding orange-coloured objects in a series of red ones than vice versa; we find it easier to find a tilted item in a series of vertical items than finding a vertical item in a series of tilted ones. Similarly, we are better at finding a mobile object in a series of stationary ones than a stationary one in a series of mobile ones, we can detect bumps in a display of bumpy and flat surfaces better than we can the absence of bumps, and we are better at finding a single stimulus in an array of different stimuli when there are many more different stimuli. It appears, then, that some stimuli have more distinctive features than others and this enhances discrimination.

Figure 6.10 contains several examples of the letter N. Although the examples vary in size and style, recognising them is not problematic because your visual system contains a specification of the distinctive features that fit the criterion for an N: two parallel vertical lines connected by

Figure 6.10 Distinctive features. We easily recognise all of these items as the letter N.

a diagonal line sloping downward from the top of the left one to the bottom of the right one.

An experiment by Neisser (1964) supports the hypothesis that perception involves analysis of distinctive features. Figure 6.11 shows one of the tasks he asked people to do. The figure shows two columns of letters. The task is to scan through them until you find the letter Z, which occurs once in each column.

You probably found the letter in the left column much faster than you did the one in the right column. Why? The letters in the left column share few features with those found in the letter Z, so the Z stands out from the others. In contrast, the letters in the right column have

GDOROC	IVEMXW
COQUCD	XVIWME
DUCOQG	VEMIXW
GRUDQO	WEKMVI

Source: Adapted from Neisser, J., Visual search. *Scientific American Mind*, 1964, 210, 94–102.

many features in common with the target letter, and thus the Z is ‘camouflaged’.

There are some phenomena that cannot easily be explained by the distinctive-features model. The model suggests that the perception of an object consists of analysis and synthesis; the visual system first identifies the component features of an object and then adds up the features to determine what the object is. We might expect, then, that more complex objects, having more distinctive features, would take longer to perceive. But often, the addition of more features, in the form of contextual cues, speeds up the process of perception. Figure 6.12 contains two sets of four items. One item in each is different from the other three.

The patterns in both sets differ with respect to only one feature: the tilt of the diagonal line. But the addition of the horizontal and vertical lines in Figure 6.12 (b) makes the perceptual task much easier. We see a triangle and three right angles bisected by a diagonal line; the triangle just pops out as being different. If we perceived individual features (such as the diagonal lines) before perceiving more complex figures (such as triangles and bisected right angles) that are composed of these features, then we should perceive simpler figures faster than we perceive more complex ones. The fact that we do not means that a perception is not simply an assembly of individual features.

The distinctive-features model appears to be a reasonable explanation for the perception of letters, but what about

Figure 6.12 Contextual cues. Perceiving a simple stimulus is facilitated by contextual cues. The line that does not match the other three is more easily recognised in (b).

more natural stimuli, which we encounter in places other than the written page? Biederman (1987, 1990) suggests a model of pattern recognition that combines some aspects of prototypes and distinctive features. He suggests that the shapes of objects that we encounter can be constructed from a set of 36 different shapes that he refers to as **geons**. Figure 6.13 illustrates a few geons and some objects that can be constructed from them. Perhaps, Biederman suggests, the visual system recognises objects by identifying the particular sets and arrangements of geons that they contain.

Even if Biederman is correct that our ability to perceive categories of common objects involves recognition of geons, it seems unlikely that the geons are involved in

Figure 6.13 Geons for perception. (a) Several different geons. (b) The combination of two or three geons (indicated by the numbers) into common three-dimensional objects.

Source: Adapted from Biederman, I., Higher-level vision. In *An Invitation to Cognitive Science. Vol. 2: Visual Cognition and Action*, edited by D.N. Osherson, S.M. Kosslyn and J. Hollerbach. Cambridge, MA: MIT Press, 1990.

perception of particular objects. For example, it is difficult to imagine how we could perceive faces of different people as assemblies of different sets of geons. The geon hypothesis appears to work best for the recognition of prototypes of generic categories: telephones or torches in general rather than the telephone on your desk or the torch a friend lent you.

Biederman points out that particular features of figures – cusps and joints formed by the ends of line segments – are of critical importance in recognising drawings of objects, presumably because the presence of these joints enables the viewer to recognise the constituent geons. Figure 6.14 shows two sets of degraded images of drawings of five common objects. One set, (a), shows the locations of cusps and joints; the other, (b), does not.

Figure 6.14 Incomplete figures. (a) With cusps and joints. (b) Without cusps and joints. Which set is easier to recognise?

Source: Adapted from Biederman, I., Higher-level vision. In *An Invitation to Cognitive Science. Vol. 2: Visual Cognition and Action*, edited by D.N. Osherson, S.M. Kosslyn and J. Hollerbach. Cambridge, MA: MIT Press, 1990.

Biederman (1990) observed that people found the items with cusps and joints much easier to recognise.

Top-down processing: the role of context

We often perceive objects under conditions that are less than optimum; the object is in a shadow, camouflaged against a similar background or obscured by fog. Nevertheless, we usually manage to recognise the item correctly. We are often helped in our endeavour by the context in which we see the object. For example, look at Figure 6.15. What do you see? Can you tell what they are? Now look at Figure 6.16. With the elements put in context it is quite easy to see what they are.

Palmer (1975b) showed that even more general forms of context can aid in the perception of objects. He first showed his participants familiar scenes, such as a kitchen. Next, he used a tachistoscope to show them drawings of individual items and asked the participants to identify them. A **tachistoscope** can present visual stimuli very briefly so that they are difficult to perceive (nowadays we would use a computer to perform the same function). Sometimes, participants saw an object that was appropriate to the scene, such as a loaf of bread. At other times, they saw an inappropriate but similarly shaped object, such as a letterbox (see Figure 6.17).

Figure 6.15 Simple elements that are difficult to recognise without a context.

Figure 6.16 An example of top-down processing. The context facilitates our recognition of the items shown in Figure 6.15.

Figure 6.17 Stimuli from the experiment by Palmer (1975b). After looking at the contextual scene, participants were shown one of the stimuli below it very briefly, by means of a tachistoscope.

Source: Palmer, S.E., The effects of contextual scenes on the identification of objects. *Memory and Cognition*, 1975, 3, 519–26. Reprinted by permission of the Psychonomic Society, Inc.

Palmer found that when the objects fitted the context that had been set by the scene, participants correctly identified about 84 per cent of them. But when they did not, performance fell to about 50 per cent. Performance was intermediate in the no-context control condition, under which subjects did not first see a scene. Thus, compared with the no-context control condition, an appropriate context facilitated recognition and an inappropriate one interfered with it.

The context effects demonstrated by experiments such as Palmer's are not simply examples of guessing. That is, people do not think to themselves, 'Let's see, that shape could be either a letterbox or a loaf of bread. I saw a picture of a kitchen, so I suppose it's a loaf of bread.' The process is rapid, unconscious and automatic; thus, it belongs to the category of perception rather than to problem-solving, which is much slower and more deliberate. Somehow, seeing a kitchen scene sensitises the neural circuits responsible for the perception of loaves of bread and other items we have previously seen in that context.

Psychologists distinguish between two categories of information-processing models of pattern recognition: bottom-up processing and top-down processing. In

bottom-up processing, also called data-driven processing, the perception is constructed out of the elements – the bits and pieces – of the stimulus, beginning with the image that falls on the retina. The information is processed by successive levels of the visual system until the highest levels (the 'top' of the system) are reached, and the object is perceived. **Top-down processing** refers to the use of contextual information – to the use of the 'big picture'. Presumably, once the kitchen scene is perceived, information is sent from the 'top' of the system down through lower levels. This information excites neural circuits responsible for perceiving those objects normally found in kitchens and inhibits others. Then, when the subject sees a drawing of a loaf of bread, information starts coming up through the successive levels of the system and finds the appropriate circuits already warmed up, so to speak.

Haenny *et al.* (1988) obtained direct evidence that watching for a particular stimulus can, indeed, 'warm up' neural circuits in the visual system. They trained monkeys to look at a pattern of lines oriented at a particular angle, to remember that pattern, and then to pick it out from a series of different patterns presented immediately afterwards. A correct response would be rewarded by a sip of fruit juice. While the animals were performing the task, the experimenters recorded the activity of individual neurons in the visual association cortex. They found that watching for a pattern of lines having a particular orientation affected the responsiveness of the neurons. For example, if the monkeys were watching for a pattern containing lines oriented at 45 degrees, neurons that detected lines of that orientation responded more vigorously than normal when that pattern was presented again. Haenny *et al.* found that this enhancement could even be produced by letting the monkeys feel the orientation of a pattern of grooves in a metal plate they could not see; when a subsequent visual pattern contained lines whose orientation matched that of the grooves, a larger neural response was seen.

In most cases, perception consists of a combination of top-down and bottom-up processing. Figure 6.18 shows several examples of objects that can be recognised only by a combination of both forms of processing. Our knowledge of the configurations of letters in words provides us with the contexts that permit us to organise the flow of information from the bottom up.

Direct perception: Gibson's affordances

In the chapter so far we have considered some of the mechanisms that underlie visual perception. But is this perception a response or a process? That is, is visual perception an

Figure 6.18 Examples of combined top-down/bottom-up processing. The effect of context enables us to perceive the letters despite the missing or ambiguous features. Note that a given letter may be perceived in more than one way, depending on the letters surrounding it.

active or passive process? We saw in an earlier section on cross-cultural differences that context is important for visual perception. The psychologist J.J. Gibson took this notion a step further. Over a period of 35 years, Gibson proposed a theory of perception which argued that perception was direct and did not depend on cognitive processes to bring together fragmented data (Gibson, 1950, 1966, 1979). Because of this, it is considered a direct theory of perception. Originally, Gibson was interested in distinguishing between unsuccessful and successful Second World War pilots. Some of the unsuccessful pilots were unable to land accurately and seemed unable to appreciate distance. However, Gibson found that even when these pilots were given training in depth perception – which may have remedied the problem – they continued to have difficulty.

According to Gibson, ‘perceiving is an act, not a response; an act of attention, not a triggered impression; an achievement, not a reflex’ (Gibson, 1979). Gibson’s view of perception was that classical optical

science ignored the complexity of real events. For example, it would focus on the effects of trivial, basic or simple stimuli on perceptual response. Gibson abandoned the depth/space perception view of the world and, instead, suggested that our perception of surfaces was more important. Surfaces comprised ground (which we discussed earlier) and texture elements in surfaces that would be attached or detached. Attached features would include bumps and indentations in the surface, such as rocks or trees; detached features would include items such as animals (which are detached from the surface).

Given the complex world in which we live, we must be able to perceive not just simple stimuli but stimuli which mean something more to us. We must decide whether an object is throwable or graspable, whether a surface can be sat upon and so on. We ask ourselves what can this object furnish us with, what does it afford us (Gibson, 1982)? These are the meanings that the environment has and Gibson called them **affordances**. Thus, Gibson highlighted the ecological nature of perception: we do not simply perceive simple stimuli but these stimuli mean something more in a wider, more complex context. This was a radical departure in visual perception because it implied that the perception of object meaning is direct. Perception involves determining whether something is capable of being sat upon or is throwable.

However, the theory is not without its problems. Costall (1995), for example, suggests that some affordances may not be able to afford. Imagine the ground covered in frost and a frozen lake. According to Gibson, the ground afforded walking. However, although the frosty ground does, the frozen lake may not. Similarly, although we might agree with Gibson that some surfaces are graspable or supporting we might disagree quite reasonably with the notion that surfaces are edible, for example, that they afford eating. Our decision that something is edible appears to rely on more than direct perception of surfaces.

Face perception

Although object perception is important to us, the perception of specific categories of stimuli may be even more important. One such category is ‘faces’. Being able to recognise and identify faces is one of the most important social functions human beings can perform (Bruce, 1994). It helps us form relationships with people, spot faces in a crowd and provides us with potential non-verbal cues as to what a person is thinking or feeling (the role of emotion in facial expression is returned to in Chapter 13).

Psychologists in the nineteenth century were interested in what makes a face attractive and constructed composites – averages of several different images – to produce a face which they believed was attractive (Galton, 1878; Stoddard, 1886). Recent work has provided a clearer account of what makes an attractive face; it has also helped to indicate which features of the face best allow us to remember a face or which make a face distinctive.

We can identify people better on the basis of the eyes than the mouth and both are more important than the nose (Bruce *et al.*, 1993), even when hairstyle, make-up and facial hair are removed or minimised. A three-dimensional image of a face – such as that seen in three-quarter profile – is better recognised than is a full-frontal photograph. Upright faces are better recognised and identified than are those upside down but there is a curious phenomenon called the ‘Thatcher effect’, first described by the British psychologist, Peter Thompson (1980). Take a look at the faces in Figure 6.19. They look fairly normal – you can easily identify the image as a face and, while you can see that the faces are inverted, the features appear to be in the right place, and are identifiable.

Now, turn the book upside down and look at the photographs again. It is a grotesque image, but only eyes and the mouth have been turned around (inverted) to create this effect. This is the Thatcher effect (so-called because

Thompson created his stimuli using the face of the British Prime Minister).

Women and girls tend to be better than men and boys at decoding people’s facial expression of emotion (McClure, 2000). Women are better at identifying upright faces even when they are masked by visual noise or when there is a delay between the presentation of the face and recall (McBain *et al.*; 2009). Figure 6.20 illustrates some of the stimuli in McBain *et al.*’s experiment.

Sex of the face

We can usually discriminate between faces more quickly on the basis of their users’ sex than familiarity (Bruce *et al.*, 1987). Enlow (1982) and Moss *et al.* (1987), for example, have suggested that men have larger noses and nasopharynxes, more prominent brows, a more sloping forehead and more deeply set eyes than do women. Shepherd (1989) noted that women had fuller cheeks and less facial hair (including eyebrows). Women are also thought to have smaller noses, a more depressed bridge of the nose, a shorter upper lip, and larger eyes with darker shadows, especially young women (Liggett, 1974).

When facial features are presented in isolation, eyes are the most reliable indicator of sex and the nose is the least reliable. With hair concealed, 96 per cent of partici-

pants were able to distinguish between faces based on sex (Burton *et al.*, 1993). When individual facial features or pairs of features (such as brow and eyes, nose and mouth) were presented to participants, the features which afforded the best opportunity to make sex discriminations were, in this order: brow and eyes, brow alone, eyes alone, whole jaw, chin, nose and mouth, and mouth alone (Brown and Perrett, 1993). These findings suggest that all facial features carry some information about sex (except the nose) but suggest that it is difficult to find even one or two features which distinguish absolutely between men's and women's faces. Some features, however, provide better clues than others.

Distinctiveness and attractiveness

Each of us finds different faces attractive: some of us find faces friendlier than others, some meaner and others more sexually alluring. Although individual differences exist at this, what seems like, subjective level, studies have shown that some features of the face are generally regarded as more attractive than others. The distinctiveness of the face – defined as the deviation from the norm – is unrelated to attractiveness (Bruce *et al.*, 1994). Galton had hypothesised that averageness was attractiveness. That is, the more average-looking the face, the more attractive it was likely to be. This hypothesis was tested and challenged by Perrett *et al.* (1994), who compared the attractiveness ratings for average, attractive and highly attractive Caucasian female faces.

Perrett *et al.*, using special computer technology, constructed an average composite of photographs of 60 female faces. The 15 faces rated as most attractive from the original 60 were then averaged. Finally, the attractiveness of this average was enhanced by 50 per cent to provide a 'highly attractive' composite. Composites similar to those used in the experiment can be seen in Figure 6.21.

Caucasian raters found the 'attractive' composite more attractive than the average composite and the highly attractive composite more attractive than the 'attractive' composite, thus disconfirming Galton's hypothesis. Furthermore, when similar composites were made of Japanese women, the same results were obtained: both Caucasian and Japanese raters found the enhanced composite more attractive. What distinguished an average face from an attractive one?

Analysis of the composites showed that the more attractive faces had higher cheek bones, a thinner jaw and larger eyes relative to the size of the face. There was also a shorter distance between mouth and chin and between nose and mouth in the attractive faces.

Evolutionary psychologists argue that we are attracted to average faces because this behaviour evolved as a solution to attracting healthy mates – best to stick with what you know and can trust. An alternative view is that we are simply attracted to the familiar – a well-known psychological phenomenon. If this were true, we should be attracted to average-looking stimuli that are non-faces too. This is what Halberstadt and Rhodes (2000) found. They asked people to rate a selection of watches, birds and dogs for attractiveness and

Figure 6.21 Faces similar to those used in Perrett *et al.*'s (1994) experiment. The faces are 'morphed' from averagely attractive (top two faces) to very attractive (bottom two faces). Most people rate the last two faces as most attractive.

Source: From Young, A.W. and Bruce, V., Pictures at an exhibition: The science of the face. *The Psychologist*, 1998, 11(3), 120–5 (see www.thepsychologist.org.uk).

prototypicality (how typical they were of a category), or averageness. The researchers found that participants rated the average-looking stimuli as being the most attractive. One reason for this may be that we have a preference for averageness which 'reflects a more general preference for familiar stimuli'.

In one experiment, Caucasian participants rated their own-race face-composites as more attractive than those of other races but this finding was limited to the male faces (Rhodes *et al.*, 2005). When average composites of Caucasian and Japanese faces were judged, Caucasians preferred the mixed race composite, especially if the face was of the opposite sex. Japanese and Caucasian participants, asked to judge the attractiveness of Caucasian and Japanese faces (from extremely Caucasian and Japanese, to the other end of the continuum) rated the mixed-race composite as most attractive.

Does the attractiveness of a face actually have consequences for us, beyond immediate physical liking for a person? Langlois *et al.* (2000) analysed over 900 studies of people's behaviour towards attractive and unattractive individuals. They found that not only was there agreement between people and cultures about who is attractive and who is not, but also that attractive children and adults were treated and judged more positively than were unattractive children and adults (even when people knew the unattractive individuals).

Although turning hoary maxims such as 'beauty is in the eye of the beholder' on its head, Langlois *et al.* note that the studies they reviewed categorised people into either attractive or unattractive only. Gradations of attractiveness may have elicited different responses in people so that averagely attractive people may have elicited more positive responses than their excessively attractive or unattractive counterparts.

There is also mixed evidence regarding the type of 'sexual' face that we like: some studies suggest that we prefer more feminised faces; others that we like masculinised ones (Johnston, 2006). The explanation for our preference for feminised faces is that they are more youthful, warm and honest; masculinised faces are more cold, dominant, dishonest. Faces morphed to look younger are rated as significantly more attractive (Ishi *et al.*, 2004).

Attractive faces whose gaze is direct can have a knock-on positive effect on our judgements of unrelated objects (Strick *et al.*, 2008). A directly gazing face is considered significantly more attractive than an indirectly gazing one. We also like objects more if we see a person smiling at them than if they show disgust. Furthermore, we are more likely to engage socially with people if they look at us directly. Strick *et al.* paired novel objects – pictures of unknown peppermint brands – with an attractive or unat-

tractive face which looked straight at the participant or which averted its gaze. Participants rated the attractiveness of these objects.

As predicted, objects paired with a directly gazing attractive face were more positively evaluated than were objects paired with an indirectly gazing attractive face or an unattractive face.

We also, naturally, spend more time looking at beautiful faces than unattractive ones, but a study from a group of US researchers has found that although women spend more time looking at beautiful male and female faces than they do unattractive ones, men spend longer than women looking at beautiful female faces (Levy *et al.*, 2008).

What do you find attractive in an attractive face? Do your preferences match those found in experimental studies? Do you think that some facial features we find attractive are so subtle that we cannot consciously detect them?

Face preference and menstrual cycle

When we see faces, we normally make judgements about them – some studies show that women prefer exaggeratedly masculine male faces whereas some studies show that men and women prefer ‘average-looking’ faces. Women’s preference for men’s faces can change across the menstrual cycle. Penton-Voak and Perrett (2000) found that women in the follicular phase of their cycle were significantly more likely to prefer a masculine face than those in menses or in the luteal phase. This, the authors provocatively suggest, shows that ‘women are attracted to relatively exaggerated male traits when conception following coitus is more likely (days 6–14 of the follicular phase) and not at other times in the menstrual cycle’.

One explanation for the preference is that during this fertile phase of the cycle, women are more likely to seek a sexual partner (and, potentially, a father for their child) who shows evidence of ‘genetic benefits’ (strength, assertiveness, etc.). This explanation is based on limited experimental data, however, and more direct behaviour – such as the interaction between men and women – has not been studied.

Gangestad *et al.* (2004) found that women during the high fertility portion of their menstrual cycle were more attracted to men who showed social presence and ‘intrasexual competitiveness’ than in their low fertility days. Social presence was characterised by composure, having an athletic presence, maintaining eye contact, lack of self-deprecation, lack of downward gaze and ‘lack of nice-guy self-presentation’. Direct intrasexual competitiveness was defined by behaviours that derogated competitors, lacked laughter and were directly sexually competitive. This pref-

erence only emerged when women wished short-term rather than long-term relationships, suggesting that a man’s demeanour can significantly alter perceived attractiveness by women high in fertility, but this attraction may be short-lived.

A study of 70 young women has found that their level of a hormone called testosterone (described in Chapter 13) is related to how attractive they found others: the greater the testosterone, the greater their attraction to masculine faces (Welling *et al.*, 2007). Another study has found that although very masculine male faces are judged to be dominant, their owners are less likely to be judged suitable as a long-term partner by women than are owners of less masculine faces (Boothroyd *et al.*, 2007).

The group also measured women’s judgements of the attractiveness of men’s faces across various points of their menstrual cycle. Symmetrical faces are usually judged to be more attractive than asymmetrical ones and there is evidence that facial symmetry in men and women is associated with perceived healthiness (Rhodes *et al.*, 2007) and self-reported extraversion (Pound *et al.*, 2007). The researchers found that women preferred more symmetrical faces when the women were at their most fertile but this preference was found only when the women were seeking a short-term partner or if the women already had a partner (Little *et al.*, 2007). The results suggest that this facial feature may maximise mating by encouraging short-term relationships.

Theories of face perception

The mechanisms that allow us to perceive faces are considered to be different from those that allow us to perceive objects; face perception has been thought of as ‘special’ (Farah *et al.*, 1998). Face perception involves a number of operations. We can perceive general characteristics such as the colour, sex and age of a face; we can perceive whether a face expresses anger, sadness or joy; we can distinguish familiar from unfamiliar faces. What model of face processing can account for these operations?

Bruce and Young (1986) have suggested that face processing is made up of three functions: perception of facial expression, perception of familiar faces and perception of unfamiliar faces. Why does the model separate these functions? Bruce and Young reviewed extensive evidence which suggested that each of these functions is dependent on different cognitive abilities. Evidence from neuropsychology also supports such a model.

Some patients with right hemisphere damage, as we will see later in the chapter, can perceive and correctly identify emotion in facial expressions, and the sex and age

of faces, but they cannot identify faces (Tranel *et al.*, 1988). In a classic study, Young *et al.* (1993) studied face perception in ex-servicemen who had sustained missile wounds to the posterior left and right hemispheres. They administered a series of face perception tests which included tests of familiar face identification, matching unfamiliar faces and facial expression identification. The experimenters found that one patient was poor at identifying familiar faces only, another was selectively poor at matching unfamiliar faces and a group of men was impaired at analysing facial expressions.

Current views of face processing argue that we exploit three strategies when we recognise faces. One strategy involves recognising the features of a face, a second involves recognising the relations between features in a face (configural processing) and a third suggests that we recognise the whole face (the holistic approach) (Gruter *et al.*, 2008). Configural processing works when faces are upright, but fails when they are inverted, à la the Thatcher effect.

Perception of space and motion

In addition to being able to perceive the forms of objects in our environment, we are able to judge quite accurately their relative location in space and their movements. Perceiving where things are and perceiving what they are

doing are obviously important functions of the visual system (Decety *et al.*, 1997; Jeannerod, 1997).

Depth perception

Depth perception requires that we perceive the distance of objects in the environment from us and from each other. We do so by means of two kinds of cues: binocular ('two-eye') and monocular ('one-eye'). Binocular cues arise from the fact that the visual fields of both eyes overlap. Only animals that have eyes on the front of the head (such as primates, cats and some birds) can obtain binocular cues. Animals that have eyes on the sides of their heads (such as rabbits and fish) can obtain only monocular cues.

One monocular cue involves movement and thus must be experienced in the natural environment or in a motion picture. The other monocular cues can be represented in a drawing or a photograph. Most of these cues were originally discovered by artists and only later studied by psychologists (Zeki, 1998). Figure 6.22 shows the most important sources of depth cues.

Binocular cues

Convergence provides an important cue about distance. The eyes make conjugate movements so that both look at (converge on) the same point of the

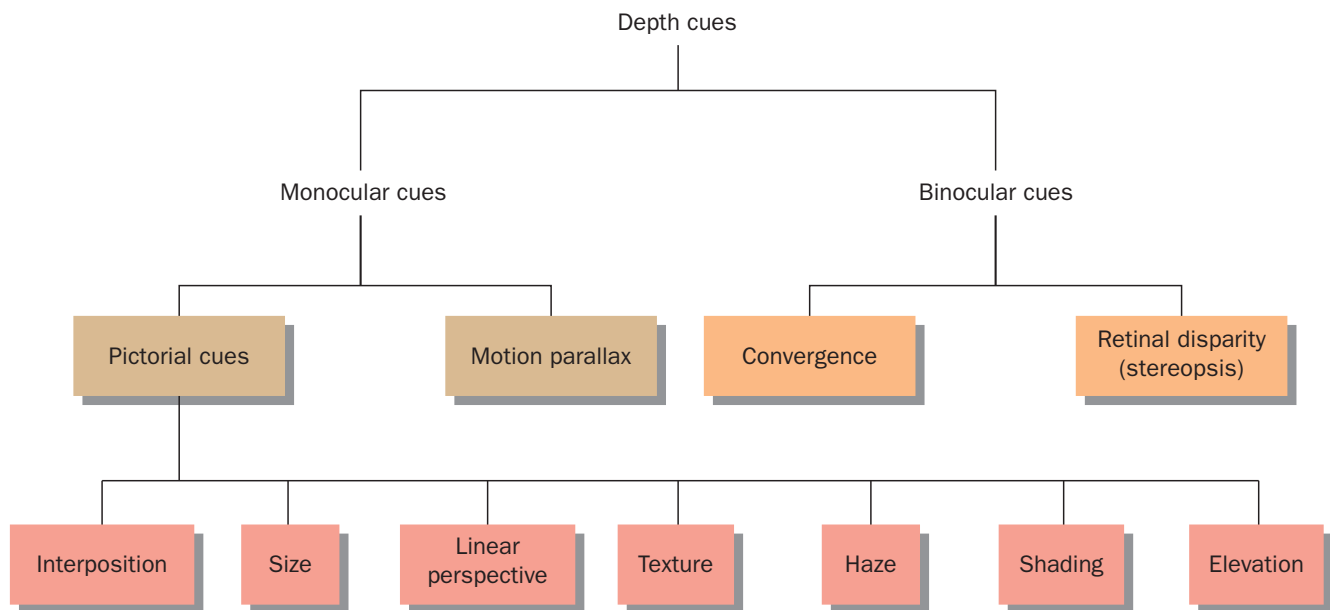

Figure 6.22 The principal monocular and binocular depth cues.

visual scene. If an object is very close to your face, your eyes are turned inwards. If it is farther away, they look more nearly straight ahead. Thus, the eyes can be used like range finders. The brain controls the extraocular muscles, so it knows the angle between them, which is related to the distance between the object and the eyes. Convergence is most important for perceiving the distance of objects located close to us, especially those we can reach with our hands (see Figure 6.23).

Another important factor in the perception of distance is the information provided by **retinal disparity** ('unlikeness' or 'dissimilarity'). Hold up a finger of one hand at arm's length and then hold up a finger of the other hand midway between your nose and the distant finger. If you look at one of the fingers, you will see a double image of the other one. Whenever your eyes are pointed towards a particular point, the images of objects at different dis-

tances will fall on different portions of the retina in each eye. The amount of disparity produced by the images of an object on the two retinas provides an important clue about its distance from us.

The perception of depth resulting from retinal disparity is called **stereopsis**. A stereoscope is a device that shows two slightly different pictures, one for each eye. The pictures are taken by a camera equipped with two lenses, located a few inches apart, just as our eyes are. When you look through a stereoscope, you see a three-dimensional image. An experiment by Julesz (1965) demonstrated that retinal disparity is what produces the effect of depth. Using a computer, he produced two displays of randomly positioned dots in which the location of some dots differed slightly. If some of the dots in one of the displays were displaced slightly to the right or the left, the two displays gave the impression of depth when viewed through a stereoscope.

Figure 6.23 Convergence. When the eyes converge on a nearby object, the angle between them is greater than when they converge on a distant object. The brain uses this information in perceiving the distance of an object.

Figure 6.24 shows a pair of these random-dot stereograms. If you look at them very carefully, you will see that some of the dots near the centre have been moved slightly to the left. Some people can look at these figures without using a stereoscope and see depth. If you want to try this, hold the book at arm's length and look at the space between the figures. Now pretend you are looking 'through' the book, into the distance. Each image will become double, since your eyes are no longer converged properly. If you keep looking, you might make two of these images fuse into one, located right in the middle. Eventually, you might see a small square in the centre of the image, raised above the background.

Monocular cues

One of the most important sources of information about the relative distance of objects is **interposition** (meaning 'placed between'). If one object is placed between us and another object so that the closer object partially obscures our view of the more distant one, we can immediately perceive which object is closer to us.

Obviously, interposition works best when we are familiar with the objects and know what their shapes should look like. Just as the Gestalt law of good continuation plays a role in form perception, the principle of good form affects our perception of the relative location of objects: we perceive the object having the simpler border as being closer. Figure 6.25 (a) can be seen either as two rectangles, located one in front of the other (Figure 6.25 (b)), or as a rectangle nested against an L-shaped object (Figure 6.25 (c)). Because we tend to perceive an ambiguous drawing according to the principle of good form, we are more likely to perceive Figure 6.25 (a) as two simple shapes – rectangles – one partly hiding the other.

Figure 6.24 A pair of random-dot stereograms.

Figure 6.25 Use of the principle of good form in the perception of depth. The two objects shown in (a) could be two identical rectangles, one in front of the other, as shown in (b) or a rectangle and an L-shaped object, as shown in (c). The principle of good form states that we will see the ambiguous object in its simplest (best) form – in this case a rectangle. As a result, the shape to the right is perceived as being partly hidden and thus further away from us.

Another important monocular distance cue is provided by our familiarity with the sizes of objects. For example, if a car casts a very small image on our retinas, we will perceive it as being far away. Knowing how large cars are, our visual system can automatically compute the approximate distance from the size of the retinal image.

Figure 6.26 shows two columns located at different distances. The drawing shows **linear perspective**: the tendency for parallel lines that recede from us to appear to converge at a single point. Because of perspective, we perceive the columns as being the same size even though they

Figure 6.26 Principle of perspective. Perspective gives the appearance of distance and makes the two columns look similar in size.

produce retinal images of different sizes. We also perceive the segments of the wall between the columns as rectangular, even though the image they cast on the retina does not contain any right angles.

Texture, especially the texture of the ground, provides another cue we use to perceive the distance of objects sitting on the ground. A coarser texture looks closer, and a finer texture looks more distant. The earth's atmosphere, which always contains a certain amount of haze, can also supply cues about the relative distance of objects or parts of the landscape. Parts of the landscape that are further away become less distinct because of haze in the air. Thus, **haze** provides a monocular distance cue (see Figure 6.27).

The patterns of light and shadow in a scene – its **shading** – can provide us with cues about the three-dimensional shapes of objects. Although the cues that shading provides do not usually tell us much about the absolute distances of objects from us, they can tell us which parts of objects are closer and which are further away. Figure 6.28 illustrates the power of this phenomenon. Some of the circles look as

Figure 6.27 Cues from atmospheric haze. Variation in detail, owing to haze, produces an appearance of distance.

Source: Powerstock SuperStock, reprinted by permission.

Figure 6.28 Depth cues supplied by shading. If the tops of the circles are dark, they look like depressions. If the bottoms are dark, they appear as bumps.

if they bulge out towards us; others look as if they were hollowed out (dimpled). The only difference is the direction of the shading. Our visual system appears to interpret such stimuli as if they were illuminated from above. Thus, the top of a convex (bulging) object will be light and the bottom will be in shadow. If you turn the book upside-down, the bulges and dimples will reverse.

These features are important to practical aspects of our lives, an example of which appears in the Psychology in Action section below.

Psychology in action – CCTV and face perception

Imagine that you are spending your Saturday afternoon in a busy shopping centre. Browsing in a store, you spot a particularly attractive shirt and take it to the sales counter. When you place the shirt and your wallet/purse on the counter, you feel someone nudge you from behind. You turn around but when you return to the shirt on the counter, you notice that your wallet/purse has disappeared. A person whose face you partly see is running out of the store. Fortunately, the police manage to apprehend a suspect and the store detective informs you that he has video surveillance footage of a man who might be the thief. The suspect does not have your wallet but the image on the surveillance camera looks like the suspect. How accurately would you be able to match the suspect to the image on the video screen?

The increasing use of CCTV has led to an increase in the reliance on CCTV evidence in prosecutions but CCTV footage is usually variable in quality with camera angles and lighting conditions producing an unclear image of the top or back of the head (Bruce, 1998). Changing the lighting conditions reduced performance in a task which required individuals to match the face they had seen with a photograph (Hill and Bruce, 1996). Changing the viewpoint also impaired recognition accuracy but changing both lighting and viewpoint did not make performance any worse. According to a 2009 UK Home Office and police report, around 80 per cent of CCTV images are of no practical use because they are of such poor quality.

Matching faces (and even recognising familiar surfaces) was more accurate when lighting was from above. Why? One explanation is that light from above provides more information by casting fewer shadows. Hill and Bruce (1996) suggest that lighting a face from the bottom reverses the brightness of

facial areas such as the eye sockets and nostrils. In fact, lighting of this sort makes the face look like a negative. This study highlights an important point about face perception (and about the erroneous testimony described at the opening of the chapter). Our recognition of faces is not simply based on ‘edge’ information, that is, on contour. The shape of the face (viewpoint) and shading are crucial in enabling us to make accurate recognition judgements.

Is recognition improved if the face is moving? After all, a moving image might give more information about shading, shape and contour than would a static one. Some researchers have reported that a moving image is more advantageous to accurate recognition than is a static one (Pike *et al.*, 1997; Knight and Johnston, 1997). Others have found little improvement in recognition when moving and static images are compared (Christie and Bruce, 1998).

Recognition is also enhanced by familiarity. Burton *et al.* (1999) took video footage of male and female university psychology lecturers caught on security cameras at the entrance to the psychology department. They then asked psychology and non-psychology students, as well as experienced police officers, to view this footage and then asked them to indicate which of the people in a set of high-quality photographs they had seen on tape. Psychology students made more correct identifications than did the non-psychology students or police officers, suggesting that previous familiarity with the target helps with recognition.

In the second experiment, the researchers looked at which specific bits of information the participants used to identify the target. They took the same video footage, but this time they either obscured the head, the body or the gait.

Psychology in action – *Continued*

Participants performed quite inaccurately when gait and body were obscured but were significantly worse at identifying the target when the head was obscured. Thus the advantage of familiarity – at least, in this experiment – was due to recognition of facial features rather than the way in which people walk or their body shape. Unusual gaits or shapes may produce different results.

When people watched CCTV footage of a person and then tried to match the image in the footage with either a single snapshot or an array of snapshots, people performed the task poorly (Bruce *et al.*, 2001). However, when the participants knew the person in the footage – the targets were the participants' teachers or colleagues – they were significantly better at the task. Even in experiments where participants were made briefly familiar with the image they were exposed to, this period of familiarisation did not help the participant recognise the face.

According to Bruce *et al.* (2001), 'where a person is recognised on a CCTV image by someone familiar to them, these identifications should be taken very seriously, even if the CCTV image is of low quality'. They refer to the case of the London nail bomber, David Copeland, as an illustration of this finding. Copeland was responsible for killing three people and injuring 129 others in nail bomb explosions in three areas of London – Soho, Brick Lane and Brixton – in the spring of 1999. Copeland's final crime was committed in the Admiral Duncan pub in Soho, Central London. He left the pub at 6.05 p.m. The bomb exploded as Copeland made his way back to his hotel. Three people were killed, four required amputations and 26 suffered burns (Hopkins and Hall, 2000). Eighty minutes before the bomb was detonated Copeland's colleague had telephoned the police and told them that he thought the bomber identified on CCTV and publicised on television looked like his workmate. By that evening, police were planning a raid on Copeland's house.

Bruce *et al.*'s research suggests that this use of CCTV may be one of its most effective.

The site of the bomb placed by David Copeland. Copeland was apprehended after a colleague recognised his face from CCTV footage shown on television. Research suggests that recognition of people seen in CCTV footage is significantly more accurate if these people are familiar. If the target person is not familiar, the likelihood of false positives (making an incorrect identification) increases.

Distance and location

When we are able to see the horizon, we perceive objects near it as being distant and those above or below it as being nearer to us. Thus, **elevation** provides an important monocular depth cue. For example, cloud B and triangle B in Figure 6.29 appear further away from us than do cloud A and triangle A.

So far, all the monocular distance cues discussed have been those that can be rendered in a drawing or captured by a camera. However, another important source of distance information depends on our own movement. Try

the following demonstrations. If you focus your eyes on an object close to you and move your head from side to side, your image of the scene moves back and forth behind the nearer object. If you focus your eyes on the background while moving your head from side to side, the image of the nearer object passes back and forth across the background. Head and body movements cause the images from the scene before us to change; the closer the object, the more it changes relative to the background. The information contained in this relative movement helps us to perceive distance.

Figure 6.29 Depth cues supplied by elevation. The objects nearest the horizontal line appear furthest away from us.

Source: Adapted from Matlin, M.W. and Foley, H.J., *Sensation and Perception* (3rd edn). Boston: Allyn & Bacon, 1992.

Figure 6.30 illustrates the kinds of cue supplied when we move with respect to features in the environment. The top part of the figure shows three objects at different distances from the observer: a man, a house and a tree. The lower part shows the views that the observer will see from five different places (P_1 – P_5). The changes in the relative locations of the objects provide cues concerning their distance from the observer. The phenomenon is known as **motion parallax** (*parallax* comes from a Greek word meaning ‘change’).

Constancies of visual perception

An important characteristic of the visual environment is that it is almost always changing as we move, as objects move, and as lighting conditions change. However, despite the changing nature of the image the visual environment casts on our retinas, our perceptions remain remarkably constant.

Visual perception across cultures

From birth onwards, we explore our environment with our eyes. The patterns of light and dark, colour and movement, produce changes in the visual system of the brain. There is evidence, however, that perception is not absolute, that it varies across cultures. Ecological variables such as those associated with geography, cultural codes and education influence perception.

The visual stimulation we receive, particularly during infancy, affects the development of our visual system. If the environment lacks certain features – certain visual patterns – then an organism might fail to recognise the significance of these features if it encounters them later in life (Blakemore and Mitchell, 1973). But this is not the only type of environment that can influence perception.

There may also be differences in the cultural codes found in pictorial representations (Russell *et al.*, 1997). Although artists have learned to represent all the monocular depth cues (except for those produced by movement) in their paintings, not all cues are represented in the traditional art of all cultures. For example, many cultures do not use linear perspective. Does the absence of particular cues in the art of a particular culture mean that people from this culture will not recognise them when they see them in paintings from another culture?

It is quite rare for a member of one culture to be totally unable to recognise a depiction as a depiction (Russell *et al.*, 1997). However, Derogowski *et al.* (1972) found that when the Me'en tribe of Ethiopia, a culture unfamiliar with pictures, were shown a series of pictures from a children's colouring book, they would smell them, listen to the pages while flexing them, examine their texture but would ignore the actual pictures. They did recognise depictions of indigenous animals, suggesting that the familiarity of a pictorial depiction is important for recognition within cultures. Familiar objects are sometimes depicted in an exaggerated way. Aboriginal depictions of the crocodile, for example, are distorted: the trunk is seen from above and the head and tail from the side (Dziurawiec and Derogowski, 1992), although this finding may be attributable to the fact that such animals are difficult to draw.

There are other geographical influences on perception. People who live in ‘carpentered worlds’, that is worlds in which buildings are built from long, straight pieces of material that normally join each other in right angles, are more likely to be subject to the Müller-Lyer illusion. This illusion is shown in Figure 6.31. Look at the two vertical lines and decide which is longer.

Actually, the lines are of equal length. Segall *et al.* (1966) presented the Müller-Lyer illusion (and several others) to groups of subjects from Western and non-Western cultures. Most investigators believe that the Müller-Lyer illusion is a result of our experience with the angles formed by the intersection of walls, ceilings and floors (Redding and Hawley, 1993). The angled lines can be seen as examples of linear perspective (see Figure 6.32). In fact, Segall and his colleagues did find that people from ‘carpentered’ cultures were more susceptible to this illusion: experience with straight lines forming right angles appeared to affect people's perception.

Figure 6.30 Motion parallax. As we move from P1 to P5, the relative locations of the man, tree and house change. These changes enable us to make inferences about the relative positions of these objects.

Figure 6.31 The Müller-Lyer illusion. The two vertical lines are actually equal in length, but the one on the left appears to be longer.

Figure 6.32 The impact of culture on the Müller-Lyer illusion. People from ‘non-carpentered’ cultures that lack rectangular corners are less likely to be susceptible to this illusion. Although the two vertical lines are actually the same height, the one on the right looks shorter.

Controversies in Psychological Science – How does language influence visual perception?

The issue

The effects on perception of another cultural code – language – have received much attention from psychologists for a good reason. Words for shades of light and colour seem to be more limited in some cultures than others. The Inuit, for example, have more than one name for various shades of snow, whereas Africans have different words for different shades of sand, presumably because these features form a crucial part of the culture's environment. There are also differences in the number of colour words that different cultures use. This has important implications for our understanding of the cross-cultural generalisability of colour perception which we discussed in Chapter 5. For example, do all cultures use all the primary and secondary colour terms? Does the word 'blue' mean the same across cultures? Do cultures have different words for various shades of blue? If so, why?

The evidence

In the mid-nineteenth century, the British statesman William Gladstone noted that the writings of the ancient Greeks did not contain words for brown or blue. Perhaps the ancient Greeks did not perceive these colours. Magnus (1880) investigated this hypothesis by gathering both linguistic and perceptual data. He sent questionnaires and colour chips to Western residents of European colonies and asked them to test the abilities of the native people to distinguish among the various colours. He assumed that language would reflect perceptual ability. If a language did not contain words to distinguish between certain colours, then the people who belonged to that culture would not be able to distinguish these colours perceptually.

Magnus was surprised to discover very few cultural differences in people's ability to perceive various colours. Linguistic differences did not appear to reflect perceptual differences. The issue emerged again in the mid-twentieth century with the principle of **linguistic relativity**. Briefly stated, this principle asserts that language used by the members of a particular culture is related to these people's thoughts and perceptions. The best-known proponent of this principle, Benjamin Whorf, stated that 'the background linguistic system. . . of each language is not merely a reproducing instrument for voicing ideas but rather is itself a shaper of ideas, the program and guide for the individual's mental activity, for his analysis of impressions, for his synthesis of his mental stock-of-trade' (Whorf, 1956, p. 212). This became known as the **Sapir-Whorf hypothesis** – the idea that language can determine thought (Kay and Kempton, 1984).

Proponents of linguistic relativity suggested that colour names were cultural conventions – that members of a given culture could divide the countless combinations of hue, saturation

and brightness (defined in Chapter 5) that we call colours into any number of different categories (Kay *et al.*, 1997). Each category was assigned a name, and when members of that culture looked out at the world, they perceived each of the colours they saw as belonging to one of these categories.

Two anthropologists, Berlin and Kay, examined this hypothesis in a linguistic study of a wide range of languages. They found the following eleven primary colour terms: black, white, red, yellow, green, blue, brown, purple, pink, orange and grey (Berlin and Kay, 1969; Kay, 1975; Kay *et al.*, 1991). The authors referred to these as focal colours. Not all languages used all eleven (as English does). In fact, some languages used only two: black and white (Heider, 1972). Others, such as Russian, had two words for blue.

If a language contained words for three primary colours, these colours were black, white and red. If it contained words for six primary colours, these were black, white, red, yellow, green and blue. Berlin and Kay suggested that basic colour terms would be named more quickly than non-basic colour terms, that basic terms would be more salient, that is, they would be elicited first if you asked people to name colours spontaneously, and that basic terms would be more common in written communications such as texts. In fact, people do respond more quickly to basic than they do to non-basic colour terms across a range of languages; when asked to write down a list of as many colour words in five minutes as possible and draw a line under the last words written, every minute, basic terms invariably appear at the beginning of the list (Corbett and Davies, 1997). Similarly, Heider (1971) found that both children and adults found it easier to remember a colour chip of a focal colour (such as red or blue) than one of a non-focal colour (such as turquoise or peach).

In a famous cross-cultural study, Heider (1972) studied members of the Dani culture of New Guinea. The language of the Dani people has only two basic colour terms: *mili* ('black') and *mola* ('white'). Heider assembled two sets of colour chips, one containing focal colours and the other containing non-focal colours. She taught her participants arbitrary names that she made up for the colours. Even though the participants had no words in their language for any of the colours, the group learning names for focal colours learned the names faster and remembered them better.

Categorical perception of colour refers to our ability to discriminate between two colours that seem to fall along a continuum. However, speakers of Berinmo and Himba do not distinguish a boundary between green and blue, which suggests that categorical perception is not universal. Roberson *et al.* (2008) tested this hypothesis in a group of native Korean and English-speaking adults. Koreans distinguish between

Controversies in Psychological Science – *Continued*

yeondu and *chorok*. The boundary between the two was described as ‘green’ by English speakers. Korean speakers were faster at discriminating between colours marked as a boundary in Korean but not English, but not at distinguishing between colours that fell within a colour category. The faster participants showed categorical perception only when stimuli appeared in the right visual field; slower participants showed categorical perception in both visual fields, suggesting that categorical perception may be verbally mediated by the left hemisphere.

Conclusion

Colour is a difficult topic to study cross-culturally. The evidence suggests, however, that although there are cultural variations in the number of colour words used, there seems to be cross-cultural agreement on the colours considered as ‘basic’.

Brightness constancy

People can judge the whiteness or greyness of an object very well, even if the level of illumination changes. If you look at a sheet of white paper either in bright sunlight or in shade, you will perceive it as being white, although the intensity of its image on your retina will vary. If you look at a sheet of grey paper in sunlight, it may in fact reflect more light to your eye than will a white paper located in the shade, but you will still see the white paper as white and the grey paper as grey. This phenomenon is known as **brightness constancy**.

Katz (1935) demonstrated brightness constancy by constructing a vertical barrier and positioning a light source so that a shadow was cast to the right of the barrier. In the shadow, he placed a grey square card on a white background. In the lighted area on the left of the barrier, he placed a number of shades of grey and asked participants to choose one that matched the grey square in the shadow (see Figure 6.33).

Figure 6.33 Brightness constancy as demonstrated by the experiment by Katz (1935).

His participants matched the greys not in terms of the light that the cards actually reflected but in terms of the light they would have reflected had both been viewed under the same level of illumination. In other words, the participants compensated for the dimness of the shadow. The match was not perfect, but it was much closer than it would have been if perception of brightness had been made solely on the basis of the amount of light that fell on the retina. The perception of white and grey, then, is not a matter of absolutes; rather, the colours are perceived relative to the surrounding environment.

Form constancy

When we approach an object or when it approaches us, we do not perceive it as getting larger. Even though the image of the object on the retina gets larger, we perceive this change as being due to a decrease in the distance between ourselves and the object. Our perception of the object's size remains relatively constant.

The unchanging perception of an object's size and shape when it moves relative to us is called **form constancy**. Psychologists also refer to size constancy, but size is simply one aspect of form. In the nineteenth century, Hermann von Helmholtz suggested that form constancy was achieved by **unconscious inference**, a mental computation of which we are unaware. We know the size and shape of a familiar object. Therefore, if the image it casts upon our retina is small, we perceive it as being far away; if the image is large, we perceive it as being close. In either case, we perceive the object itself as being the same size.

Form constancy also works for rotation. The drawing in Figure 6.34 (a) could be either a trapezoid or a rectangle rotated away from us. However, the extra cues clearly identify the drawing in Figure 6.34 (b) as a window, and experience tells us that windows are rectangular rather than trapezoidal; thus, we perceive it as rectangular. Obviously, this effect will not be seen in members of cultures that do not have buildings fitted with rectangular windows (or seen by people unfamiliar with the object).

Figure 6.34 Form constancy. **(a)** This figure can be perceived as a trapezoid. **(b)** Because we recognise this figure as a window, we perceive its shape as rectangular.

The process just described works for familiar objects. However, we often see unfamiliar objects whose size we do not already know. If we are to perceive the size and shape of unfamiliar objects accurately, we must know something about their distance from us. An object that produces a large retinal image is perceived as big if it is far away and small if it is close. Figure 6.35 illustrates this phenomenon. Although the two letterboxes are exactly the same size, the one that appears to be further away looks larger. If you turn the book upside-down and look at the figure again, the appearance of depth is greatly diminished, and the two letterboxes appear to be approximately the same size.

Perception of motion

Detection of movement is one of the most primitive aspects of visual perception (Milner and

Figure 6.35 Effect of perceived distance. Although both letterboxes are exactly the same size, the upper one looks larger because of the depth cues (perspective and texture) that surround it. If you turn the book upside-down and look at the picture, thus disrupting the depth cues, the letterboxes look the same size.

Goodale, 1995). This ability is seen even in animals whose visual systems do not obtain detailed images of the environment. Of course, our visual system can detect more than the mere presence of movement. We can see what is moving in our environment and can detect the direction in which it is moving.

Adaptation and long-term modification

One of the most important characteristics of all sensory systems is that they show adaptation and rebound effects. For example, when you stare at a spot of colour, the adaptation of neurons in your visual system will produce a negative after-image if you shift your gaze to a neutral background; and if you put your hand in some hot water, warm water will feel cool to that hand immediately afterwards.

Cutting edge – Content over style?

When we see a work of art, what do we perceive first – the content, the style, the colour? A new development in the study of art perception is microgenesis – the process whereby our perception of art can be broken down into sub-types of perception, each varying in complexity. For example, which perceptual features are necessary for us to identify an image presented for 1 ms or 50 ms?

Researchers from the University of Salzburg and Vienna used this technique to examine the point at which people were able to distinguish between two works of art that varied in style or content (Augustin *et al.*, 2008). The researchers pre-

sented participants with two images on a computer monitor and asked them how similar they were. The images varied according to content (trees, flowers, houses, men/boys) and style (Cezanne, Chagall, Kirchner, Van Gogh). Presentation times were 10, 50, 202 and 3,000 ms. The time taken to make the judgement was recorded.

Participants were able to distinguish between content at all presentation times, but effects of style became apparent at 50 ms. That is, participants were able to distinguish between works of art of different styles even when presented for only 50 ms, despite having no prior education in art.

Motion, like other kinds of stimuli, can give rise to adaptation and after-effects. Tootell *et al.* (1995) presented participants with a display showing a series of concentric rings moving outwards, like the ripples in a pond. When the rings suddenly stopped moving, participants had the impression of the opposite movement – that the rings were moving inwards. During this time, the experimenters scanned the participants' brains to measure their metabolic activity. The scans showed increased activity in the motion-sensitive region of the visual association cortex, which lasted as long as the illusion did. Thus, the neural circuits that give rise to this illusion appear to be located in the same region that responds to actual moving stimuli.

Interpretation of a moving retinal image

As you read this book, your eyes are continuously moving. Naturally, the eye movements cause the image on your retina to move. You can also cause the retinal image to move by holding the book close to your face, looking straight ahead, and moving it back and forth. In the first case, when you were reading normally, you perceived the book as being still. In the second case, you perceived it as moving. Why does your brain interpret the movement differently in these two cases? Try another demonstration. Pick a letter on this page, stare at it, and then move the book around, following the letter with your eyes. This time you will perceive the book as moving, even though the image on your retina remains stable. Thus, perception of movement requires coordination between movements of the image on the retina and those of the eyes.

Obviously, the visual system must know about eye movements in order to compensate for them in interpreting the significance of moving images on the retina. Another simple demonstration suggests the source of this information. Close your left eye and look slightly down and to the left. Gently press your finger against the outer corner of the upper eyelid of your right eye and make your right eye move a bit. The scene before you appears to be moving, even though you know better. This sensation of movement occurs because your finger – not your eye muscles – moved your eye. When your eye moves normally, perceptual mechanisms in your brain compensate for this movement. Even though the image on the retina moves, you perceive the environment as being stationary. However, if the image moves because the object itself moves or because you push your eye with your finger, you perceive movement (see Figure 6.36).

In general, if two objects of different size are seen moving relative to each other, the smaller one is perceived as moving and the larger one as standing still. We perceive people at a distance moving against a stable background and flies moving against an unmoving wall. Thus, when an experimenter moves a frame that encloses

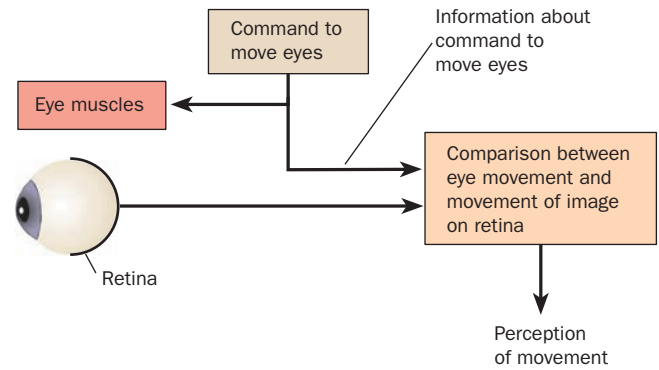

Figure 6.36 A schematic representation of the brain mechanisms responsible for the interpretation of a moving retinal image. This system must compensate for eye movements.

a stationary dot, we tend to see the dot move, not the frame. This phenomenon is also encountered when we perceive the moon racing behind the clouds, even though we know that the clouds, not the moon, are moving.

Perception of movement can even help us perceive three-dimensional forms. Johansson (1973) demonstrated just how much information we can derive from movement. He dressed actors in black and attached small lights to several points on their bodies, such as their wrists, elbows, shoulders, hips, knees and feet. He made films of the actors in a darkened room while they were performing various behaviours, such as walking, running, jumping, limping, doing push-ups, and dancing with a partner who was also equipped with lights. Even though observers who watched the films could only see a pattern of moving lights against a dark background, they could readily perceive the pattern as belonging to a moving human and could identify the behaviour the actor was performing. Subsequent studies (Kozłowski and Cutting, 1977; Barclay *et al.*, 1978) showed that people could even tell, with reasonable accuracy, the sex of the actor wearing the lights. The cues appeared to be supplied by the relative amounts of movement of the shoulders and hips as the person walked.

Combining information from successive fixations

As Chapter 5 showed, when examining a scene, our eyes do not roam slowly around; rather, they make rapid step-like movements called saccades. After each saccade, the eyes rest for a while, gathering information before moving again. These stops are called **fixations**. The visual system combines the information from each fixation and perceives objects too large or too detailed to see in a single glance. Obviously, in doing so, it must keep track of the locations of each of the fixations.

Figure 6.37 (a) illustrates an impossible object. At first glance, the lines represent a three-dimensional object. However, careful inspection shows that the object cannot

Figure 6.37 (a) An impossible figure. Only after carefully studying the figure do we see that it cannot be a drawing of a real three-dimensional object. (b) An unconvincing impossible figure. When the legs are short enough so that the entire figure can be perceived during a single fixation, the figure does not look paradoxical.

possibly exist. But the drawing in Figure 6.37 (b) creates a very different impression; it does not look at all like a unified three-dimensional object. The difference in the two impressions is that the details of the larger figure cannot be gathered in a single glance. Apparently, when we look from one end of the figure to the other, the information we gather from the first fixation is slightly modified to conform to the image of the second one. Of course, the two images do not exactly match, as a careful inspection shows.

Clearly, what we see during one fixation affects what we see in another. If two visual stimuli are presented, one after the other, the second stimulus could sometimes erase the image of the first. That is, under the appropriate conditions, the subject would fail to perceive the image that came first. This phenomenon is known as **backward masking** (Werner, 1935).

You can read ~~this sentence clearly~~

- (a) if material from every fixation pause were retained during the later fixation pauses, a sentence might look like this at the third fixation pause.

You can read this sentence clearly

- (b) Fortunately, masking prevents the persistence of earlier material, and so we see a sentence that looks like this.

Figure 6.38 The role of backward masking. If each saccade did not erase the remaining image from the previous fixation, we probably would not be able to read.

Source: From Margaret W. Matlin and Hugh H.J. Foley, *Sensation and Perception*, 3rd edn © 1992. Published by Allyn & Bacon, Boston, MA. Copyright © by Pearson Education. By permission of the publisher.

Normally, backward masking can be demonstrated only in the laboratory, where the shape and intensity of the stimuli and the time interval between them can be carefully controlled. Breitmeyer (1980) suggests that the explanation for this phenomenon lies in the nature of the saccadic movements made by the eyes when gathering information about the visual environment. For example, consider the saccadic movements that your eyes make as you read a line of text in this book. You do not stop and look at each letter or even at each word; instead, you make several fixations on each line. During each one, your visual system gathers information and begins decoding the letters and words. Your eyes move on, and you perceive more words. Breitmeyer suggests that each saccade erases the image remaining from the previous fixation, leaving only the information that has been analysed by the visual system. Figure 6.38 illustrates what might happen if this erasure did not occur.

Perception and the environment – An international perspective

A good science tries to create theories that apply generally to most contexts, events or people. In psychology's case, a good theory should apply to all people. However, there are instances where group differences test this assumption, such as when cultures are compared across some variable. For example, there is a small amount of evidence to suggest that differences in visual perception exist between Western people and those from East Asia – Westerners tend to perceive objects more analytically and in a more focused way; East Asians are more likely to attend to the context in which objects appear (i.e. they perceive a scene 'holistically') (Choi and Nisbett, 1998; Chua *et al.*, 2005a).

In one study where American and Japanese participants were asked to describe an underwater scene, Americans were more likely to describe objects in the water but the Japanese reported 60 per cent more information about the background environment (Masuda and Nisbett, 2001). In a different scenario, Americans were also able to identify an object (a tiger) more accurately than were the Japanese when it appeared against a different background from that in which it was originally seen. Why does this focal v. context effect occur? One reason might be the types of eye movement made by different cultures.

To test this hypothesis, Chua *et al.* (2005) asked American and Chinese participants to view scenes in which objects

Perception and the environment – *Continued*

appeared against complex backgrounds. The eye movement of participants as they viewed the object and scene were then tracked. Compared with the Chinese, Americans focused on specific objects and more quickly. The Chinese made more saccades – eye movements – to the background.

The researchers suggest that this effect could partly be explained by socialisation. East Asians grow up and live in complex social networks in which paying attention to context is important (perhaps more important than focusing on individual objects or people); Westerners, however, are educated to value individuality and independence (and eye movement is, therefore, directed accordingly). This extends even to cultural products. An analysis of advertising and popular texts in Western and Asian (Korea, Japan, China)/Mexican cultures found that the latter were more individualistic and less collectivistic (Morling and Lamoreaux, 2008).

Similar cultural effects can occur when rating facial expressions. Participants in one experiment were asked to rate the degree of emotion shown in cartoons depicting happy, sad, angry or neutral facial expressions. These faces were surrounded by other people expressing the same or different emotion (Masuda *et al.*, 2008). The surrounding stimuli influenced the ratings of Japanese participants significantly more than they did Westerners. This was evidenced by eye-tracking data. The Japanese spent more time looking at the surrounding stimuli than did the Westerners. The lack of self-absorption of Japanese participants was also seen in an experiment in which people completed a verbal fluidity task – where there was an opportunity to cheat – in front of a mirror (Heine *et al.*, 2008). North Americans were more self-critical and less likely to cheat in front of the mirror; the Japanese participants were unaffected by the presence of a mirror.

Perception of movement in the absence of motion

If you sit in a darkened room and watch two small lights that are alternately turned on and off, your perception will be that of a single light moving back and forth between two different locations. You will not see the light turn off at one position and then turn on at the second position. If the distance and timing are just right, the light will appear to stay on at all times, quickly moving between the positions. This

response is known as the **phi phenomenon**. ‘Moving’ neon signs and some computer animations make use of it.

This characteristic of the visual system accounts for the fact that we perceive the images in cinema films, video tapes and television as continuous rather than separate. The images actually jump from place to place, but we see smooth movement.

The psychology of art – An international perspective

Different nations and different cultures as well as groups within those nations and cultures produce art that can be as similar as it is different. Researchers, however, have found significant differences in the art and artistic depictions of people from the East and the West. In one study, Masuda *et al.* (2008) analysed the artistic styles in art sourced from the archives of various museums. A total of 365 Western and 218 Eastern landscapes were analysed and 286 and 151 portrait paintings from these cultures were compared.

Eastern landscape art was more likely to place the horizon higher than was Western art. This creates more space for field information. For portrait paintings, the size of the models was smaller in the Eastern sample – the Western sample was less likely to include more background.

In a second study, groups of American and Taiwanese, Korean, Japanese and Chinese students were asked to draw and photograph landscapes and portraits. The use of context was greater in both types of stimuli in the Eastern sample. It was more likely to draw the horizon in a high position and draw more objects. It was also more likely to use the zoom function to minimise the size of the model in portrait photographs and make the context larger.

Finally, American and East Asians students were asked to rate their preference for portrait photographs where the model and the background varied. Japanese participants were significantly less likely to prefer narrow backgrounds and larger models.

The findings are consistent with those of other studies. Miyamoto *et al.* (2006) took photographs of significant cultural institutions in the US and Japan. These included schools, post offices, hotels, etc. The institutions in Japan featured more objects and were visually more complex.

Why do these differences occur? Masuda *et al.* (2008) cite Cohen *et al.*'s insider/outsider view of how we organise information about the world (Cohen and Gunz, 2002; Cohen *et al.*, 2007). The insider is dominant in the West – this person dwells on his/her own private experiences and sees the world from his/her point of view. The outsider views the world from the point of view of an outsider looking at the self. It seems as if these roles can change. For example, people who have been exposed to Japanese scenes for a few minutes notice more context than those who are exposed to American scenes (Miyamoto *et al.*, 2006).

Brain mechanisms of visual perception

Although the eyes contain the photoreceptors that detect areas of different brightnesses and colours, perception takes place in the brain. As you saw in Chapters 4 and 5, the optic nerves send visual information to the thalamus, which relays the information to the primary visual cortex located in the occipital lobe at the back of the brain. In turn, neurons in the primary visual cortex send visual information to two successive levels of the visual association cortex. The first level, located in the occipital lobe, surrounds the primary visual cortex. The second level is divided into two parts, one in the middle of the parietal lobe and one in the lower part of the temporal lobe. Figure 6.39 illustrates the various regions involved in visual perception.

Visual perception by the brain is often described as a hierarchy of information processing. According to this scheme, circuits of neurons analyse particular aspects of visual information and send the results of their analysis on to another circuit, which performs further analysis. At each

step in the process, successively more complex features are analysed. Eventually, the process leads to the perception of the scene and of all the objects in it. The higher levels of the perceptual process interact with memories: the viewer recognises familiar objects and learns the appearance of new, unfamiliar ones. Deprivation of the visual system or damage to it during the early years of development can have significant consequences for visual function.

The primary visual cortex

Our knowledge about the characteristics of the earliest stages of visual analysis has come from investigations of the activity of individual neurons in the thalamus and primary visual cortex. For example, Hubel and Wiesel inserted microelectrodes – extremely fine wires having microscopically sharp points – into various regions of the visual system of cats and monkeys to detect the action potentials produced by individual neurons (Hubel and Wiesel, 1977, 1979). The signals detected by the microelectrodes are electronically amplified and sent to a recording device so that they can be studied later.

After positioning a microelectrode close to a neuron, Hubel and Wiesel presented various stimuli on a large screen in front of the anaesthetised animal. The anaesthesia makes the animal unconscious but does not prevent neurons in the visual system from responding. The researchers moved a stimulus around on the screen until they located the point where it had the largest effect on the electrical activity of the neuron. Next, they presented the animal with stimuli of various shapes in order to learn which ones produced the greatest response from the neuron.

From their experiments, Hubel and Wiesel (1977, 1979) concluded that the geography of the visual field is retained in the primary visual cortex. That is, the surface of the retina is ‘mapped’ on the surface of the primary visual cortex. However, this map on the brain is distorted, with the largest amount of area given to the centre of the visual field. The map is actually like a mosaic. Each piece of the mosaic (usually called a module) consists of a block of tissue, approximately 0.5×0.7 mm in size and containing approximately 150,000 neurons.

All of the neurons within a module receive information from the same small region of the retina. The primary visual cortex contains approximately 2,500 of these modules. Because each module in the visual cortex receives information from a small region of the retina, that means that it receives information from a small region of the visual field – the scene that the eye is viewing. If you looked at the scene before you through a straw, you would see the amount of information received by an individual module. Hubel and Wiesel found that neural circuits within each module analysed various characteristics of

Figure 6.39 The visual system of the brain. Arrows represent the flow of visual information. Sensory information from the eye is transmitted through the optic nerve to the thalamus, and from there it is relayed to the primary visual cortex. The results of the analysis performed there are sent to the visual association cortex of the occipital lobe (first level) and then on to that of the temporal lobe and parietal lobe (second level). At each stage, additional analysis takes place.

their own particular part of the visual field, that is, of their **receptive field**. Some circuits detected the presence of lines passing through the region and signalled the orientation of these lines (that is, the angle they made with respect to the horizon). Other circuits detected the thickness of these lines. Others detected movement and its direction. Still others detected colours.

Figure 6.40 shows a recording of the responses of an orientation-sensitive neuron in the primary visual cortex. This neuron is located in a cluster of neurons that receive information from a small portion of the visual field. That is, the neuron has a small receptive field. The neuron responds when a line oriented at 50 degrees to the vertical is placed in this location – especially when the line is moving through the receptive field. This response is specific to that orientation; the neuron responds very little when a line having a 70-degree or 30-degree orientation is passed through the receptive field. Other neurons in this cluster share the same receptive field but respond to lines of different orientations. Thus, the orientation of lines that pass through this receptive field is signalled by an increased rate of firing of particular neurons in the cluster.

Because each module in the primary visual cortex receives information about only a restricted area of the visual field, the information must be combined somehow for perception to take place. This combination takes place in the visual association cortex.

How different are imagining and perceiving visual stimuli?

Does visual imagery use the same brain areas as those involved in visual perception? Does the imagining of different types of ‘mental’ content activate different brain areas and if so, are they areas that would be normally activated by the actual perception of such content? Would imagining faces, for example, activate the same area(s) as that or those activated by the viewing of actual faces?

In one study, functional Magnetic Resonance Imaging was used to determine whether the brain areas activated during the mental imagining of faces were similar to or different from those activated during the mental imagining of places (O’Craven and Kanwisher, 2000). A region at the back of the brain, the human fusiform face area (HFFA), was significantly more active during the mental imagining of faces than places. They also found that imagining places activated a region called the parahippocampal place area (PPA) to a much greater extent than did the faces (as for the HFFA, the PPA becomes active when people look at places). Both of these regions can be seen in Figures 6.41.

These results are similar to those obtained by Goebel *et al.* (1998), who found that the brain region activated during visual motion was also activated during the mental imagery of motion. Studies at the level of individual

Figure 6.40 Responses of a single neuron to lines of particular orientations that are passed through its receptive field.

Figure 6.41 The parahippocampal place area **(a)** and the fusiform face area **(b)** of the brain.

groups of cells also show overlap in activation during actual perception and imagination. Kreiman *et al.* (2000), for example, recorded electrical activity from 276 neurons from the lateral (side) regions of the brain (the medial temporal lobes) as participants imagined previously viewed faces, objects, spatial layouts and animals. The purpose of the experiment was to determine whether the same neurons would respond when viewing images as when imagining them. As predicted, the authors found that when neurons responded selectively to a stimulus (that is, responded to that stimulus but not to another, indicating that the response is stimulus-specific), the same neurons were active whether the person viewed or imagined the stimulus. There was a great deal of overlap between neural response during actual viewing and imagining what was viewed.

These studies suggest that the mechanisms responsible for visual perception of images and those responsible for the mental imagining of the same images are similar. The mechanisms may be shared – the results from O’Craven and Kanwisher’s study (2000), for example, suggest that the difference in activation between the two types of condition (imagery v. viewing) was one of degree, rather than type.

The visual association cortex

The first level of the visual association cortex, which surrounds the primary visual cortex, contains several subdivisions, each of which contains a map of the visual scene. Each subdivision receives information from different types of neural circuit within the modules of the

primary visual cortex. One subdivision receives information about the orientation and widths of lines and edges and is involved in perception of shapes. Another subdivision receives information about movement and keeps track of the relative movements of objects (and may help compensate for movements of the eyes as we scan the scene in front of us). Yet another subdivision receives information concerning colour (Zeki, 1993; Milner, 1998). You can see these subdivisions in Figure 6.42.

The two regions of the second level of the visual association cortex put together the information gathered and processed by the various subdivisions of the first level. Information about shape, movement and colour are combined in the visual association cortex in the lower part of the temporal lobe. Three-dimensional form perception takes place here. The visual association cortex in the parietal lobe is responsible for perception of the location of objects. It integrates information from the first level of the visual association cortex with information from the motor system and the body senses about movements of the eyes, head and body.

Researchers have studied the anatomy and functions of the visual association cortex in laboratory animals. Neuroimaging studies have also been used to locate comparable subregions in humans. For example, when a person looks at a display containing irregular patches of different colours, one region of the visual association cortex becomes active. When a person looks at a display of moving black-and-white squares, another region becomes active (see Figure 6.43). Presumably, these areas are involved in the analysis of colour and movement, respectively.

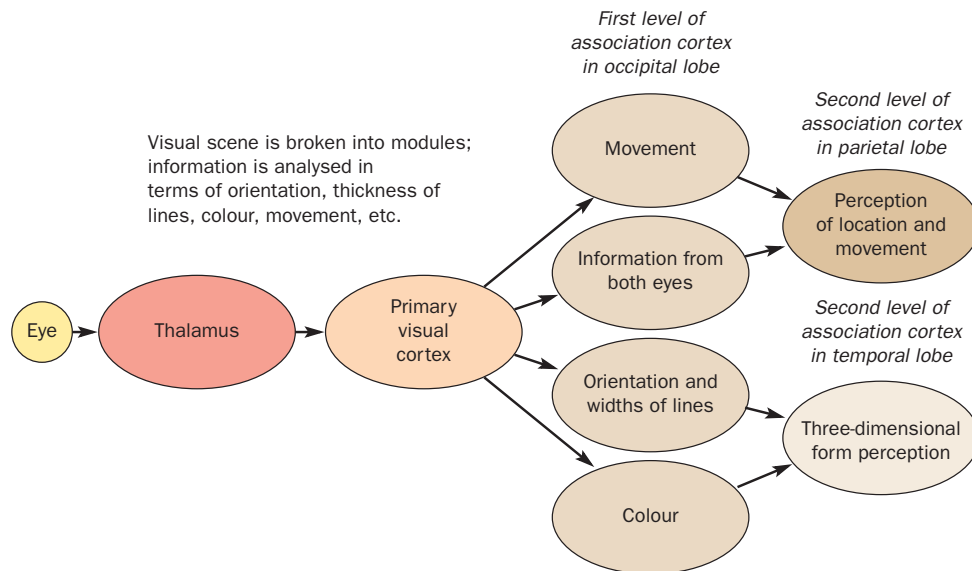

Figure 6.42 Schematic diagram of the types of analysis performed on visual information in the primary visual cortex and the various regions of the visual association cortex.

Brain damage and visual perception

Research with laboratory animals and data from individuals with brain damage have shown that certain areas of the visual cortex, the lingual and fusiform gyri, are important for discriminating between colours (Damasio *et al.*, 1980; Davidoff, 1997). Damage

to this area causes **achromatopsia**, a form of colour blindness in which the world is seen in shades of grey, as Figure 6.44 shows.

Neuroimaging studies also suggest that these areas are active in healthy individuals during a simple task where participants perceive colours (McKeefry and Zeki, 1997). McKeefry and Zeki suggest that there is an area or areas outside the primary visual cortex – V4, in the ventral occipitotemporal cortex – which mediates colour perception.

Figure 6.44 A photograph illustrating the way the world would look to a person who had achromatopsia in the right visual field, caused by damage on the left side of the brain to the region of the visual association cortex.

The finding that damage to different parts of the visual system results in different types of impairment in visual perception suggests that some visual system pathways carry one type of information whereas others carry different types of information. Schneider (1969) had proposed that there were two major visual system pathways: a geniculostriate pathway which was responsible for identifying stimuli and discriminating between patterns, and a retinotectal pathway which was responsible for locating objects in space. Schneider's theory has since been modified, although the idea that different brain regions are responsible for the perception of an object's qualities and its location is valid.

Ungerleider and Mishkin (1982), for example, have suggested that different parts of the brain are involved in object identification and object location: the appreciation of an object's qualities is the role of the inferior temporal cortex; the ability to locate an object is the role of the posterior parietal cortex. Primates with posterior parietal cortex lesions make consistent errors in accurately reaching out for or grasping objects although their ability to discriminate between objects is intact. Similar damage in humans also results in difficulties performing visuospatial tasks such as estimating length and distance (Von Cramon and Kerkhoff, 1993; Jeannerod *et al.*, 1994). Recall from Chapter 4 that the parietal cortex plays an important role in visually guiding movement and in grasping or manipulating objects (Sakata, 1997). Importantly, Ungerleider and Mishkin distinguished between a ventral and dorsal pathway or stream which projected from the primary visual cortex (PVC) to these areas. Thus, although originating in the PVC, the two pathways were independent and projected to different areas of the brain (to the temporal and posterior parietal cortices, respectively).

Goodale and Milner (1992; Milner and Goodale, 1995) developed the theory further. What is important, they argue, is not 'what' and 'where', but 'what' and 'how'. In Ungerleider and Mishkin's model, the ventral stream processes the 'what' component of visual perception (identification of an object) whereas the dorsal stream processes the 'where' component (the spatial location of an object). Goodale and Milner's research has focused on the 'what' and 'how' areas. The brain regions representing these streams can be seen in Figure 6.45.

Goodale and Milner have made an extensive study of DF, a woman with substantial bilateral damage to the occipital cortex (but sparing the PVC) resulting from carbon monoxide poisoning (Goodale and Milner, 1992; Milner and Goodale, 1995). DF is unable to discriminate between geometric shapes and is unable to recognise or identify objects, despite having no language or visual sensory impairment (Milner *et al.*, 1991). That is, she exhibits visual form agnosia (agnosia is described in more detail in the next section). DF is able to respond to objects. For example, she can place her hand into a slot of varying orientations or grasp blocks (Goodale *et al.*, 1991). However, when she is asked to estimate the orientation of the slot or the width of the box by verbally reporting or by gesturing, she is unable to do so. Why?

DF may be using the intact visuomotor processing system in the parietal cortex to perform the grasping and orientation tasks (Milner and Goodale, 1995; Milner, 1998). The guidance of motor behaviour relies on a primitive dorsal stream in the parietal cortex which is spared in DF. This is why the execution of her motor behaviour is accurate. When asked to indicate which of two boxes is a rectangle and which is a square, she can respond correctly when holding the boxes but less correctly when making a verbal response (Murphy *et al.*, 1996). DF would make partial movements towards one of the boxes before correcting herself. When these initial reaches were analysed, they showed the same level of accuracy as if she had verbally reported which box was which. Did DF monitor the size of her anticipatory grip before making a decision?

There is evidence that she does. When asked to look at a series of lines of varying orientation and then copy them on a separate piece of paper, DF would outline the line in the air before making a copy. When asked not to do this, her copies were still relatively accurate. She found the task easier if she imagined herself drawing the line: when she was asked to copy the line immediately – thereby preventing rehearsal from taking place – she failed (Dijkerman and Milner, 1997). DF must have generated a motor image of the lines to allow her to accomplish this task, a behaviour which would have been made possible by intact functioning of the frontal and parietal lobes.

On the basis of DF's behaviour, research from neuroimaging studies of motor movement and vision, and animal lesions to parietal and occipital areas, Milner and

Goodale (1995) propose that the dorsal stream sends information about object characteristics and orientation that is related to movement from the primary visual cortex to the parietal cortex. Damage to the ventral stream, which projects to the inferior temporal cortex, is what is responsible for DF's inability to access perceptual information.

Projections to the primary visual cortex

Two specific cellular pathways – the parvocellular (P) and magnocellular (M) pathways – run from the retina to the cortex and terminate in different layers of the primary visual cortex (V1). Other layers of V1 project to other dorsal and ventral stream areas. Layers 2 and 3 of V1, for example, provide input to the ventral stream areas whereas layer 4B sends input to dorsal stream areas. Layer 4B also receives input from the M and P pathways and projects to areas such as V5, a region known to be involved in motion perception. Many other circuits such as this are made within the visual system but comparatively little is known about how functionally relevant such connections are or how different types of cell contribute to the circuitry. One study has shown that different types of neurons in area V1 receive different signals from the M and P pathways and forward this information to other specific cortical areas (Yabuta *et al.*, 2001). The results of the study suggest that if two types of cell project to different layers, perhaps each type carries different types of information in the cortical visual system.

Perceptual disorders

When the brain is damaged and visual perception is impaired, the patient is said to exhibit a **perceptual disorder**. There are several perceptual disorders and each is associated with damage to different parts of the visual system. It is important to note that these disorders are strictly perceptual, that is, there is no underlying impairment in sensation (patients retain visual acuity and the ability to tell light from dark and so on). The basic visual sensory system itself is, therefore, unimpaired. Three of the most important perceptual disorders are blindsight, agnosia and spatial neglect. Each is important in its own way because they demonstrate how brain damage can affect different aspects of visual perception.

Blindsight

When the primary visual cortex is damaged, a person becomes blind in some portion of the visual field. Some individuals, however, can lose substantial areas of the PVC and yet show evidence of perceiving objects despite being 'cortically blind'. This phenomenon is called **blindsight** (Weiskrantz, 1986, 1997) because although patients are unable to see properties of objects they are aware of other

aspects such as movement of objects. Moving objects are better detected than still ones, objects can be located if they are pointed at and they can detect movement and colour, despite being 'unable' to see the stimuli. (There are equivalent phenomena in the auditory and somatosensory systems called deaf hearing and blindtouch.)

The earliest case of blindsight was reported at the beginning of the last century (Riddoch, 1917). Riddoch was an army medical officer who had made a study of soldiers whose primary visual cortex had been damaged by gunshot wounds. Although none of the patients could directly describe objects placed in front of them (neither shape, form nor colour), they were conscious of the movement of the objects, despite the movement being 'vague and shadowy'. This suggested to Riddoch that some residual visual ability in the PVC remained which allowed the perception of object motion but no other aspect of visual perception. Some patients need to be prompted to 'guess' (Blindsight Type 1) whereas others will report vague sensations (Blindsight Type 2) although both types claim that they cannot see anything. That the PVC is damaged led to the hypothesis that this area was responsible for conscious visual perception (Radoeva *et al.*, 2008).

Since Riddoch's study, several other cases of blindsight have been reported, notably Larry Weiskrantz's famous patient, DB (Weiskrantz, 1986). DB had undergone surgery for a brain tumour, which necessitated removal of the area of the visual cortex in the right occipital lobe. This surgery resulted in a scotoma – an area of complete blindness in the visual field. DB could indicate whether a stick was horizontal or vertical, could point to the location of an object when instructed, and could detect whether an object was present or absent. Other tasks presented greater difficulty: DB could not distinguish a triangle from a cross or a curved triangle from a normal one. The most intriguing feature of DB's behaviour, however, was a lack of awareness of the stimuli presented. According to DB, he 'couldn't see anything' when test stimuli were seen. Why could DB, and patients like DB, make perceptual decisions despite being unaware of visual stimuli?

One hypothesis suggests that perceptual tasks can be completed successfully because stray light emitted by stimuli makes its way from the intact field of vision because it reflects from surfaces outside the eye area – what is called extraocular scatter. Cowey (2004) has suggested that one way of controlling for this light scatter is to mask the blind field from view by placing a half-patch over the viewing eye, but this control is rarely employed. There can also be an intraocular source of light scatter – according to Cowey (2004), visual stimuli always 'smear' the retina. Because stimuli in blindsight studies have been presented very close to the eye, this has allowed the retina to be smeared with the image and to be stimulated, leading to crude visual perception.

The stray light hypothesis, however, appears to be an unlikely explanation because DB is able to make perceptual decisions in the presence of strong ambient light which reduces the amount of stray light emitted by stimuli. More to the point, this theory does not explain how DB can still make decisions based on the spatial dimensions of objects.

An alternative hypothesis suggests that the residual perceptual abilities of patients such as DB are attributable to the degrading of normal vision, possibly due to the presence of some residual striatal cortex ('islands' of PVC cortex that are undamaged) (Scharli *et al.*, 1999; Wessinger *et al.*, 1999). Implicit in this hypothesis is the notion that residual abilities are not attributable to the functioning of another visual system pathway. There are ten known pathways from the retina to the brain (Stoerig and Cowey, 1997). As you have seen, there appear to be two distinct pathways in the visual system which mediate different aspects of vision. The visual location of objects, for example, is thought to be a function of a system which includes the superior colliculus, the posterior thalamus and areas 20 and 21, whereas the analysis of visual form, pattern or colour is thought to be a function of the geniculostriate system which sends projections from the retina to the lateral geniculate nucleus, then to areas 17, 18 and 19, and then to areas 20 and 21. Blindsight could, therefore, conceivably be due to a disconnection between these two systems. Again, there are arguments against this hypothesis.

Curiously, DB, although unable to 'see' objects when presented to him – even 30 years after his deficit was first studied, appears to be aware of a visual 'after-image' after a stimulus on a monitor is switched off (Weiskrantz *et al.*, 2002). The colour and spatial structure of the stimulus can be described, a phenomenon that is correlated with increased prefrontal cortex activity (Weiskrantz *et al.*, 2003). It is unclear whether this ability is due to spared striate cortex, however, because DB has surgical clips which prevent him from undergoing an MRI scan which would demarcate the preserved cortex.

Another patient, GY, has no spared striate cortex, but still exhibits signs of blindsight (Azzopardi and Cowey, 2001). When the visual cortex of blindsight patients with spared striate cortex is imaged, there is no activation observed to visual stimuli that produce the blindsight phenomenon (Storeig *et al.*, 1998). Both lines of evidence suggest that the spared striate cortex explanation is weak (although not completely dismissible – perhaps the degree and type of spared cortex are the important factors).

What seems reasonable, but for which there is no hard evidence, is the hypothesis that blindsight relies on a primitive, early visual system that is not dependent on the striate cortex. A note of caution should be struck, however. Blythe *et al.* (1987), for example, found only 5 cases of blindsight in a sample of 25 patients; Marzi *et al.* (1986) found a similar ratio (4 patients out of 20) in their sample. The degree of variability in the appearance of

blindsight following striatal removal, therefore, suggests some restraint in extrapolating from individual cases.

Visual agnosia

Patients with posterior lesions to the left or right hemisphere sometimes have considerable difficulty in recognising objects, despite having intact sensory systems. We saw an example of this in an earlier section when we discussed the perceptual impairments seen in patient DF. This disorder is called agnosia (literally 'without knowledge'), a term coined by Sigmund Freud. Agnosia can occur in any sense (tactile agnosia refers to the inability to recognise an object by touch, for example) but **visual agnosia** is the most common type (Farah, 1990; Farah and Ratcliff, 1994).

The existence of specific types of agnosia is a controversial topic in perception and neuropsychology. A distinction is usually made between two types of visual agnosia: associative and apperceptive. **Apperceptive agnosia** is the inability to recognise objects whereas **associative agnosia** is the inability to make meaningful associations to objects that are visually presented. Some neuropsychologists have argued that the boundaries between these two types are 'fuzzy' (DeRenzi and Lucchelli, 1993), and other sub-types of visual agnosia have been suggested (Humphreys and Riddoch, 1987a). Apperceptive agnosics have a severe impairment in the ability to copy drawings, as patient DF did. Associative agnosics, conversely, can copy accurately but are unable to identify their drawings. For example, Humphreys and Riddoch's patient, HJA, spent six hours completing an accurate drawing but was unable to identify it when he had finished. Figure 6.46 shows you an example of HJA's drawings.

Figure 6.46 The drawing of a building by HJA reflects great attention but he was unable to name it. The line drawings beneath are of very simple objects but HJA was unable to name them.

Source: Humphreys and Riddoch (1987). *To See or Not to See*. Andover: Psychology Press, reprinted by permission of Thomson Publishing Services.

There has been considerable debate concerning the specificity of visual object agnosia, that is, whether some patients are able to recognise some categories of object but not others (Newcombe *et al.*, 1994). The commonest dissociation is seen between living and non-living things. Generally, it has been found that recognition of living objects (such as animals) is less accurate in agnosic patients than is recognition of non-living objects (Warrington and Shallice, 1984; Silveri *et al.*, 1997). To determine whether different brain regions were responsible for this dissociation, Martin *et al.* (1996) conducted a PET study of healthy individuals' brain activity as the subjects named pictures of tools or animals. Both categories of words were associated with activation in the visual cortex and Broca's area (because the participants saw and spoke) but some areas were activated by the naming of animals (left occipital region) and others by the naming of tools (right premotor regions).

Some psychologists, however, have argued that these studies do not show differences between the categories of object but between the ways in which these two different types of stimulus are presented. Parkin and Stewart (1993), for example, have suggested that it is more difficult to recognise drawings of animate than inanimate objects. An inanimate object such as a cup, is a lot less detailed than an animate object, such as a fly. The dissociation seen in agnosic patients, therefore, may be due to the complexity and/or familiarity of the perceived stimulus. Stewart *et al.* (1992) have suggested that when these artefacts are controlled for, these dissociations disappear. However, the issue continues to be controversial. Sheridan and Humphreys (1993), for example, have shown that patients show such dissociations even under well-controlled conditions and a recent review suggests that specific brain regions may mediate the recognition of objects from different semantic categories (Gainotti, 2000).

Prosopagnosia

A more category-specific form of agnosia is **prosopagnosia**. Some individuals with damage to specific areas of the posterior right hemisphere (and sometimes left and right hemispheres) show an impairment in the ability to recognise familiar faces. This condition is known as prosopagnosia ('loss of knowledge for faces'). Some patients are unable to recognise famous faces (Warrington and James, 1967) or familiar people such as spouses (DeRenzi, 1986). This disorder, while rare, can have dramatic effects on a person's everyday life. For example, here are some comments from patients with prosopagnosia on how their condition affects them (all from Yardley *et al.*, 2008):

"I was getting off a bus and somebody got on it and grabbed me, and I pushed them out of the way and it was only when they opened their mouth that I realized it was my own mother."

"Sometimes if I see someone and I'm not sure if I know them I just try and keep out of their way and hope they don't see me, 'cause I don't know how to act."

"The condition makes me less interested in the social events, the partying, the getting to know lots of people, because that just gives me a whole set of things I'll get wrong."

"I'd try, spend three days chatting up some girl and then cut her dead in the street without knowing that I'd done it."

Barry Wainwright, who suffers from prosopagnosia: 'If I look at a photograph of myself, I don't know it's me. I don't recognise my wife or my seven children, either, even when I'm looking right at them.'

Source: From *The Guardian Weekend Magazine*, 22 November 2008, p. 12.

Much of the recent neuropsychological work on face recognition has exploited neuroimaging techniques in order to determine whether different regions of the human brain respond to faces selectively. One controversy in the area surrounds whether such selective activation is specific to faces or to some other perceptual aspect of faces, such as whether they appear in greyscale or in two-tone. Kanwisher *et al.* (1998), for example, found that the brain region which you encountered in the earlier section, the human fusiform face area (HFFA), was significantly activated when people viewed upright and inverted greyscale faces. Inverted two-tone faces, however, were associated

with significantly reduced brain activation. The results suggest that the HFFA does not respond specifically to low-level features of faces (if it did, the inverted and upright two-tone faces would have produced similar activation) but does respond to face stimuli. The authors acknowledge, however, that this may not be the only brain region specialised for face processing.

Current neuroimaging data make HFFA a strong contender for the role of the brain's primary face processor. Its response is stronger when viewing faces, followed by whole humans and animal heads (Kanwisher *et al.*, 1999) and appears to be involved in remembering, as well as seeing, faces (Kuskowski and Pardo, 1999). Gorno-Tempini *et al.* (1998) compared the human brain's ability to process, implicitly or explicitly, famous and unknown face stimuli, proper names and object names and report that the perceptual analysis of faces was associated with selective activation of the HFFA in both hemispheres of the brain. Other regions were implicated in famous name processing (relative to common names). The same research group also reported a study in which activation to famous and non-famous faces and buildings was recorded (Gorno-Tempini and Price, 2001). In this experiment, they found that the HFFA and the PPA were selectively activated by faces and buildings, respectively, regardless of fame (although other regions were activated during exposure to the famous stimuli).

One view, however, suggests that the FFA, rather than being specialised for recognising faces, is responsible for distinguishing between members of a homogeneous class of objects (not just faces). A related argument suggests that the FFA is active when it distinguishes between members of object classes that we are expert in identifying. Because we are very familiar with faces, and expert at recognising them, the FFA is, therefore, active when we view faces. This argument also suggests, however, that expert identifiers should activate the FFA when they view objects they are expert in recognising (and not just faces).

To test these various hypotheses, Rhodes *et al.* (2004) set up two experiments in which people were either trained or were not trained to recognise Lepidoptera (moths and butterflies). Brain activation was monitored using fMRI while participants viewed faces and Lepidoptera. In the second experiment, experts in identifying moths and butterflies passively watched examples of the species while brain activity was recorded. If the FFA is active during expert discrimination, then it should be just as active during face perception and Lepidoptera perception in experts.

The authors found no support for this hypothesis. In the first experiment, the FFA was more significantly activated when people watched faces than Lepidoptera, regardless of whether people had been trained to recognise examples of

the species. In the second experiment, activation was greater in the FFA when the butterfly experts watched faces than Lepidoptera. There was no overlap in the areas activated by faces and moths and butterflies.

The results suggest that the FFA contains neurons that allow 'individuation' of (i.e. discrimination between) faces.

Spatial neglect

Patients with lesions in the right parietotemporal cortex sometimes have difficulty in perceiving objects to their left (Vallar, 1998). In fact, in 80 per cent of patients with right hemisphere stroke, patients are unable to attend automatically to any stimuli in left space (Halligan and Marshall, 1994). This is called **spatial neglect** (or unilateral spatial hemineglect) and occurs on the side of the body that is contralateral to the side of the brain damage (the regions damaged can be seen in Figure 6.47). Neglect for the left side is more common than right neglect (which would be caused by damage to the left hemisphere).

Patients exhibiting spatial neglect behave as if half of the world does not exist. They may forget to attend to their clothing on the left-hand side, neglect food on the left side of the plate or ignore the left-hand side of their newspaper (Halligan and Cockburn, 1993; Halligan and Marshall, 1994).

Spatial neglect patients show a characteristic pattern of behaviour on visuospatial tests. For example, if they are required to bisect lines of varying length, they will err to the right. If they are presented with an array of stimuli (such as small lines) and asked to mark off as many as possible, they mark off those on the right-hand side but fail to mark off those on the left, as seen in Figure 6.48.

Figure 6.47 The areas of the brain damaged in spatial neglect patients. Most patients have damage to region A; some can have damage to region B.

Figure 6.48 The line cancellation task. Spatial neglect patients consistently neglect one side of the display (in this example, the left side).

Similarly, neglect patients, when asked to draw (or mentally imagine a scene) fail to draw or report details from the left side of the object or image (Halligan and Marshall, 1994; Guariglia *et al.*, 1993). Sometimes, patients will transfer details from the left to the right-

Figure 6.49 The famous clock-drawing task at which spatial neglect patients are impaired. Patients either neglect the numerals on the left side completely or bunch them up on the right.

hand side, as seen in Figure 6.49. This is called **allesthesia** or **allochiria** (Meador *et al.*, 1991).

The examples shown in Figure 6.51 illustrate the profound consequences that brain damage can have on perceptual behaviour, not just in terms of behavioural impairment but also in terms of disruption to a patient's life and work.

The reasons for spatial neglect are unclear (see Halligan and Marshall, 1994, and Mozer *et al.*, 1997, for a discussion).

Psychology in action – How does brain injury affect artists?

Losing the ability to speak, to recall information, or organise and plan everyday life efficiently are all unwelcome intruders in the world of the normally functioning. But what if the disrupted function is essential to the person's life and provides him or her with a livelihood? Beethoven composed symphonies, Evelyn Glennie plays exceptional xylophone, Stevie Wonder is an accomplished keyboardist; even James Joyce managed to produce *Ulysees* and *Finnegan's Wake* despite his chronic sight loss (although this is thought to explain some of Joyce's eccentric text). None of these, however, despite their sensory losses, sustained brain injury. Chatterjee (2004) has reviewed the type of effects brain injury has on an artist's performance and output.

The loss of the ability to perceive colour is clearly one of the most challenging problems for an artist who exploits his or her chromatic palette. Sacks (1995) describes an artist who developed an injury leaving him achromatopsic – the artist's world appeared 'dirty grey' and he reported being unable to imagine colours (or even being able to dream in colour). Before the accident leading to the injury, the patient painted colourful, abstract creations; after the accident, the paintings became figurative and abstract. Contrast, figure and form were

good as was the patient's ability to understand and describe colour but his use of colour became haphazard.

Unilateral spatial neglect has more intriguing, if predictable, consequences. Jung (1974) described four early cases of painters who developed neglect following brain injury. One, the German artist Lovis Corinth, had suffered a right hemisphere stroke. His painting changed dramatically: the contours on the left of his work disappeared and details became misplaced. Blanke *et al.* (2003) reported the case of a 71-year-old artist who could colour the right side of her paintings normally and evenly but paid minimal attention to the left. Figure 6.50 gives an example of the patient's art following injury. Neglect for colour was greater than neglect for form in the majority of the patient's paintings. Painter IK showed right neglect where entire canvasses would be created in exuberant colour but the right side lacked detail and form (Marsh and Philwin, 1987).

Perhaps the most famous example of unilateral spatial neglect is the Italian film director, Federico Fellini, whose disorder was reported by Cantagallo and Della Sala (1998). At the age of 73, Fellini suffered a stroke in the middle cerebral artery of the right parietal lobe that caused left extrapersonal spatial

Psychology in action – Continued

neglect that persisted for two months. As well as being a celebrated film director, Fellini was an accomplished cartoonist and his completion of neglect tests was peppered with his cartoonish embellishments. His original cartoons showed neglect of the left side. Figure 6.51 (a) and (b) illustrates some of Fellini's attempts.

Fellini's neglect did not appear to be representational (he could imagine both sides of his visual field) and he was completely aware of his deficits. Unlike patients in previous reports, his increased awareness did not lead to a decrease in his neglect (Guariglia *et al.*, 1993).

Halligan and Marshall (1997) reported the consequences of neglect for a 75-year-old artist and sculptor who had suffered a right hemisphere stroke. Six months after the stroke, his drawings were poorer and less elaborate than they were before the stroke. His family also noted that he seemed to concentrate on the right-hand side of the drawings. In fact, on all the standard tests of neglect, he showed impairment. Figure 6.52 (a)–(c) shows examples of the patient's sculptures before and 3 to 4 months after the stroke.

As Fellini did, some artists can recover their ability to attend to the left to some extent; sometimes they will use broader strokes than normal or may be more expressive, as the painters Loring Hughes and Lovis Corinth found.

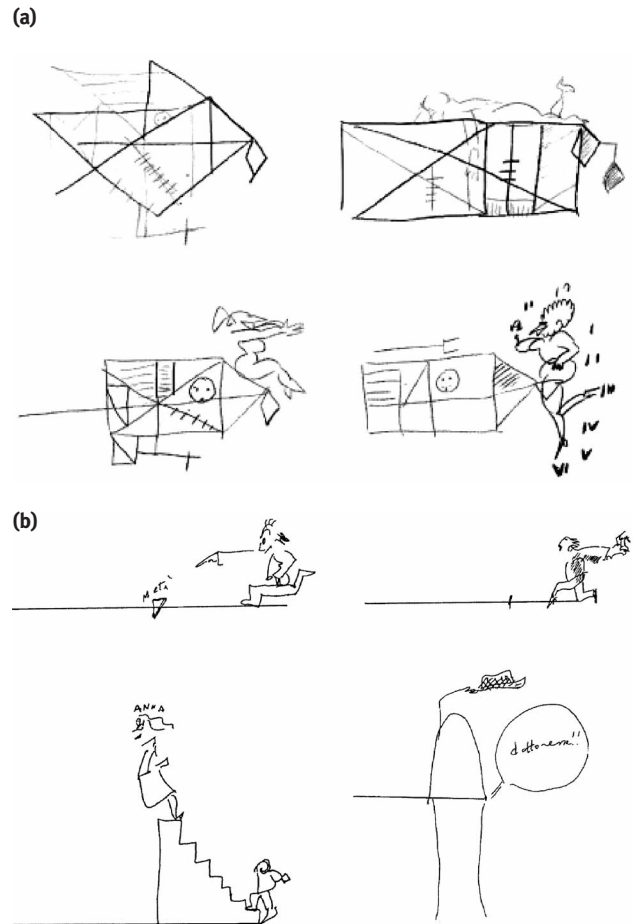

Figure 6.51 Italian film director Federico Fellini developed spatial neglect after suffering a stroke. As well as being a director, Fellini was also a talented cartoonist and he doodled comically on his psychological tests. (a) and (b) Examples of Fellini's spatial neglect test performance.

At least neglect patients can recognise their creations. Some patients with visual agnosia are unable to do this. Wapner *et al.* (1978) report the case of a 73-year-old amateur artist who developed visual agnosia following a stroke. The artist would draw extremely laboriously but failed to recognise what he drew. He could identify the general shape of the object and describe its function, and even tried to identify it from its parts, but could not put a label to it. His agnosia was perceptual, rather than conceptual, because he would sometimes describe the functions of parts of the object he drew (e.g. what a telephone was for).

Agnosic patients can sometimes imagine the objects they would like to draw. Botez *et al.* (1985), however, report the case of a 38-year-old teacher and amateur charcoal drawer who was unable to imagine people, places or objects, following dilation of one of the brain's chambers. Copying objects presented little problem but when the object was removed from sight, her drawings became simple and schematic. When she was given the name of an object to draw, she could not do this competently.

Perception seems the most likely casualty in the artist's battle with brain damage but there are some cases of impairment to other functions which lead to some unusual artistic

sequences. The Bulgarian artist Zlatko Boiyadjiev, exhibited a natural, pictorial style prior to the development of aphasia (Zaimov *et al.*, 1969). After the aphasia, his art became bold, rich and colourful, full of striking, energetic lines and replete with bizarre imagery. Another artist with aphasia, the Polish artist RL (an Assistant Professor in Lublin), was known for highly symbolic paintings. Following aphasia, he produced very well-executed charcoal drawings, self-portraits and landscapes (Kaczmarek, 1991). No matter how hard he tried, he never did recover the symbolism of his art that existed before the aphasia.

Chapter review

Perception of form

- Perception of form requires recognition of figure and ground. The Gestalt organisational laws of proximity, similarity, good continuation and common fate describe some of the ways in which we distinguish figure from ground even when the outlines of the figures are not explicitly bounded by lines.
- One hypothesis concerning the mechanism of pattern perception, or visual recognition of particular shapes suggests that our brain contains templates of all the shapes we can perceive. We compare a particular pattern of visual input with these templates until we find a fit. A second hypothesis suggests that our brain contains prototypes, which are more flexible than simple templates. Some psychologists believe that prototypes are collections of distinctive features (such as the two parallel lines and the connecting diagonal of the letter N).
- Perception involves both bottom-up and top-down processing. Our perceptions are influenced not only by the details of the particular stimuli we see, but also by their relations to each other and our expectations. Thus, we may perceive a shape either as a loaf of bread in the kitchen or as a letterbox alongside a country road, for example.
- We can usually distinguish male and female faces on the basis of eyes, mouth and nose but rarely on the basis of single features alone.
- Lighting, form and contour significantly influence our ability to recognise faces correctly.

Perception of space and motion

- Because the size and shape of a retinal image vary with the location of an object relative to the eye, accurate form perception requires depth perception – perception of the locations of objects in space.
- Depth perception comes from binocular cues (from convergence and retinal disparity) and monocular cues (from interposition, size, linear perspective, texture, haze shading, elevation, and the effects of head and body movements).
- The Sapir–Whorf hypothesis suggests that language can strongly affect the way we perceive the world although there is not much research to support it. It is possible that experience with some environmental features, such as particular geographical features or buildings composed of straight lines and right angles, has some influence on the way people perceive the world.
- We perceive the brightness of an object relative to that of objects around it; thus, objects retain a constant brightness under a variety of conditions of illumination. In addition, our perception of the relative distance of objects helps us maintain form constancy.
- Because our bodies may well be moving while we are visually following some activity in the outside world, the visual system has to make further compensations. It keeps track of the commands to the eye muscles and compensates for the direction in which the eyes are pointing.
- Movement is perceived when objects move relative to one another. In particular, a smaller object is likely to be perceived as moving across a larger one. Movement is also perceived when our eyes follow a moving object, even though its image remains on the same part of the retina and supplies important cues about an object's three-dimensional shape.
- Because a complex scene, covering a large area, cannot be seen in a single glance, the visual system must combine information from successive fixations. The phenomenon of backward masking suggests that the image received from the previous fixation is erased immediately after a saccade so that blurring does not occur.
- The phi phenomenon describes our tendency to see an instantaneous disappearance of an object and its

reappearance somewhere else as movement of that object. Because of the phi phenomenon, we perceive television shows and films as representations of reality, not as a series of disconnected images.

Brain mechanisms of visual perception

- Visual information proceeds from the retina to the thalamus, and then to the primary visual cortex (PVC). The PVC is organised into modules, each of which receives information from a small region of the retina.
- Neural circuits within each module analyse specific information from their part of the visual field, including the orientation and width of lines, colour and movement.
- The different types of information analysed by the neural circuits in the modules of the PVC are sent to separate maps of the visual field in the first level of the visual association cortex. The information from these maps is combined in the second level of the visual association cortex: form perception in the base of the temporal lobe and spatial perception in the parietal lobe.
- The brain seems to contain visual systems which process (1) features of objects and (2) the space indication of objects. The first, the ventral stream, projects from the PVC to the inferior temporal cortex; the second, the dorsal stream projects from the PVC to the posterior parietal cortex.
- Visual agnosia is the inability to perceive objects accurately (apperceptive agnosia) or assign meaning to visually presented objects (associative agnosia). Prosopagnosia is the inability to identify familiar faces and results from bilateral or unilateral posterior brain damage.
- The agnostic deficits seen in patient DF may be due to an intact dorsal stream but an impaired ventral stream.
- Blindsight refers to the ability to perform visual perceptual tasks despite a lack of awareness of the perceived stimuli; it is normally associated with damage outside the primary visual cortex.
- Spatial neglect is the inability to attend to stimuli in one half of space. Patients usually neglect the left-hand side as a result of right parietotemporal cortex damage (that is, the deficit is contralesional – occurs on the opposite side to the brain damage).

Learning and behaviour

Luck can change your life

Ms V is a compulsive gambler. It wrecked her marriage and drained her wallet long ago. Her kids don't like her because she is always barely scraping by – and borrowing money from them – waiting for the next big win that she hopes will give her all the cash she needs to escape her current mess.

How did it all begin? The answer lies in the schedules of reinforcement. At college, one of her boyfriends liked to bet on the horses and V went along one day. She bet £10 on a filly named Flo and won £300. What a rush! Luck brought her a giant reinforcer without much effort – with no 'down side' in sight. Her boyfriend was excited, too. V saved the money and went back to the track several more times over the next several weeks – sometimes alone, sometimes with her boyfriend – making more £10 bets. Most lost. A few made small wins. But the betting was exciting, and there was lots of sensory stimulation when her horse took one of the front positions.

When V's £300 was about half gone, she bet on a long shot with big odds. No one expected Viceroy to win, but V put down £75 on a hunch. Viceroy . . . won by a nose. V walked away with £4,500 in her pocket. Early periods of generous reinforcement can have a big effect on our later behavioural decisions.

WHAT YOU SHOULD BE ABLE TO DO AFTER READING CHAPTER 7

- Describe the concept of habituation and the phenomena of classical conditioning and operant learning.
- Understand the principles underlying classical conditioning.
- Understand the principles underlying operant conditioning.
- Describe and explain conditioned aversions.
- Describe the nature of insight.
- Apply the principles of learning theory to behaviour.
- Describe some of the factors that influence academic learning.

QUESTIONS TO THINK ABOUT

- Do different aspects of learning have different underlying principles? Is learning to ride a bike governed by different principles from those used for learning to find your way around college or university or learning a foreign language?
- Does all learning have to be intentional? Can you learn something without knowing it or without wanting to learn it?
- Is learning a process that depends on innate ability, the ability to adopt successful learning strategies or both?
- What factors do you think enhance and promote the process of learning?
- What psychological factors can enhance (or impair) your academic learning?
- In what way is the brain like a computer (and vice versa)?

Explore the accompanying video, simulations, and animations on MyPsychLab. This chapter includes activities on: Acquisition of conditioned responses • Stimulus generalisation and stimulus discrimination • Classical conditioning of Little Albert • Schedules of reinforcement • Check your understanding and prepare for your exams using the multiple choice, short answer and essay practice tests also available

The purpose of learning

Behaviours that produce favourable consequences are repeated and become habits, but those that produce unfavourable consequences tend not to recur (Ouellette and Wood, 1998). In other words, we learn from experience. **Learning** is an adaptive process in which the tendency to perform a particular behaviour is changed by experience. As conditions change, we learn new behaviours and eliminate old ones.

This chapter considers three kinds of learning: habituation, classical conditioning and operant conditioning. All three involve cause-and-effect relations between behaviour and the environment. We learn which stimuli are trivial and which are important, and we learn to make adaptive responses and to avoid maladaptive ones. We learn to recognise those conditions under which a particular response is useful and those under which a different response is more appropriate. The types of learning described in this chapter serve as the building blocks for more complex behaviours, such as problem-solving and thinking, which we consider in later chapters.

Learning, however, cannot be truly observed in a direct sense; it can only be inferred from changes in behaviour. As you saw in Chapter 1, the influential field of behaviourism which dominated experimental psychology in the early twentieth century demanded that only observable behaviour could be valid subject matter for psychologists. However, even the founding father of behaviourism, John B. Watson, argued that there could be two categories of observable behaviour: explicit behaviour, which is directly observable to the eye, and implicit behaviour, which could be measured by special equipment (an example would be the measurement of bodily response using psychophysiological recording equipment).

But not all changes in behaviour are caused by learning. For example, your performance in an examination or the skill with which you operate a car can be affected by your physical or mental condition, such as fatigue, fearfulness or distraction. Moreover, learning may occur without noticeable changes in observable behaviour taking place. In some cases, learning is not apparent – at least, not right away – from our observable behaviour. In other cases, we may never have the opportunity to demonstrate what we have learned. For example, although you may have received training in how to conduct an orthogonally rotated factor analysis in your computer's statistics package, you may never need to demonstrate the results of your learning again. In still other cases, you may not be sufficiently motivated to demonstrate something you have learned. For example, a tutor might pose a question in a seminar but although

you know the answer, you do not say anything because you get nervous when speaking in front of others.

Learning takes place within the nervous system. Experience alters the structure and chemistry of the brain, and these changes affect the individual's subsequent behaviour. Performance is the behavioural change (or new behaviour) produced by this internal change.

Habituation

Many events may cause us to react automatically. For example, a sudden, unexpected noise causes an **orienting response**: we become alert and turn our heads towards the source of the sound. However, if the noise occurs repeatedly, we gradually cease to respond to it; we eventually ignore it. **Habituation**, learning not to respond to an unimportant event that occurs repeatedly, is the simplest form of learning. As you will see in Chapter 12, even infants a few months old show evidence of habituation.

From an evolutionary perspective, habituation makes adaptive sense. If a once-novel stimulus occurs again and again without any important result, the stimulus has no significance to the organism. Obviously, responding to a stimulus of no importance wastes time and energy.

The simplest form of habituation is temporary, and is known as short-term habituation. Imagine entering a new room in an inhabited house. It is likely that you will perceive the distinctive odour of the room. Eventually, however, you begin not to notice the odour; you will have become habituated. If you return to the same house the next day, however, you will perceive that distinctive smell again but if you stay in the room for long enough, you will again become habituated.

Classical conditioning

Unlike habituation, **classical conditioning** involves learning about the conditions that predict that a significant event will occur. We acquire much of our behaviour through classical conditioning. For example, if you are hungry and smell a favourite food cooking, your mouth is likely to water. If you see someone with whom you have recently had a serious argument, you are likely to experience again some of the emotional reactions that occurred during the encounter. If you hear a song that you used to listen to with a loved one, you are likely to experience a feeling of nostalgia. If you listen to a piece of music that can be distinctly identified by nation, then people will buy more of that nation's wine. How does such classical conditioning take place?

Imagine that you have an uninflated balloon directly before you. Someone starts inflating the balloon with a pump; the balloon gets larger and larger. What are you likely to do? You will probably grimace and squint your eyes as you realise that the balloon is about to burst in your face.

Now consider how a person learns to flinch defensively at the sight of a tightly stretched balloon. Suppose that we inflate a balloon in front of a young boy who has never seen one before. The boy will turn his eyes towards the enlarging balloon, but he will not flinch. When the balloon explodes, the noise and the blast of air will cause a defensive startle reaction: he will squint, grimace, raise his shoulders and suddenly move his arms towards his body. A bursting balloon is an important stimulus, one that causes an automatic, unlearned defensive reaction.

We will probably not have to repeat the experience many times for the boy to learn to react the way we all do – flinching defensively before the balloon actually bursts. A previously neutral stimulus (the over-inflated balloon), followed by an important stimulus (the explosion that occurs when the balloon bursts), can now trigger the defensive flinching response by itself. The defensive flinching response has been classically conditioned to the sight of an over-inflated balloon. Two stimuli have become associated with each other.

Pavlov's serendipitous discovery

In December 1904, the Russian physiologist Ivan Pavlov was awarded the Nobel Prize in physiology and medicine for his work on the digestive system. Invited to Stockholm to accept the award and to deliver an acceptance speech, the 55-year-old Pavlov did not speak of his pioneering work on digestion (Babkin, 1949). Instead, his address, entitled 'The first sure steps along the path of a new investigation', focused on his more recent work involving conditional reflexes or 'involuntary' responses. Pavlov's new line of research was to take him far from the research for which he was awarded the Nobel Prize, and today he is remembered more for his work in psychology than in physiology. But it was while studying the digestive system that Pavlov stumbled on the phenomenon that was to make a lasting impact on psychology (Windholz, 1997).

Pavlov's chief ambition as a physiologist was to discover the neural mechanisms controlling glandular secretions during digestion. He measured the secretions during the course of a meal by inserting a small tube in a duct in an animal's mouth and collecting drops of saliva as they were secreted by the salivary gland. During each of the test sessions, he placed dry food powder inside the dog's mouth and then collected the saliva. All went well until the dogs became experienced subjects. After several

testing sessions, the dogs began salivating before being fed, usually as soon as they saw the laboratory assistant enter the room with the food powder. What Pavlov discovered was a form of learning in which one stimulus predicts the occurrence of another. In this case, the appearance of the laboratory assistant predicted the appearance of food.

Rather than ignoring this phenomenon or treating it as a confounding variable that needed to be controlled, Pavlov designed experiments to discover exactly why the dogs were salivating before being given the opportunity to eat. He suspected that salivation might be triggered by stimuli that were initially unrelated to eating. Somehow, these neutral stimuli came to control what is normally a natural reflexive behaviour. After all, dogs do not naturally salivate when they see laboratory assistants.

To do so, he placed an inexperienced dog in a harness and occasionally gave it small amounts of food powder. Before placing the food powder in the dog's mouth, Pavlov sounded a bell, a buzzer or some other auditory stimulus. At first, the dog showed only a startle response to the sound, perking its ears and turning its head towards the sound. The dog salivated only when the food powder was placed in its mouth. But after only a dozen or so pairings of the bell and food powder, the dog began to salivate when the bell rang. Placing the food powder in the dog's mouth was no longer necessary to elicit salivation; the sound by itself was sufficient. Pavlov showed that a neutral stimulus can elicit a response similar to the original reflex when the stimulus predicts the occurrence of a significant stimulus (in this case, food powder).

This type of learning is called classical or **Pavlovian conditioning**. Pavlov demonstrated that conditioning occurred only when the food powder followed the bell within a short time. If there was a long delay between the sound and the food powder or if the sound followed the food powder, the animal never learned to salivate when it heard the sound. Thus, the sequence and timing of events are important factors in classical conditioning. Classical conditioning provides us with a way to learn cause-and-effect relations between environmental events. We are able to learn about the stimuli that warn us that an important event is about to occur. Obviously, warning stimuli must occur prior to the event about which we are being warned.

Figure 7.1 shows the basic classical conditioning procedure – the special conditions that must exist for an organism to respond to a previously neutral stimulus.

A stimulus, such as food, that naturally elicits reflexive behaviour, such as salivation, is called an **unconditional stimulus** (UCS). The reflexive behaviour itself is called the **unconditional response** (UCR). If, for a certain dog, a bell signals food, then the bell may also come to elicit salivation through classical conditioning. Another dog may hear the sound of an electric can opener just before it is

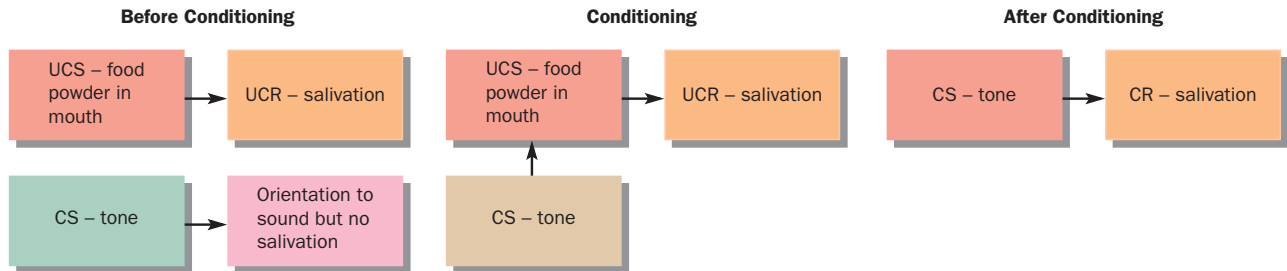

Figure 7.1 Basic components of the classical conditioning procedure. Prior to conditioning, the UCS but not the CS elicits a response (the UCR). During conditioning, the CS is presented in conjunction with the UCS. Once the conditioning is completed, the CS alone elicits a response (the CR).

fed, in which case that sound will come to elicit salivation. A neutral stimulus paired with the unconditional stimulus that eventually elicits a response is called a **conditional stimulus (CS)**. The behaviour elicited by a conditional stimulus is called a **conditional response (CR)**. In the case of Pavlov's dogs, food powder was the UCS: it elicited the UCR, salivation.

At first, when Pavlov presented the sound of the bell or buzzer, the dogs did not salivate; the sound was merely a neutral stimulus, not a CS. However, with repeated pairings of the sound and the food powder, the sound became a CS, reliably eliciting the CR – salivation.

The biological significance of classical conditioning

Salivation is an innate behaviour and is adaptive because it facilitates digestion. Through natural selection, the neural circuitry that underlies salivation has become part of the genetic endowment of many species. Pavlov's experiments demonstrated that an innate reflexive behaviour, such as salivation, can be elicited by novel stimuli. Thus, a response that is naturally under the control of appropriate environmental stimuli, such as salivation caused by the presence of food in the mouth, can also come to be controlled by other kinds of stimulus.

Classical conditioning accomplishes two functions. First, the ability to learn to recognise stimuli that predict the occurrence of an important event allows the learner to make the appropriate response faster and perhaps more effectively. For example, hearing the buzz of a wasp near your head may make you duck and avoid being stung. Seeing a rival increases an animal's heart rate and the flow of blood to its muscles, makes it assume a threatening posture, and causes the release of hormones that prepare it for vigorous exercise.

The second function of classical conditioning is even more significant. Through classical conditioning, stimuli that were previously unimportant acquire some of the

properties of the important stimuli with which they have been associated and thus become able to modify behaviour. A neutral stimulus becomes desirable when it is associated with a desirable stimulus or it becomes undesirable when it is associated with an undesirable one. In a sense, the stimulus takes on symbolic value. For example, we respond differently to the sight of a stack of money and to a stack of paper napkins. The reason for the special reaction to money is that money has, in the past, been associated with desirable commodities, such as food, clothing, cars, electrical equipment and so on.

Basic principles of classical conditioning

Classical conditioning involves several learning principles, including acquisition, extinction, spontaneous recovery, stimulus generalisation and discrimination.

Acquisition

In laboratory experiments, a single pairing of the CS with the UCS is not usually sufficient for learning to take place. Only with repeated CS–UCS pairings does conditional responding gradually appear. The learning phase of classical conditioning, during which the CS gradually increases in frequency or strength, is called **acquisition**.

In one study (Trapold and Spence, 1960), a tone (CS) was paired with a puff of air into the eye (UCS). The puff of air caused the participants' eyes to blink automatically (UCR). Conditioning was measured as the percentage of trials in which conditional eyeblinks (CR) occurred. Note that at the beginning of the experiment, the tone elicited very few CRs. During the first 50 trials, the percentage of CRs increased rapidly but finally stabilised.

Two factors that influence the strength of the CR are the intensity of the UCS and the timing of the CS and UCS. The intensity of the UCS can determine how quickly the CR will be acquired: more intense UCSs usu-

ally produce more rapid learning. For example, rats will learn a conditioned fear response faster if they receive higher levels of a painful stimulus (Annau and Kamin, 1961). Classical conditioning of a salivary response in dogs occurs faster when the animals are given larger amounts of food (Wagner *et al.*, 1964). Generally speaking, the more intense the UCS, the stronger the CR.

The second factor affecting the acquisition of the CR is the timing of the CS and UCS. Classical conditioning occurs fastest when the CS occurs shortly before the UCS and both stimuli end at the same time. In his experiments on salivary conditioning, Pavlov found that one half-second was the optimal delay between the onset of the CS and the onset of the UCS. With shorter or longer delays between the CS and UCS, conditioning generally was slower and weaker (see Figure 7.2).

Extinction and spontaneous recovery

Once a classically conditioned response has been acquired, what happens to that response if the CS continues to be presented but is no longer followed by the UCS? This procedure, called **extinction**, eventually eliminates the CR. Returning to our classically conditioned eyeblink response, suppose that after we reduce the intensity of the UCS, we stop presenting the UCS (the puff of air). However, we do continue to present the CS (the tone).

It is important to realise that extinction occurs only when the CS occurs but the UCS does not. For example, the eyeblink response will extinguish only if the tone is presented without the puff of air. If neither stimulus is presented, extinction will not occur. In other words, the subject must learn that the CS no longer predicts the occurrence of the UCS – and that cannot happen if neither stimulus is presented.

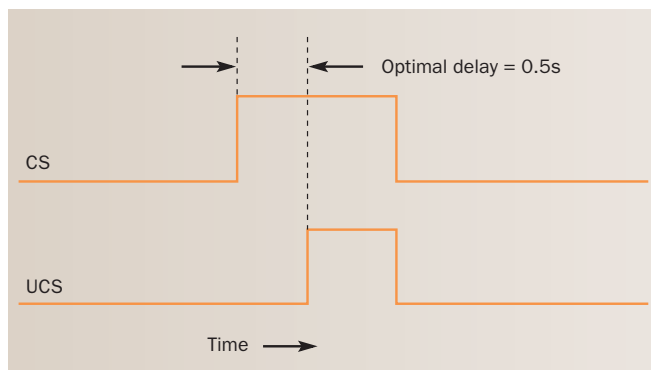

Figure 7.2 The timing of the CS and UCS in classical conditioning. The CS precedes the UCS by a brief interval of time, and both stimuli end simultaneously.

Once a CR has been extinguished, it may not disappear from the organism's behaviour permanently. Pavlov demonstrated that after responding had been extinguished, the CR would often suddenly reappear the next time the dog was placed in the experimental apparatus. Pavlov referred to the CR's reappearance after a 'time out' period as **spontaneous recovery**. He also found that if he began presenting the CS and the UCS together again, the animals would acquire the conditional response very rapidly – much faster than they did in the first place.

Stimulus generalisation and discrimination

No two stimuli are exactly alike. Once a response has been conditioned to a CS, similar stimuli will also elicit that response. The more closely the other stimuli resemble the CS, the more likely they will elicit the CR. For example, Pavlov discovered that once a dog learned to salivate when it heard a bell, it would salivate when it heard a bell having a different tone or when it heard a buzzer. This phenomenon is called **generalisation**: a response produced by a particular CS will also occur when a similar CS is presented. Of course, there are limits to generalisation. A dog that learns to salivate when it hears a bell will probably not salivate when it hears a door close in the hallway.

In addition, an organism can be taught to distinguish between similar but different stimuli – a phenomenon called **discrimination**. Discrimination training is accomplished by using two different CSs during training. One CS is always followed by the UCS; the other CS is never followed by the UCS. For example, suppose that we regularly direct a puff of air at an animal's eye during each trial in which a low-pitched tone (CS+) is sounded, but on trials in which a high-pitched tone (CS-) is sounded, we present no air puff. At first, increased amounts of blinking will occur in response to both stimuli (generalisation). Gradually, however, fewer and fewer blinks will occur after the CS- but they will continue to be elicited by the CS+ (see Figure 7.3). Discrimination, then, involves learning the difference between two or more stimuli. An animal learns that differences among stimuli are important – it learns when to respond to one stimulus and when not to respond to a different stimulus.

Conditional emotional responses

Many stimuli are able to arouse emotional responses, such as feelings of disgust, contempt, fear, anger, sadness, tenderness, longing or sexual desire. Many of these stimuli, such as a place, a phrase, a song or someone's voice and face, originally had no special significance. But because these stimuli were paired with other stimuli that

Figure 7.3 Behaviour produced through discrimination training. The CS+ is always followed by the UCS (a puff of air directed towards the eye); the CS- is always presented without the UCS.

elicited strong emotional reactions, they came, through classical conditioning, to take on emotional significance.

If you read or hear words such as ‘enemy’, ‘ugly’, ‘bitter’ or ‘failure’, you are likely to experience at least a weak negative emotional response. In contrast, the words ‘gift’, ‘win’, ‘happy’ and ‘beauty’ may elicit positive responses. These words had no effect on you before you learned what they meant. They took on their power through being paired with pleasant or unpleasant events or perhaps with descriptions of such events.

Staats and Staats (1957) found that if people read neutral nonsense words such as ‘yof’ or ‘laj’ while hearing positive or negative words, they later said that they liked those that had been associated with the positive words and disliked those that had been associated with the negative ones. The researchers found that this procedure could even affect people’s ratings of the pleasantness of names such as Tom or Bill or nationalities such as Italian or Swedish (Staats and Staats, 1958). Berkowitz (1964) found that when people had received unpleasant electrical shocks while in the company of another person, they later acted in a hostile manner towards that person. Thus, classical conditioning may play a role in the development of ethnic prejudices and personal dislikes (and, of course, of positive reactions as well). We are often not aware of the reason for our emotional reactions, we simply feel them and conclude that there is something ‘nice’ or something ‘nasty’ about the stimulus (or the person).

Phobias

Many people are troubled by behaviours that they wish they could stop or by thoughts and fears that bother them. Phobias are unreasonable fears of specific objects or situations, such as spiders, cars or enclosed spaces, and we will look at phobias in more detail in Chapter 18.

Presumably, at some time early in life, the person having the phobia was exposed to the now-feared object in conjunction with a stimulus that elicited pain or fear. For example, being stuck in a hot, overcrowded lift with a group of frightened and sweating fellow passengers might be expected to lead to a fear of lifts or perhaps even to produce a fully-fledged phobia.

Classical conditioning can occur even without direct experience with the conditional and unconditional stimuli. For example, a child of a parent who has a snake phobia can develop the same fear simply by observing signs of fear in his or her parent. The child need not be attacked or menaced by a snake. In addition, people can develop phobias vicariously – by hearing about or reading stories that vividly describe unpleasant episodes. The imaginary episode that we picture as we hear or read a story (UCS) can provide imaginary stimuli (CSs) that lead to real conditional emotional responses (CRs).

The case of Little Albert

A famous example of an experimentally induced learned phobia is that of Little Albert. In Chapter 1 you came across the work and ideas of John B. Watson. To Watson, behaviour had to be observable in order to be measured. He was excited by Pavlov’s finding that dogs could be conditioned to respond in a specific way to a previously neutral stimulus. He and Rosalie Rayner set up the first experiment in which fear was experimentally conditioned in a human being (Watson and Rayner, 1920).

At the age of nine months, a healthy infant called Albert B was shown to have no fear of live animals such as rats and rabbits (Albert is for ever known in textbooks as Little Albert). When a steel bar was unexpectedly struck by a claw hammer, however, he became distressed and frightened. Watson and Rayner attempted to condition fear of a previously unfeared object (a white rat) in Little Albert by pairing it with a feared stimulus (the noise of the hammer hitting the bar). They paired the rat with the noise seven times in two sessions, one week apart. When the rat was presented on its own, Albert became distressed and avoided the rat. Five days later, Albert was exposed to a number of other objects such as familiar wooden blocks, a rabbit, a dog, a sealskin coat, white cotton, the heads of Watson and two assistants and a Santa Claus mask. Albert showed a fear response to the rabbit, the dog and the seal-skin coat. The initial conditioned response had generalised to some objects but not others.

Watson and Rayner’s experiment is famous for two reasons. The first is the successful attempt at experimentally conditioning fear in a human being; the second is the number of inaccuracies reported in articles and textbooks

describing the experiment (Harris, 1979). These include inaccurate information about Albert's age, the conditioned stimulus and the list of objects that Albert was believed to be frightened of after conditioning (the list includes fur pelt, a man's beard, a cat, a puppy, a glove, Albert's aunt and a teddy bear). These inaccuracies teach a valuable lesson, and that is the wisdom of consulting original sources of information. Because the study of Albert is part of psychology's history, details become distorted when information is passed down from textbook to textbook, a form of memory distortion described in more detail in the next chapter.

What is learned in classical conditioning?

Research shows that for classical conditioning to occur, the CS must be a reliable predictor of the UCS (Rescorla, 1991). Imagine yourself as the subject in a classical conditioning demonstration involving a tone as the CS, a puff of air into your left eye as the UCS and an eyeblink as the CR. Your psychology lecturer asks you to come to the front of the class and seats you in a comfortable chair.

Occasionally, a tone sounds for a second or two, and then a brief but strong puff of air hits your eye. The puff of air makes you blink. Soon you begin to blink during the tone, before the puff occurs. Now consider all the other stimuli in the seminar room – your tutor explaining the demonstration to the group, your colleagues' questions, squeaks from students moving in their chairs, and so on. Why don't any of these sounds become CSs? Why do you blink only during the tone? After all, some of these stimuli occur at the same time as the puff of air. The answer is that among the stimuli present during the demonstration, only the tone reliably predicts the puff of air. All the other stimuli are poor forecasters of the UCS. The neutral stimulus becomes a CS only when the following conditions are satisfied:

- 1 The CS must regularly occur prior to the presentation of the UCS.
- 2 The CS does not regularly occur when the UCS is absent.

Consider another example. The smell of food is more likely to elicit feelings of anticipation and excitement about supper if you are hungry than is the smell of your mother's cologne because the smell of the food is the best predictor of a meal about to be served. Similarly, the sound of footsteps behind you as you are walking is more apt to make you afraid than the sound of a car passing by or the wind blowing in the trees because the footsteps are better predictors of being mugged or threatened with danger.

It also appears that conditioned responses are more common to novel than familiar stimuli. Pavlov had observed that a novel CS was more successfully paired with a UCS than was a familiar one. This phenomenon is

known as **latent inhibition** (Lubow, 1989), and because familiar stimuli are associated less successfully with conditioning than are novel ones, this effect is called the **CS pre-exposure effect** (because participants will have already been pre-exposed to the CS). Similarly, when an organism is presented with the UCS (which may be novel) before it is used as a UCS in the experiment proper, the link between CS and UCS is weaker. This is called the **UCS pre-exposure effect** (Randich and LoLordo, 1979).

Why does latent inhibition occur? No one quite knows for sure, but one explanation is related to the degree of exposure to the stimulus. A familiar CS is familiar to individuals by being in the environment; because the CS is part of the environment of context then the CS becomes merged into the context of the conditioning. To use a description from signal detection theory which you learned about in Chapter 5, the signal-to-noise ratio is weak – the CS sends a weak signal because it cannot be distinguished from the context very well.

Neurobiological correlates of Pavlovian conditioning

In an experiment to determine the brain regions involved in Pavlovian fear conditioning, participants were exposed to lights that signalled the appearance of a painful electric shock (conditioned stimulus, CS) or ones that did not (Knight *et al.*, 1999). Functional magnetic resonance imaging (fMRI) was used to monitor differences in brain activation. As training and learning progressed, the amount of neuronal activity seen during the warning CS increased in a part of the brain called the anterior cingulate, in the front of the brain. When the light and shock were not paired (i.e. they were not associated), this activation did not occur. Although the researchers suggest that this part of the brain may not be necessary for learning fear, it does facilitate the learning of fear. Another crucial structure for fear conditioning is the amygdala, and you will discover more about its role in fear recognition and conditioning in Chapter 13.

After behaviourism

Pavlov's work greatly influenced his colleagues abroad, especially the pioneers of behaviourist thinking such as John B. Watson. Behaviourism was a robust and experimentally strict discipline whose principles were laid out by Watson in the first and second decades of the twentieth century. It viewed behaviour and learning in terms of stimulus and response and, as the next evolution of behaviourism described in the next section shows, rein-

forcement. The inner mind or introspective self-reports played no part in behaviourist thinking; these were unverifiable and held the same status as superstition to the behaviourist. Both stimulus and response could be observed and the effect of one on the other recorded. Behaviourism left a unique and historical legacy that is seen in almost all experimental work undertaken in psychology today; its effects were such that modern psychology has absorbed its principles and aims.

The torch-bearers of behaviourism, however, began to modify elements of its thinking in the mid-twentieth century and although the effects of these modifications made no significant or lasting impact on psychology by themselves, the attempts at modification did because other, more dominant approaches to studying behaviour arose from them. Two influential psychologists, whose specific work did not have a long-lasting effect on the way psychology is studied, but did bequeath a way of thinking about learning and behaviour, were Clark L. Hull (1884–1952) and Edward Chase Tolman (1886–1959).

Hull's computational approach to learning

Of all the learning theories reviewed in this chapter, Hull's is probably the most ambitious and complicated of them. In his two published books, *Principles of Behaviour* (1943) and *A Behaviour System* (1952), Hull made extremely detailed predictions about behaviour that could occur in specific situations. The books contained 153 theorems that ranged from considering how we learn to discriminate, to moving in space, to how we acquire our values, and Hull's aim was to develop a system whereby behaviour could be predicted from specified independent variables (IVs). You can quickly appreciate why the approach is seen as ambitious and complicated.

Hull organised his system by considering what Watson's behaviourism did not wish to: **intervening variables**, the variables that could modify the relationship between stimulus and response. In Hull's system, analysis of behaviour comprised four stages:

- Stage 1 Analysis of the IVs from which behaviour was predicted.
- Stage 2 Computing values for intervening variables.
- Stage 3 Computing values at this stage, using values at stage 2.
- Stage 4 Analysis of the dependent variables (DVs).

In summary, the stage process argued that knowing the values of an independent variable at stage 1 meant computing values of the intervening variables at stage 2, using these computed values to compute those at stage 3 and from this predict the outcome (or the dependent variable). Figure 7.4 summarises the main points of the system.

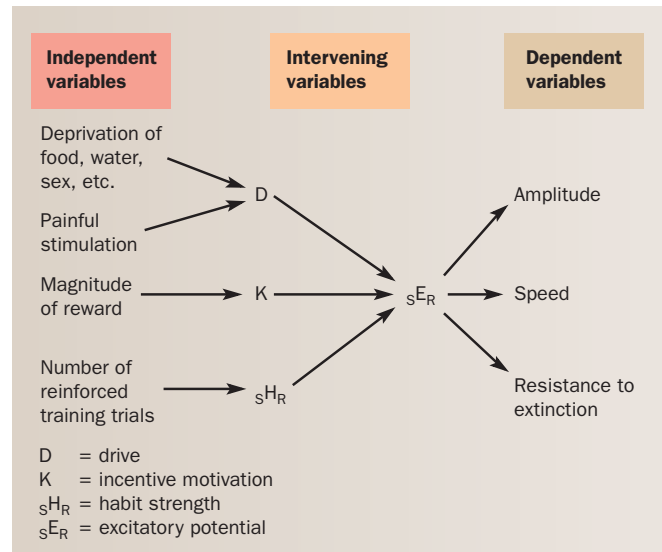

Figure 7.4 A simplified version of Hull's system.

Source: Adapted from Hill W.F., *Learning: A survey of psychological interpretation*, 7th edn. Published by Allyn & Bacon, Boston, MA. Copyright © 1997 by Pearson Education. By permission of the publisher.

The number of independent variables were limitless and could range from direct stimulation (the brightness of light or the loudness of noise) to events that preceded the moment of study (such as degree of exercise taken or the amount of food consumed) to experiential episodes (such as the number of times a person had responded to the stimulus before). To produce a response (the DV), the IV would interact with the intervening variables at stages 3 and 4.

These intervening variables were not directly observable and were hypothetical states (you might see why Watson's behaviourism would have rejected Hull's approach). According to Hull, there were two types of intervening variable: habit strength and drive. You will find out more about these concepts and their validity in Chapter 13, but for now a simple definition of each would be: habit strength is the strength of the connections that had been learned between a stimulus and a response after reinforced practice had occurred; drive is a state of activation that propels an organism to seek stimulation (a reduction in the drive would serve as a reward). A drive represents a temporary state which is produced when the body has been deprived of something it needs, such as food, water, relief from pain, and so on. The greater the reward, therefore, the greater the reduction in drive: a slice of bread would not significantly reduce the drive for food, but a four course meal might. The greater the number of times a response was followed by reinforcement, the greater the formation of habit strength and the connections between a stimulus and its response. Hull also suggested another variable, incentive

motivation, which would account for the organisms's response to rewards of increasing size.

As the above cursory description of the system suggests, Hull's theory was complex and followed detailed mathematical formulae. His second book contained 133 theorems which, for good measure, followed on from 17 postulates and 15 corollaries. The apparent beauty and strength of Hull's system was that one variable could be computed from another using these formulae. Where the system failed, however, was in using the values from a single experiment to predict later behaviour: this often did not work. Hull later stated that the values were meant to be regarded as illustrations rather than as fixed numbers and that, of course, values would vary across individuals. While Hull's work has not had the direct influence and impact on later theory of some other schools of learning and behaviour, it represented an ambitious and laudable attempt at pinning down behaviour to values that could be computed and used to predict later behaviour.

Tolman and the cognitive map

Like Hull, Tolman argued that there was more to the study of learning and behaviour than simply recording the stimulus and measuring the response.

Tolman's view was that a theory of behaviour should consider the cognitive variables that intercede between stimulus and response: our thoughts, beliefs, attitudes, motivation to succeed and so on are all important determinants of our response to a stimulus.

Tolman's approach was called purposive behaviourism and although, like the behaviourism it followed, it concerned itself with objective and observable behaviour and the external influences that could change it, it was also concerned with the cognitive processes that guided or gave rise to that behaviour. Behaviour had a purpose; it was executed to achieve a goal, hence, purposive behaviourism.

According to Tolman, the behaviour that we engage in to achieve our goals is underpinned by our cognitions. Our cognitive processing can be measured by observing the way in which a person behaves or has experienced specific stimuli. For example, we might learn that chilli con carne tastes nicer with added ginger, cinnamon and three, rather than two, red chillies, so we make the chilli again adding these ingredients. None or any might make the chilli nicer but if none do, we experiment again either by adding or subtracting ingredients. Our experience – our cognitions – modifies our behaviour.

Tolman's most famous illustration of learning and the cognitions that lead to a response is that of reward loca-

tion. If an organism finds a way of locating a reward, it may eventually find a different, more efficient method, of locating it. If you imagine yourself in a strange town centre for the first time, your first successfully navigated route to a shop may be the longest, or least efficient one. With increasing knowledge of the environment, you will eventually find the shortest, quickest route to the shop you want.

In Tolman's experiment, rats were allowed to run on a table and through an enclosed alleyway which led to various elevated pathways at the end of one of which was some food (Tolman *et al.*, 1946). When the rat had learned the location of the food, the alleyway was removed and replaced with new routes which went in different directions. Figure 7.5 shows you the difference between the two conditions.

Tolman *et al.* found that, in the second condition, the rats did not take the route they had previously learned in order to obtain the food. Instead, they took a short-cut towards the direction of the food. According to Tolman, the rat had learned a 'cognitive map' of the routes and chose the shortest one. Although this seems eminently plausible, Tolman did not seem to consider that the rat may have taken the shortest route because the smell of the food led the rodent to it.

This objection aside, Tolman's influence was important because it rejected the stiff stimulus–response (S–R) approaches of behaviourism and encouraged an emphasis on the cognitive variables that shape behaviour. The essential principles of the approach can be seen in much

Figure 7.5 The two pathways used in Tolman's experiment. In the first, the rat takes the longer route in order to find the food. In the second, the original route is blocked and 18 new routes made available. The rats chose the tunnel marked C (that corresponding most closely to the location of the food), rather than D or E, the routes closest to that originally taken.

of modern-day experiments on transfer of learning: the principle whereby learning in one environment can be successfully transferred to a different one. Work in virtual reality technology, for example, has been able to present participants with 'virtual' versions of environments which participants can navigate and explore before encountering the actual environment, thereby assisting navigation in the real version (Wilson *et al.*, 1999). An example of one of these virtual images (part of an animated tour) can be seen in Figure 7.6. This image shows the ground floor central corridor of a simulated building (based on the psychology department at Leicester University, England).

Wilson *et al.* (1996a) found that severely disabled children who explored this computer simulation were able to point successfully to objects in the real building when they later encountered it. A group of undergraduates who guessed the location of the objects, without having had the benefit of exposure to the computer simulation, performed less accurately.

Tolman died just before the beginning of what is called in psychology, 'the cognitive revolution', which you read about in Chapter 1. However, his approach was a precursor to the cognitive revolution and prompted other disciplines, such as linguistics, to consider cognitive variables in their study. While Tolman's ideas were superseded to some extent by developments in cognitive psychology, his work could be seen as the bedrock on which cognitive psychology's general approach is based.

Operant conditioning

Habituation and classical conditioning teach us about stimuli in the environment: we learn to ignore unimportant stimuli, and we learn about those that predict the occurrence of important ones. These forms of learning deal with relations between one stimulus and another. In contrast, **operant conditioning** tells about the relations between environmental stimuli and our own behaviour; it is also called instrumental learning. The term 'operant' refers to the fact that an organism learns through responding – through operating on the environment. The principle behind operant conditioning is already familiar to you: when a particular action has good consequences, the action will tend to be repeated; when a particular action has bad consequences, the action will tend not to be repeated.

The law of effect

Operant conditioning was first discovered in the basement of a house in Cambridge, Massachusetts, by a 24-year-old man who would later become one of the twentieth century's most influential educational psychologists, Edward L. Thorndike. Thorndike placed a hungry cat inside a 'puzzle box'. The animal could escape and eat some food only after it operated a latch that opened the door. At first, the cat engaged in random behaviour: meowing, scratching, hissing, pacing and so on. Eventually, the cat would accidentally activate the latch and open the door. On successive trials, the animal's behaviour would become more and more efficient until it was operating the latch without hesitation. Thorndike called this process 'learning by trial and accidental success'.

Thorndike explained that the cat learned to make the correct response because only the correct response was followed by a favourable outcome: escape from the box and the opportunity to eat some food. The occurrence of the favourable outcome strengthens the response that produced it. Thorndike called this relation between a response and its consequences the **law of effect**.

The impact of Thorndike's discovery of the law of effect on the early development of scientific psychology would be difficult to overstate. It affected research in the study of learning in one very important way: it stimulated an enormous number of experimental studies aimed at understanding behaviour–environment interactions, a line of research that is known today as behaviour analysis. Nowhere was this effect more evident than in the work of B.F. Skinner.

Skinner and operant behaviour

Although Thorndike discovered the law of effect, Harvard psychologist Burrhus Frederic Skinner championed the laboratory study of the law of effect and advocated the application of behaviour analysis and its methods to solving human problems (Skinner, 1953, 1971; Mazur, 1994). He devised objective methods for studying behaviour, invented apparatus and methods for observing it, and created his own philosophy for interpreting it (Bolles, 1979). Moreover, he wrote several books for the general public, including a novel, *Walden Two*, that showed how his discoveries might be used for improving society (Skinner, 1948).

One of Skinner's most important inventions was the **operant chamber** (or Skinner box), an apparatus in which an animal's behaviour can be easily observed, manipulated and automatically recorded (as seen in Figure 7.7).

For example, an operant chamber used for rats is constructed so that a particular behaviour, such as pressing on a lever, will occasionally cause a pellet of food to be delivered. An operant chamber used for pigeons is built so that a peck at a plastic disc on the front wall will occasionally open a drawer that contains some grain. Behaviour analysts who study human behaviour use special devices suitable to the unique characteristics of their human subjects (Baron *et al.*, 1991). In this case, instead of giving their participants some food, they give them points (as in a video game) or points exchangeable for money.

Behaviour analysts manipulate environmental events to determine their effects on response rate, the number of responses emitted during a given amount of time. Events that increase response rate are said to strengthen responding; events that decrease response rate weaken

responding. To measure response rate, Skinner devised the **cumulative recorder**, a device that records each response as it occurs in time.

The invention of the operant chamber and the cumulative recorder represent clear advances over Thorndike's research methods because subjects can (1) emit responses more freely over a greater time period, and (2) be studied for longer periods of time without interference produced by the experimenter handling or otherwise interacting with them between trials. Under highly controlled conditions such as these, behaviour analysts have been able to discover a wide range of important behavioural principles.

The three-term contingency

Behaviour does not occur in a vacuum. Sometimes a response will have certain consequences; sometimes it will not. Our daily behaviour is guided by many different kinds of discriminative stimuli – stimuli that indicate that behaviour will have certain consequences and thus sets the occasion for responding. For example, consider answering the telephone. The phone rings, you pick it up and say 'hello' into the receiver. Most of the time, someone on the other end of the line begins to speak. Have you ever picked up a telephone when it was not ringing and said, 'hello'? Doing so would be absurd, because there would be no one on the other end of the line with whom to speak. We answer the phone (make a response) only when the phone rings (the preceding event) because, in the past, someone with whom we enjoy talking has been at the other end of the line (the following event). Skinner referred formally to the relationship among these three items – the preceding event, the response and the following event – as the **three-term contingency** (see Figure 7.8).

Figure 7.7 An operant chamber. (This operant chamber is used for lever pressing by rats.)

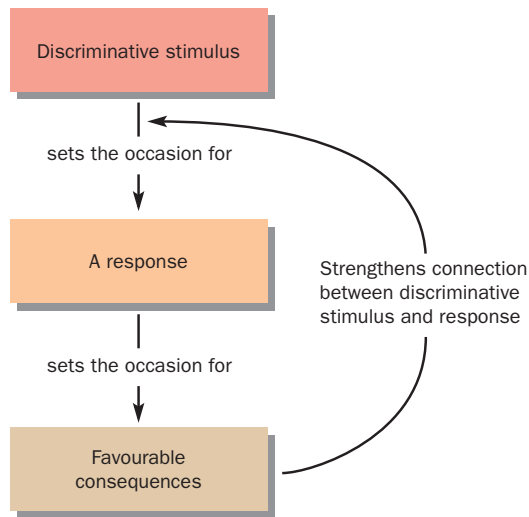

Figure 7.8 The three-term contingency.

The preceding event – the discriminative stimulus – sets the occasion for responding because, in the past, when that stimulus occurred, the response was followed by certain consequences. If the phone rings, we are likely to answer it because we have learned that doing so has particular (and generally favourable) consequences. The response we make – in this case, picking up the phone when the phone rings and saying ‘hello’ – is called an operant behaviour. The following event – the voice on the other end of the line – is the consequence of the operant behaviour.

Operant behaviour, therefore, occurs in the presence of discriminative stimuli and is followed by certain consequences. These consequences are contingent upon behaviour, that is, they are produced by that behaviour. In the presence of discriminative stimuli, a consequence will occur if and only if an operant behaviour occurs. In the absence of a discriminative stimulus, the operant behaviour will have no effect. Once an operant behaviour is established, it tends to persist whenever the discriminative stimulus occurs, even if other aspects of the environment change (Nevin, 1988; Mace *et al.*, 1990). Of course, motivational factors can affect a response. For example, you might not bother to answer the telephone if you are doing something you do not want to interrupt.

Reinforcement, punishment and extinction

Behaviour analysts study behaviour–environment interactions by manipulating the relations among components of the three-term contingency. Of the three elements, the consequence is the most frequently manipulated variable. In general, operant behaviours can be followed by five different kinds of consequence: positive reinforcement,

negative reinforcement, punishment, response cost and extinction. These consequences are always defined in terms of their effect on responding.

Positive reinforcement

Positive reinforcement refers to an increase in the frequency of a response that is regularly and reliably followed by an appetitive stimulus. An appetitive stimulus is any stimulus that an organism seeks out. If an appetitive stimulus follows a response and increases the frequency of that response, we call it a positive reinforcer. For example, the opportunity to eat some food can reinforce a hungry pigeon’s pecking of a plastic disc. Money or other rewards (including social rewards) can reinforce a person’s behaviour. Suppose that you visit a new restaurant and really enjoy your meal. You are likely to visit the restaurant several more times because you like the food. This example illustrates positive reinforcement. Your enjoyment of the food (the appetitive stimulus) reinforces your going to the restaurant and ordering dinner (the response).

Negative reinforcement

Negative reinforcement refers to an increase in the frequency of a response that is regularly and reliably followed by the termination of an aversive stimulus. An aversive stimulus is unpleasant or painful. If an aversive stimulus is terminated (ends or is turned off) as soon as a response occurs and thus increases the frequency of that response, we call it a negative reinforcer. For example, after you have walked barefoot across a stretch of hot pavement, the termination of the painful burning sensation negatively reinforces your response of sticking your feet into a puddle of cool water.

It is important to remember that both positive and negative reinforcement increase the likelihood that a given response will occur again. However, positive reinforcement involves the occurrence of an appetitive stimulus, whereas negative reinforcement involves the termination of an aversive stimulus. Negative reinforcement is thus not the same as punishment.

Punishment

Punishment refers to a decrease in the frequency of a response that is regularly and reliably followed by an aversive stimulus. If an aversive stimulus follows a response and decreases the frequency of that response, we call it a punisher. For example, receiving a painful bite would punish the response of sticking your finger into a parrot’s cage. People often attempt to punish the behaviour of their children or pets by scolding them.

Although punishment is effective in reducing or suppressing undesirable behaviour in the short term, it can also produce several negative side effects: unrestrained use of physical force (for example, child abuse) may cause serious bodily injury. Punishment often induces fear, hostility and other undesirable emotions in people receiving punishment. It may result in retaliation against the punisher. Through punishment, organisms learn only which response not to make. Punishment does not teach the organism desirable responses.

Reinforcement and punishment are most effective in maintaining or changing behaviour when a stimulus immediately follows the behaviour. It may occur to you that many organisms, particularly humans, can tolerate a long delay between their work and the reward that they receive for it. This ability appears to contradict the principle that reinforcement must occur immediately. However, the apparent contradiction can be explained by a phenomenon called conditioned reinforcement.

Why is immediacy of reinforcement or punishment essential for learning? The answer is found by examining the function of operant conditioning: learning about the consequences of our own behaviour. Normally, causes and effects are closely related in time; you do something, and something immediately happens, good or bad. The consequences of our action teach us whether to repeat that action. Events that follow a response by a long delay were probably not caused by that response.

It is important not to confuse punishment with negative reinforcement. Punishment causes a behaviour to decrease, whereas negative reinforcement causes a behaviour to increase.

Response cost

Response cost refers to a decrease in the frequency of a response that is regularly and reliably followed by the termination of an appetitive stimulus. Response cost is a form of punishment. For example, suppose that you are enjoying a conversation with an attractive person that you have just met. You make a disparaging remark about a political party. Your new friend's smile suddenly disappears. You quickly change the topic and never bring it up again. The behaviour (disparaging remark) is followed by the removal of an appetitive stimulus (your new friend's smile). The removal of the smile punishes the disparaging remark.

Response cost is often referred to as time-out from positive reinforcement (or simply time-out) when it is used to remove a person physically from an activity that is reinforcing to that person.

As we have just seen, there are four types of operant conditioning – two kinds of reinforcement and two kinds of punishment – caused by the occurrence or termination

of appetitive or aversive stimuli. Another way to change behaviour through operant conditioning is extinction, which involves no consequence at all. See Figure 7.9.

Extinction

Extinction is a decrease in the frequency of a previously reinforced response because it is no longer followed by a reinforcer. Behaviour that is no longer reinforced decreases in frequency: it is said to extinguish. For example, a rat whose lever pressing was reinforced previously with food will eventually stop pressing the lever when food is no longer delivered. People soon learn to stop dropping money into vending machines that don't work. A young boy will stop telling his favourite 'knock-knock' joke if no one laughs at it any more.

Extinction is not the same as forgetting. Forgetting takes place when a behaviour is not rehearsed (or a person does not think about a particular memory) for a long time. Extinction takes place when an organism makes a response that is no longer reinforced. If the organism does not have an opportunity to make that response, it will not extinguish. For example, if you go out of town for a few weeks, you will not forget how to operate the vending

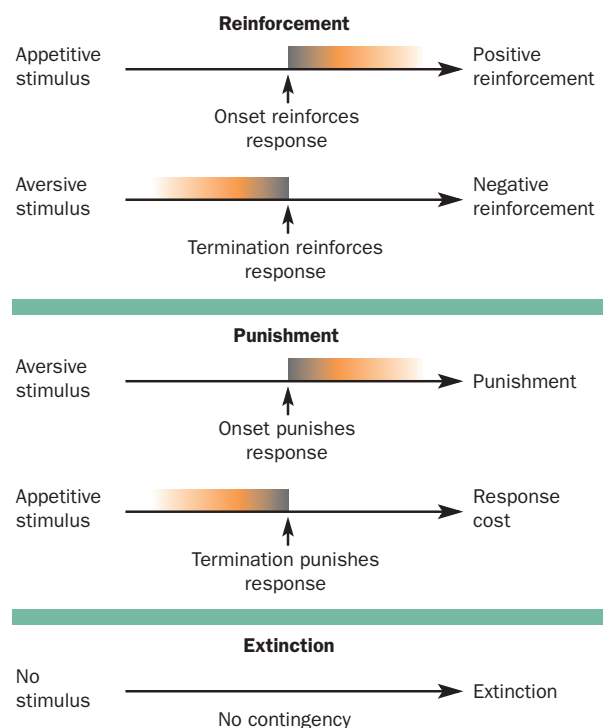

Figure 7.9 Reinforcement, punishment and extinction produced by the onset, termination or omission of appetitive or aversive stimuli. The upward-pointing arrows indicate the occurrence of a response.

machine where you often buy a bar of chocolate. However, if you put money in the machine and do not receive anything in return, your response will extinguish.

Other operant procedures and phenomena

The basic principles of reinforcement, punishment and extinction described above are used in other operant procedures to teach an organism a new response, to teach it when or when not to respond, or to teach it how to respond in a particular way.

Shaping

Most behaviour is acquired through an organism's interaction with reinforcing and punishing events in its environment. In fact, Skinner developed a technique, called **shaping**, to teach new behaviours to his subjects. Shaping involves reinforcing any behaviour that successively approximates the desired response. Imagine that we want to train a rat to press a lever when a red light is lit (the discriminative stimulus) in an operant chamber. Although the rat has used its paws to manipulate many things during its lifetime, it has never before pressed a lever in an operant chamber. And when it is first placed in the chamber, it is not likely to press the lever even once on its own.

The lever on the wall of the chamber is attached to an electrical switch that is wired to electronic control equipment or a computer. A mechanical dispenser can automatically drop pellets of food into a dish in the chamber. Thus, the delivery of a food pellet can be made dependent on the rat's pressing the lever.

Before we can shape lever pressing, we must make the rat hungry. We do so by letting the animal eat only once a day. When we know that it is hungry, we place the animal in the operant chamber and then train it to eat the food pellets as they are dispensed from the pellet dispenser. As each pellet is delivered, the dispenser makes a clicking sound. This sound is important. No matter where the rat is in the operant chamber, it can hear the sound, which indicates that the food pellet has been dispensed. Once the rat is hungry and has learned where to obtain food, we are ready to shape the desired response. We make the operation of the pellet dispenser contingent on the rat's behaviour. We start by giving the rat a food pellet for just facing in the direction of the lever. Next, we wait until the rat makes a move towards the lever. Finally, we give the rat a piece of food only if it touches the lever. Soon, our rat performs like Thorndike's cats: it makes the same response again and again.

Shaping is a formal training procedure, but something like it also occurs in the world outside the laboratory. A teacher praises poorly formed letters produced by a child

who is just beginning to print. As time goes on, only more accurately drawn letters bring approval. The method of successive approximations can also be self-administered. Consider the acquisition of skills through trial and error. To begin with, you must be able to recognise the target behaviour – the behaviour displayed by a person having the appropriate skill. Your first attempts produce behaviours that vaguely resemble those of a skilled performer, and you are satisfied by the results of these attempts. In other words, the stimuli that are produced by your behaviour serve as reinforcers for that behaviour. As your skill develops, you become less satisfied with crude approximations to the final behaviour; you are satisfied only when your behaviour improves so that it more closely resembles the target behaviour. Your own criteria change as you become more skilled. Skills such as learning to draw a picture, catching a ball, or making a bed are all behaviours that are acquired through shaping. After all, when a child learns these skills, they first learn behaviours that only approximate the final level of skill that they will attain. This process is perfectly analogous to the use of changing criteria in training an animal to perform a complex behaviour.

Intermittent reinforcement

So far, we have considered situations in which a reinforcing stimulus is presented after each response (or, in the case of extinction, not at all). But usually not every response is reinforced. Sometimes a kind word is ignored; sometimes it is appreciated. Not every fishing trip is rewarded with a catch, but some are, and that is enough to keep a person trying.

The term **intermittent reinforcement** refers to situations in which not every occurrence of a response is reinforced. The relation between responding and reinforcement usually follows one of two patterns: each response has a certain probability of being reinforced, or responses are reinforced after particular intervals of time have elapsed. Probability-based patterns require a variable number of responses for each reinforcer. Consider the performance of an archer shooting arrows at a target. Suppose that the archer hits the bull's-eye one-fifth of the time. On average, he will have to make five responses for every reinforcement (hitting the bull's-eye); the ratio of responding to reinforcement is five to one. The number of reinforcers the archer receives is directly proportional to the number of responses he makes. If he shoots more arrows (that is, if his rate of responding increases), he will receive more reinforcers, assuming that he does not get tired or careless.

Behaviour analysts refer to this pattern of intermittent reinforcement as a ratio schedule of reinforcement. In the laboratory, the apparatus controlling the operant chamber

may be programmed to deliver a reinforcer after every fifth response (a ratio of five to one), after every tenth, after every two hundredth, or after any desired number. If the ratio is constant – for example if a reinforcer is programmed to be delivered following every tenth response – the animal will respond rapidly, receive the reinforcer, pause a little while, and then begin responding again. This type of ratio schedule is called a **fixed-ratio schedule** (specifically, a fixed-ratio 10 schedule).

If the ratio is variable, averaging a particular number of responses but varying from trial to trial, the animal will respond at a steady, rapid pace. For example, we might programme a reinforcer to be delivered, on average, after every 50 responses. This type of ratio schedule is called a **variable-ratio schedule** (specifically, a variable-ratio 50 schedule). A slot machine is sometimes programmed to deliver money on a variable-ratio schedule of reinforcement. Variable in this instance means that the person cannot predict how many responses will be needed for the next pay-off.

The second type of pattern of reinforcement involves time. A response is reinforced, but only after a particular time interval has elapsed. Imagine that you wanted to know what the weather was going to be like because your friends are due to visit, but the weather where they are is quite snowy. In order to keep abreast of the weather, you listen to the half-hourly bulletin on your local radio station. This pattern of intermittent reinforcement is called an interval schedule of reinforcement. After various intervals of time, a response will be reinforced. If the time intervals are fixed, the animal will stop responding after each reinforcement. It learns that responses made immediately after reinforcement are never reinforced. Then it will begin responding a little while before the next reinforcer is available. This type of interval schedule is called a **fixed-interval schedule**.

If the time intervals are variable, an animal will respond at a slow, steady rate. That way, it will not waste energy on useless responses, but it will not miss any opportunities for reinforcement either. This type of interval schedule is called a **variable-interval schedule**. In a variable-interval 60-second schedule of reinforcement, a reinforcer would be delivered immediately following the first response after different time intervals had elapsed. The interval might be 30 seconds at one time, and 90 seconds at another, but, on the average, it will be 60 seconds. An animal whose behaviour is reinforced by this schedule would learn not to pause immediately after a reinforcer was delivered. Instead, it would steadily respond throughout the interval, regardless of the length of the interval.

Schedules of reinforcement are important because they show us that different reinforcement contingencies affect the pattern and rate of responding. Think about your own behaviour. How would you perform in subjects in

which your grades were determined by a mid-term and a final exam, or by weekly quizzes, or by unannounced quizzes that occur at variable intervals? What kind of schedule of reinforcement is a salesperson on while waiting on potential customers?

Some people work at a slow, steady rate, but others work furiously after long periods of inactivity. Can it be that in the past their work habits were shaped by different schedules of reinforcement?

Resistance to extinction and intermittent reinforcement

A response that has been reinforced intermittently is more resistant to extinction. A response that has been continuously reinforced is much less likely to be so resistant. Baldwin and Baldwin (1998) illustrate this by citing the example of two girls who were prone to throwing temper tantrums. Connie (for it is she) received continuous reinforcement for her tantrums by her parents. Whenever she would throw a tantrum, her parents would pay her attention. Paula (for it is she), however, received only intermittent reinforcement – her parents had two other children and would only pay attention to her tantrums about once in every six episodes. This, as you now know, is a typical variable-ratio 6 method of reinforcement.

When they joined school, the teacher expressed unhappiness at the tantrums and suggested that the parents undertake a programme of extinction: they were asked to ignore all tantrums. What happened? On the first day of extinction, Connie actually experienced more tantrums (20 per cent more – Lerman and Iwata, 1995) but this dropped to zero in the next few days. Paula's behaviour, on the other hand, was less resistant to extinction. It took 2–3 weeks for the tantrums gradually to reduce. She continued to throw tantrums long after Connie had stopped.

Why? Well, Connie's behaviour changed because previously continuously reinforced behaviour was now not reinforced at all. Her behaviour received no reinforcement and because her tantrums did not attract the necessary attention, they stopped. They increased on the first day because Connie believed she had to produce more behaviour to receive her reinforcement. When she realised that this behaviour would not be reinforced, she stopped. Paula's behaviour, however, had previously been intermittently reinforced (every sixth tantrum) and so the new schedule had little effect on her tantrums because she had become accustomed to receiving no reinforcement for her behaviour. On the first day of the programme, therefore, she behaved as she normally would because it was pretty much like normal. Her extinction was gradual and longer than Connie's because it took a longer period to realise that reinforcement was completely absent rather than intermittent.

Generalisation and discrimination

In classical conditioning, generalisation means that stimuli resembling the CS also elicit the CR. In operant conditioning, generalisation means that stimuli resembling a discriminative stimulus also serve as discriminative stimuli for a particular response.

In operant conditioning, as in classical conditioning, generalisation can be reduced through discrimination training. In classical conditioning, discrimination means that CRs occur only in response to certain CSs and not to other, similar stimuli. In operant conditioning, discrimination means that responding occurs only when a particular discriminative stimulus is present – one that was present while responding was reinforced in the past. Responding does not occur when discriminative stimuli associated with extinction or punishment are present.

Obviously, recognising certain kinds of similarities between different categories of stimuli is a very important task in our everyday lives. When we encounter a problem to solve – for example, diagnosing a puzzling disease or improving a manufactured product – we attempt to discover elements of the situation that are similar to those we have seen in other situations and try to apply the strategies that have been successful in the past. That is, we try to generalise old solutions to new problems.

Discriminative stimuli can exert powerful control over responding because of their association with the consequences of such responding. In or out of the laboratory, we learn to behave appropriately to environmental conditions. For example, we usually talk about different things with different people. We learn that some friends do not care for sports, so we do not talk about this topic with them because we will receive few reinforcers (such as nods or smiles). Instead, we discuss topics that have interested them in the past.

Conditioned reinforcement and punishment

We have studied reinforcement mainly in terms of primary reinforcers and primary punishers.

Primary reinforcers are biologically significant appetitive stimuli, such as food when one is hungry. **Primary punishers** are biologically significant aversive stimuli, such as those that produce pain. Behaviour can also be reinforced with a wide variety of other stimuli: money, a smile, kind words, a pat on the back, or prizes and awards. These stimuli, called **conditioned (or secondary) reinforcers**, acquire their reinforcing properties through association with primary reinforcers. Because it can be exchanged for so many different kinds of primary reinforcers in our society, money is the most common conditioned reinforcer among humans. That money is a conditioned reinforcer can be demonstrated by asking

yourself whether you would continue to work if you could no longer exchange money for food, drink, shelter and other items.

Similarly, **conditioned punishers** acquire their punishing effects through association with aversive events. For example, the sight of a flashing light on top of a police car serves as a conditioned punisher to a person who is driving too fast because such a sight precedes an unpleasant set of stimuli: a lecture by a police officer and a ticket for speeding.

A stimulus becomes a conditioned reinforcer or punisher by means of classical conditioning. That is, if a neutral stimulus occurs regularly just before an appetitive or aversive stimulus, then the neutral stimulus itself becomes an appetitive or aversive stimulus. The primary reinforcer or punisher serves as the UCS because it produces the UCR – good or bad feelings. After classical conditioning takes place, these good or bad feelings are produced by the CS – the conditioned reinforcer or punisher. Once that happens, the stimulus can reinforce or punish behaviours by itself. Thus, operant conditioning often involves aspects of classical conditioning.

Conditioned reinforcement and punishment are very important. They permit an organism's behaviour to be affected by stimuli that are not biologically important in themselves but that are regularly associated with the onset or termination of biologically important stimuli. Indeed, stimuli can even become conditioned reinforcers or punishers by being associated with other conditioned reinforcers or punishers. The speeding ticket is just such an example. If an organism's behaviour could be controlled only by primary reinforcers and punishers, its behaviour would not be very flexible. The organism would never learn to perform behaviours that had only long-range benefits. Instead, its behaviour would be controlled on a moment-to-moment basis by a very limited set of stimuli. Conditioned reinforcers and punishers, such as money, grades, smiles and frowns, allow for behaviour to be altered by a wide variety of contingencies.

Conditioning of complex behaviours

The previous sections considered rather simple examples of reinforced behaviours. But people and many other animals are able to learn very complex behaviours. Consider the behaviour of a young girl learning to print letters. She sits at her school desk, producing long rows of letters. What kinds of reinforcing stimuli maintain her behaviour? Why is she devoting her time to a task that involves so much effort?

The answer is that her behaviour produces stimuli – printed letters – which serve as conditioned reinforcers. In previous class sessions, the teacher demonstrated how to print the letters and praised the girl for printing them herself. The act of printing was reinforced, and the printed letters that this act produces come to serve as conditioned reinforcers. The child prints a letter, sees that it looks close to the way it should, and her efforts are reinforced by the sight of the letter. Doing something correctly or making progress towards that goal can provide an effective reinforcer.

This fact is often overlooked by people who take a limited view of the process of reinforcement, thinking that it has to resemble the delivery of a small piece of food to an animal being taught a trick. Some people even say that because reinforcers are rarely delivered to humans immediately after they perform a behaviour, operant conditioning cannot play a major role in human learning. This assertion misses the point that, especially for humans, reinforcers can be very subtle events.

Aversive control of behaviour

Your own experience has probably taught you that punishment can be as effective as positive reinforcement in changing behaviour. Aversive control of behaviour is common in our society, from fines given to speeding motorists to the prison sentences given to criminals. Aversive control of behaviour is common for two main reasons. First, it can be highly effective in inducing behaviour change, producing nearly immediate results. A person given a fine for jumping a red light is likely, at least for a short while, to heed the sign's message. The very effectiveness of punishment as a means of behaviour change can serve as an immediate reinforcer for the person doing the punishing.

Secondly, society cannot always control the positive reinforcers that shape and maintain the behaviour of its members. However, it can and does control aversive stimuli that may be used to punish misconduct. For example, suppose that a young person's peers encourage antisocial behaviours such as theft. Society has no control over reinforcers provided by the peer group, but it can control stimuli to punish the antisocial behaviours, such as fines and imprisonment.

How punishing stimuli work

How does a punishing stimulus suppress behaviour? Punishment, like reinforcement, usually involves a discriminative stimulus. A child's shouting is usually punished in the classroom but not outdoors during a break. A dog chases a

porcupine, gets stuck with quills, and never chases one again. However, it continues to chase the neighbour's cat.

Most aversive stimuli elicit some sort of protective or defensive response, such as cringing, freezing, hiding or running away. The response depends on the species of animal and, of course, on the situation. If you slap your dog for a misdeed, the dog will cower and slink away, looking clearly 'apologetic', because you are in a position of dominance. However, if the dog is struck by a stranger, it may very well react by attacking the person. Both types of behaviour are known as species-specific defence reactions (Bolles, 1970).

Escape and avoidance

Negative reinforcement teaches organisms to make responses that terminate aversive stimuli. These responses can make a stimulus cease or the organism can simply run away. In either case, psychologists call the behaviour an **escape response**: the organism endures the effects of the aversive stimulus until its behaviour terminates the stimulus. In some cases, the animal can do more than escape the aversive stimulus; it can learn to do something to prevent it occurring. This type of behaviour is known as an **avoidance response**.

Avoidance responses usually require some warning that the aversive stimulus is about to occur in order for the organism to be able to make the appropriate response soon enough. Imagine that you meet a man at a party who backs you against the wall and engages you in the most boring conversation you have ever had. In addition, his breath is so bad that you are afraid you will pass out. You finally manage to break away from him (an escape response). A few days later, you attend another party. You begin walking towards the buffet table and see the same man (discriminative stimulus) standing nearby. You decide that you will get some food later and turn away to talk with some friends at the other end of the room (an avoidance response).

As we saw earlier, phobias can be considered to be conditioned emotional responses – fears that are acquired through classical conditioning. But unlike most classically conditioned responses, phobias are especially resistant to extinction. If we classically condition an eyeblink response in a rabbit and then repeatedly present the CS alone, without the UCS (puff of air), the response will extinguish. However, if a person has a phobia for cockroaches, the phobia will not extinguish easily even if they encounter cockroaches and nothing bad happens. Why does the response persist?

Most psychologists believe that the answer lies in a subtle interaction between operant and classical conditioning. The sight of a cockroach makes a person with a

cockroach phobia feel frightened, that is, they experience an unpleasant conditional emotional response. The person runs out of the room, leaving the cockroach behind and reducing the unpleasant feelings of fear. This reduction in an aversive stimulus reinforces the avoidance response and perpetuates the phobia.

Conditioning of flavour aversions

You have probably eaten foods that made you sick and now avoid them on the basis of their flavour alone. The association of a substance's flavour with illness, which is often caused by eating that substance, leads to **conditioned flavour-aversion learning**.

The study of flavour-aversion learning is important not only because it is a real-life experience, but also because it has taught psychologists about unique relations that may exist between certain CSs and certain UCSs. Just as punishment is a result of classical conditioning where a species-typical defensive response becomes classically conditioned to a discriminative stimulus, conditioned flavour aversions are acquired in the same way. The flavour is followed by an unconditional stimulus (sickness) that elicits the unpleasant responses of the autonomic nervous system, such as cramping and retching. Then, when the animal encounters the flavour again, the experience triggers unpleasant internal reactions that cause the animal to stop eating the food.

Many learning researchers once believed that nearly any CS could be paired with nearly any UCS to produce nearly any CR. However, in a now classic experiment, Garcia and Koelling (1966) showed that animals are more prepared to learn some types of relation among stimuli than others.

In the first phase of their experiment, Garcia and Koelling permitted rats to drink saccharine-flavoured water from a tube. Each lick from the tube produced three CSs: taste, noise and bright lights. This phase ensured that rats were equally familiar with each of the CSs. In the next phase, the rats were divided into four groups, each experiencing either 'bright-noisy' water or 'tasty' water. Each CS was paired with illness or electric shock.

After several trials, the experimenters measured the amount of saccharine-flavoured water the rats consumed. They found that the rats learned the association between flavour and illness but not between flavour and pain produced by electric shock. Likewise, the rats learned the association between the 'bright-noisy' water and shock-induced pain but not between the 'bright-noisy' water and illness. The results make sense; after all, the animal has to taste the flavour that makes it ill, not hear it, and in the world outside the laboratory, a particular flavour does not usually indicate that you are about to receive an electric shock.

This experiment draws two important conclusions: (1) rats can learn about associations between internal sensations (being sick) and novel tastes, and (2) the interval between the two stimuli can be very long. These facts suggest that the brain mechanisms responsible for a conditioned flavour aversion are different from the ones that mediate an aversion caused by stimuli applied to the outside of the body (such as a painful foot shock). It appears that conditioned flavour aversions serve to protect animals from poisonous foods by enabling them to learn to avoid eating them. Because few naturally occurring poisons cause sickness immediately, neural mechanisms that mediate conditioned flavour aversions must be capable of learning the association between events that are separated in time. Most other cause-and-effect relations involve events that occur close in time; hence the neural mechanisms that mediate an organism's ability to learn about them operate under different time constraints.

Some animals have eating habits quite different from those of rats; they eat foods that they cannot taste or smell. For example, some birds eat seeds that are encased in a tasteless husk. They do not have teeth, so they cannot break open the husk and taste the seed. Thus, they cannot use odour or taste as a cue to avoid a poison. However, Wilcoxon *et al.* (1971) found that quail (a species of seed-eating birds) can form a conditioned aversion to the sight of food that earlier made them sick. People can also acquire conditioned flavour aversions. A friend of mine often took trips on aeroplanes with her parents when she was a child. Unfortunately, she usually got airsick. Just before take-off, her mother would give her some spearmint-flavoured chewing gum to help relieve the pressure on her eardrums that would occur when the plane ascended. She developed a conditioned flavour aversion to spearmint gum. In fact, the odour of the gum still makes her feel nauseated.

Conditioned flavour aversions, like most learning situations, involve both classical and operant conditioning. From one point of view, we can say that the aversive stimuli produced by the poison punish the behaviour of eating a particular food. That is, the flavour serves as a discriminative stimulus for a punishment contingency (operant conditioning). However, it also serves as a conditioned stimulus for a classical conditioning situation: the flavour is followed by an unconditional stimulus (the poison) that elicits unpleasant responses of the autonomic nervous system, such as cramping and retching. Then, when the animal encounters the flavour at a later date, it experiences unpleasant reactions that cause it to leave the source of the stimulus and avoid the food.

Psychology in action – Flavour aversions

Because conditioned flavour aversions can occur when particular flavours are followed by feelings of nausea, even several hours later, this phenomenon has several implications for situations outside the laboratory. An unfortunate side effect of chemotherapy or radiation therapy for cancer is nausea. Besides killing the rapidly dividing cells of malignant tumours, both chemotherapy and radiation kill the rapidly dividing cells that line the digestive system and thus cause nausea and vomiting.

Knowing what we know about conditioned flavour aversions, we might predict that chemotherapy or radiation therapy would cause a conditioned aversion to the foods a patient ate during the previous meal. Bernstein (1978) showed that this prediction is correct. She gave ice cream to some cancer patients who were about to receive a session of chemotherapy and found that several months later, 75 per cent of these patients refused to eat ice cream of the same flavour. In contrast, control subjects who did not taste it before their chemotherapy said that they liked it very much. Only one trial was necessary to develop the conditioned flavour aversion. Even when patients have a clear understanding that the drugs are responsible for their aversion and that the food is really wholesome, they still cannot bring themselves to eat it (Bernstein, 1991). Thus, a conditioned food aversion is not a result of cognitive processes such as reasoning or expectation.

Questionnaires and interviews reveal that cancer patients develop aversions to the foods that they normally eat even if their treatment sessions occur several hours after the previous meal (Bernstein *et al.*, 1982; Mattes *et al.*, 1987). When patients receive many treatment sessions, they are likely to develop aversions to a wide variety of foods. Because a treatment that produces nausea may cause the development of a conditioned flavour aversion to the last thing a person has

eaten, Broberg and Bernstein (1987) attempted to attach the aversion to a flavour other than one that patients encounter in their normal diets. Cancer patients ate either a coconut or root beer Lifesaver (a sweet) after the last meal before a chemotherapy session. The experimenters hypothesised that the unique flavour would serve as a scapegoat, thus preventing a conditioned aversion to patients' normal foods. The procedure worked; the patients were much less likely to show an aversion to the food eaten during the last meal before the treatment.

Conditioned flavour aversions can also have useful applications. For example, psychologists have applied conditioned aversions to wildlife control. In regions where coyotes have been attacking sheep, they have left chunks of dog food laced with an emetic drug wrapped in pieces of fresh sheepskin. The coyotes eat the bait, become sick and develop a conditioned aversion to the smell and taste of sheep (Gustavson and Gustavson, 1985). These methods can help protect endangered species as well as livestock. Mongooses have been introduced into some islands in the Caribbean, where they menace the indigenous population of sea turtles. Nicolaus and Nellis (1987) found that a conditioned aversion to turtle eggs could be established in mongooses by feeding them eggs into which an emetic drug had been injected.

Evidence suggests that for some species, conditioned flavour aversions can become cultural traditions. Gustavson and Gustavson (1985) reported that after adult coyotes had developed a conditioned aversion to a particular food, their offspring, too, avoided that food. Apparently, the young coyotes learned from their mothers what food was fit to eat. However, Nicolaus *et al.* (1982) found that adult raccoons having a conditioned aversion to chickens did not teach their offspring to avoid chickens. In fact, after seeing the young raccoons kill and eat chickens, the adults overcame their aversion and began preying on chickens again.

Applications of operant conditioning to human behaviour

Instructional control

Human behaviour is influenced not only by reinforcement but also by the interactions of reinforcement with rules, that is, verbal descriptions of the relation between behaviour and reinforcement. In fact, much of our everyday behaviour involves following rules of one sort or another. Cooking from a recipe, following directions to a friend's house, and obeying the speed limit are common examples. Because

rules have the potential to influence our behaviour in almost any situation, behaviour analysts are interested in learning more about how rules and reinforcement interact.

One way to investigate this interaction is to give subjects rules that are false, that is, rules that are inaccurate descriptions of the behaviour required for reinforcement (Galizio, 1979; Baron and Galizio, 1983). In such experiments, people may behave in accordance with either the rule or the reinforcement requirement. Other researchers have shown that people sometimes generate their own rules about the consequences of their behaviour (Lowe, 1979). Lowe argues that our ability to describe verbally the consequences of our behaviour explains why humans

often respond differently from other animals when placed under similar reinforcement contingencies (Lowe *et al.*, 1983). When exposed to fixed interval schedules, animals do not respond immediately after each reinforcement. As time passes, though, responding gradually increases until the next reinforcer is delivered. Humans, on the other hand, tend to follow one of two strategies: responding very slowly or responding very rapidly. Those people who respond slowly often describe the schedule as interval-based and they respond accordingly. Those who respond rapidly usually describe the schedule as ratio-based – which it is not – and they respond accordingly. Thus, the language one uses may indeed exert some control over one's own behaviour. The extent to which language and other behaviours interact is the subject of ongoing experimental and theoretical work (Hayes, 1989; Cerruti, 1990).

Stimulus equivalence

Stimulus equivalence refers to the emergence of novel behaviour without direct reinforcement of that behaviour (Fields, 1993; Fields *et al.*, 1995). Imagine that you were asked to learn the relationship among a group of symbols: A, B and C. Suppose further that after training without reinforcement, you discovered that $A = B$ and $A = C$. How then would you respond to the following question: does $B = C$? You would probably reason that if $A = B$ and $A = C$, then B, too, is equal to C. But notice that you were never trained or received any direct reinforcement for learning that $B = C$. Rather, the equivalent relationship between B and C emerged from your previous learning; hence, the term 'stimulus equivalence'.

Stimulus equivalence is an important area of research because it represents one way we learn to use and understand symbols, such as language. For example, let A

represent a picture of a dog, B represent the spoken word 'dog', and C represent the printed word 'dog'. Suppose that we teach a child to point to the picture of the dog (A) and say the word 'dog' (B). In this case, the child learns that $A = B$ and $B = A$. Next, suppose that we teach the child to point to the picture of the dog (A) when he sees the printed word 'dog' (C). The child learns that $A = C$ and that $C = A$. What we are really interested in, though, is whether the child will have learned that the spoken word 'dog' (B) is equivalent to, or means the same thing as, the printed word 'dog' (C).

This is precisely what children learn under these circumstances, even though the equivalent relationship, $B = C$, has not been directly trained (Sidman and Tailby, 1982). Rather, it emerged as a consequence of the child's learning history. Understanding how stimulus equivalence develops is likely to lead to a better understanding of language development.

Drug use and abuse

Soon after Skinner outlined the principles of operant behaviour, others were quick to apply them to the study of drug action and drug-taking (Thompson and Schuster, 1968). In fact, Skinner's three-term contingency is now partly the basis of an entirely separate discipline of pharmacology known as behavioural pharmacology, the study of how drugs influence behaviour. In this field, the terms 'discriminative stimuli', 'responding' and 'consequences' translate into drugs as discriminative stimuli, the direct effects of drugs on behaviour, and the reinforcing effects of drugs, respectively. Perhaps the most interesting discovery in behavioural pharmacology is the finding that most psychoactive drugs function as reinforcers in both humans and animals.

Controversies in Psychological Science – What is insight?

The issue

Many problems we have to solve in our daily lives require us to make responses that we have never made before and that we have never seen anyone else make either. We often think about a problem, looking at the elements and trying to imagine various solutions. We try various responses in our heads, but none seems to work. Suddenly, we think of a new approach: maybe this one will work. We try it, and it does. We say that we have solved the problem through insight (Sternberg and Davidson, 1996).

But what is insight? Some people see it as almost a magical process: a sudden flash of inspiration, a bolt from the blue. At

the simplest level, it is a form of understanding that changes a person's perception of a problem and its solution (Dominowski and Dallob, 1996). Most people regard insight as a particularly human ability – or, at least, as an ability that belongs to our species and, perhaps, some of the higher primates. Some psychologists, however, regard the term as fairly meaningless.

The evidence

During the early part of the twentieth century, the German psychologist Wolfgang Köhler studied the problem-solving behaviours of chimpanzees. In one famous example (Köhler, 1927), he hung some bananas from the ceiling of an animal's

Controversies in Psychological Science – Continued

cage, just high enough to be out of reach. The cage also contained a large box. Sultan, one of the chimps, first tried to jump up to reach the bananas, then paced around the cage, stopped in front of the box, pushed it towards the bananas, climbed onto the box, retrieved and ate the fruit. Later, when the bananas were suspended even higher, he stacked up several boxes, and on one occasion when no boxes were present, he grabbed Köhler by the hand, led him over to the bananas and climbed on top of him. Figure 7.10 illustrates the attempts at solving the problem.

Köhler believed that the insightful problem-solving behaviour shown by the chimpanzees was different from the behaviour of Thorndike's cats as they learned to escape the puzzle boxes. The cats clearly showed trial-and-error behaviour, coming upon the solution by accident. The escape from the box served as a reinforcing stimulus, and eventually the animals learned to operate the latch efficiently. But the behaviour of the chimpanzees seemed very different. They suddenly came upon a solution, often after looking at the situation (and, presumably, thinking about it). Köhler saw no accidental trial-and-error behaviour. The problem used in Köhler's experiment is an example of an object-use problem. Another type of problem, a spatial insight problem (Dominowski and Dallob, 1996) is seen in Figure 7.11. This is the nine dot problem in which you have to connect all the dots using four straight lines and without lifting your pen from the page or retracing any of the lines.

Research suggests that insight may be less mysterious than it appears and may be based on combinations of behaviours initially learned through trial and error. In one study (Epstein *et*

al., 1984), the experimenters used operant procedures (with food as the reinforcer) to teach a pigeon two behaviours: (1) to push a box towards a target (a green spot placed at various locations on the floor), and (2) to climb onto a box and peck at a miniature model of a banana which was suspended overhead. Once these behaviours had been learned, the experimenters confronted the pigeon with a situation in which the box was in one part of the chamber and the banana was in another. The pigeon acted much the way that Sultan did:

At first, the bird appeared to be confused: it stretched toward the banana, turned back and forth from the banana to the box, and so on. Then, rather suddenly, it began to push the box toward the banana, sighting the banana and readjusting the path of the box as it pushed. Finally, it stopped pushing when the box was near the banana, climbed onto the box, and pecked the banana.

Source: Epstein, 1985, p. 132.

Pigeons will show insightful behaviour only after they have learned the individual behaviours that must go together to solve a problem. For example, only if pigeons have learned to push a box towards a goal will they move it under a model banana hanging from the top of the cage. It is not enough to have learned to push a box; they must have learned to push it towards a goal. Presumably, the chimpanzees' experience with moving boxes around and climbing on them was necessary for them to solve the hanging banana problem.

In Chapter 2, you read about the concept of nominal fallacy: we tend to think that we have explained a phenomenon simply by naming it. Simply labelling behaviour as insightful does not help us to understand it. If we do not know what

Controversies in Psychological Science – *Continued*

behaviours an animal has already learned, a novel and complex sequence of behaviours that solves a problem seems to come from nowhere. To understand the necessary conditions for insight to occur, we need to know more than what is happening during the current situation; we also need to know what kinds of learning experiences the animal has had.

Conclusion

The scientist's challenge is to dissect even the most complex behaviours and try to understand their causes. Perhaps

chimpanzees, like humans, are capable of solving problems by using some sort of mental imagery, testing possible solutions in their heads before trying them. But neither humans nor chimpanzees will be able to think about objects they have never seen or imagine themselves performing behaviours they have never performed or seen others perform. But the raw material for problem-solving – including the thinking that may accompany some forms of insightful behaviour – must come from experience. That is what this chapter has been all about.

When administered as a consequence of responding, these drugs will induce and maintain high rates of responding (Griffiths *et al.*, 1980). There is a very high correlation between drugs that will maintain animal responding in experimental settings and those that are abused by humans (Griffiths *et al.*, 1980). Cocaine, for example, maintains very high rates of responding and drug consumption, to the point that food and water consumption decreases to life-threatening levels. Unlimited access to cocaine in rhesus monkeys can lead, in some cases, to death. These findings have allowed psychologists to study the abuse potential of newly available drugs in order to predict their likelihood of becoming drugs of abuse. The realisation that drugs are reinforcers has, in turn, led behavioural pharmacologists to treat cocaine dependence in people successfully by scheduling reinforcement for non-drug-taking behaviour (Higgins *et al.*, 1994).

Just as the telephone ringing can serve as a discriminative stimulus for you answering it, the stimulus effects of drugs can also exert control over human behaviours that are reinforced by non-drug stimuli. People become more sociable under the influence of alcohol not only because the drug reduces their inhibitions, but also because people have some successful social interactions while under the drug's effects. These interactions reinforce their sociability. In fact, many laboratory studies have shown that certain drugs actually increase social responding and social reinforcement (Higgins *et al.*, 1989).

Observation and imitation

Normally, we learn about the consequences of our own behaviour or about stimuli that directly affect us. We can also learn by a less direct method: observing the behaviour of others.

Evidence suggests that imitation does seem to be an innate tendency. Many species of birds must learn to sing the song of their species; if they are raised apart from other birds of their species,

they will never sing or they will sing a peculiar song that bears little resemblance to that of normally raised birds (Marler, 1961). However, if they hear the normal song played over a loudspeaker, they will sing it properly when they become adults. They have learned the song, but clearly there were no external reinforcement contingencies; nothing in the environment reinforced their singing of the song.

Classically conditioned behaviours, as well as operantly conditioned behaviours, can be acquired through observation. For example, suppose that a young girl sees her mother show signs of fear whenever she encounters a dog. The girl herself will likely develop a fear of dogs, even if she never sees another one. In fact, Bandura and Menlove (1968) reported that children who were afraid of animals – in this case, dogs – were likely to have a parent who feared dogs, but they usually could not remember having had unpleasant direct experiences with them. As you will see in Chapter 13, we tend to imitate, and feel, the emotional responses of people we observe.

Under normal circumstances, learning by observation may not require external reinforcement. In fact, there is strong evidence that imitating the behaviour of other organisms may be reinforcing in itself. However, in some cases in which the ability to imitate is absent, it can be learned through reinforcement. For example, Baer *et al.* (1967) studied three severely retarded children who had never been seen to imitate the behaviour of other people. When the experimenters first tried to induce the children to do what they themselves did, such as clap their hands, the children were unresponsive. Next, the experimenters tried to induce and reinforce imitative behaviour in the children. An experimenter would look at a child, say 'do this,' and perform a behaviour. If the child made a similar response, the child was immediately praised and given a piece of food. At first, the children were physically guided to make the response. If the behaviour to be imitated was clapping, the experimenter would clap their hands, hold

the child's hands and clap them together, and then praise the child and give them some food.

The procedure worked. The children learned to imitate the experimenters' behaviours. More importantly, however, the children had not simply learned to mimic a specific set of responses. They had acquired the general tendency to imitate. When the researchers performed new behaviours and said 'do this', the children would imitate them.

Recent approaches to learning: computational modelling and neural networks

In his editorial of an issue of the journal *Perception*, Gregory (1998) asked, 'Is the brain a computer?' If a computer is anything that solves problems, then 'yes', says Gregory, 'the brain is a computer'. Similarly, if perception is problem-solving (such as being able to perceive an object from poor amounts of sensory data), then the visual brain is also a computer.

Although cognitive psychology has a history that dates back to the early part of the twentieth century, most of its philosophy and methodology has developed since the 1960s. During this time, the best-known physical device that performs functions similar to those of the human brain has been the general-purpose serial computer. Thus, it is the computer that provided (and still provides) much of the inspiration for the models of human brain function constructed by cognitive psychologists.

Modern general-purpose computers consist of four major parts:

- Input and output devices (or, collectively, I/O devices) permit us to communicate with the computer – to give it instructions or data and to learn the results of its computations.
- Memory permits information to be stored in the computer. This information can contain instructions or data we have given the computer or the intermediate steps and final results of its calculations.
- A central processor contains the electronic circuits necessary for the computer to perform its functions – to read the information received by the input devices and to store it in memory, to execute the steps specified by the instructions contained in its programs, and to display the results by means of:
- the output devices.

Modern general-purpose computers can be programmed to store any kind of information that can be coded in numbers or words, can solve any logical problem that can be explicitly described, and can compute any mathematical equations that can be written. Therefore, in principle, at least, they can be programmed to do the things we do: per-

ceive, remember, make deductions, solve problems. The power and flexibility of computers seem to make them an excellent basis for constructing models of mental processes.

For example, psychologists, linguists and computer scientists have constructed computer-inspired models of visual pattern perception, speech comprehension, reading, control of movement, and memory (Rolls, 1997; 2008), as well as robots which can mimic aspects of behaviour. Some of these are more successful than others. The computer Deep Blue, for example, played a six-game chess match against the World Chess Champion Gary Kasparov in 1997, and won by two games to one (the players drew three times). The advantage that such a computer has is its speed of processing; its disadvantage is that its depth of understanding is limited and not as sophisticated as that of humans. It can be programmed with all the moves in chess that are known to date, but it may not understand why those moves may work. While speed is one of a computer's advantages – and at this they are far superior to humans: chips are faster than neurons – its disadvantage is seen clearly in exercises such as language translation, at which its performance is generally execrable. It can understand grammar and it may understand specific words, but it has no sense of the meaning of a sentence. Sentences such as 'He was killing time' are problematic for it. We understand this to mean occupying our time while we wait; a computer may understand this to mean murdering a clock.

Artificial intelligence

The construction of computer programs that simulate human mental functions is called **artificial intelligence**. The aim of such enterprises is to try to clarify the nature of mental functions. For instance, to construct a program and simulate perception and classification of certain types of pattern, the investigator must specify precisely what the task of pattern perception requires. If the program fails to recognise the patterns, then the investigator knows that something is wrong with the model or with the way it has been implemented in the program. The investigator revises the model/program, tries again, and keeps working until it finally works (or until they give up the task as being too ambitious). So far, no program is advanced enough to deal with more than a small fraction of the patterns a human can recognise.

Ideally, the task of discovering what steps are necessary in a computer program to simulate some human cognitive abilities tells the investigator the kinds of process the brain must perform. However, there is usually more than one way to accomplish a particular goal. Critics of artificial intelligence have pointed out that even if it is entirely possible to write a program that performs a task that the human brain performs – and comes up with exactly the

Scientists at the Massachusetts Institute of Technology have developed a number of 'intelligent' machines and instruments. The software worn by the pool player analyses the position of the balls on the table and then works out the easiest shot to attempt.

Source: Sam Ogden/Science Photo Library Ltd.

same results – the computer may perform the task in an entirely different way. In fact, some say, given the way that computers work and what we know about the structure of the human brain, the computer program is guaranteed to work differently.

Serial computers work one step at a time and each step takes time. A complicated program will contain more steps and will take more time to execute. But we do some things extremely quickly that computers take a very long time to do. One of the best examples is visual perception. We can recognise a complex figure about as quickly as we can a simple one. For us, it takes about the same amount of time to recognise a friend's face as it does to identify a simple triangle. The same is not true at all for a serial computer. A computer must 'examine' the scene through an input device something like a television camera. Information about the brightness of each point of the picture must be converted into a number and stored in a memory location. Then the program examines each memory location, one at a time, and does calculations that determine the locations of lines, edges, textures and shapes. Finally, it tries to determine what these shapes represent. Recognising a face takes much longer than recognising a triangle.

If the brain were a serial device, its maximum speed would probably be around ten steps per second, considering the rate at which neurons can fire (Rumelhart *et al.*, 1986). This rate is extremely slow compared with modern serial computers. Obviously, when we perceive visual images, our brain does not act like a serial device.

Parallel processing and neural networks

Instead, the brain appears to be a **parallel processor**, in which many different modules (collections of circuits of neurons) work simultaneously at different tasks. A complex task is broken down into many smaller ones, and separate modules work on each of them. Because the brain consists of many billions of neurons, it can afford to devote different clusters of neurons to different tasks, as we saw in Chapters 4 and 6. With so many things happening at the same time, the task gets done quickly.

Recently, psychologists have begun to devise models of mental functions that are based, very loosely, on the way the brain seems to be constructed. These models are called **neural networks**, and the general approach is called **connectionism**. One area of psychology where neural networks have been applied is language, and we turn to this in Chapter 10.

Computer simulation specialists have discovered that when they construct a network of simple elements interconnected in certain ways, the network does some surprising things. The elements have properties like those of neurons. They are connected to each other through junctions similar to synapses. Like synapses, these junctions can have either excitatory or inhibitory effects. When an element receives a critical amount of excitation, it sends a message to the elements with which it communicates, and so on. Some of the elements of a network have input lines that can receive signals from the 'outside', which could represent a sensory organ or the information received from another network. Other elements have output lines, which communicate with other networks or control muscles, producing behaviour. Thus, particular patterns of input can represent particular stimuli, and particular patterns of output can represent responses.

Investigators do not construct physical networks. Instead, they write computer programs that simulate them. The programs keep track of each element and the state of each of its inputs and outputs and calculate what would happen if a particular pattern of input is presented. Neural networks can be taught to 'recognise' particular stimuli. They are shown a particular stimulus, and their output is monitored. If the response on the output lines is incorrect, the network is given a signal indicating the correct response. This signal causes the strength of some of the junctions to be changed, just as learning is thought to alter the strength of synapses in the brain. After several trials, the network learns to make correct responses.

If the network uses a sufficiently large number of elements, it can be trained to recognise several different patterns, producing the correct response each time one of the patterns is shown to it. In addition, it will even recognise the patterns if they are altered slightly, or if only parts of the patterns are shown. Thus, neural networks can

recognise not only particular patterns but also variations on that pattern. Thus, they act as if they had learned general prototypes, not specific templates. For example, they may learn that the letter A reproduced in Times Roman font is the same as an A reproduced in Palatino font.

So, does the brain work like a computer? The answer seems to be that it does, but not like the most familiar kind of computer, which cognitive psychologists first used as a basis for constructing models of brain function. The brain appears to be a parallel processor made up of collections of neural networks. Neural networks' attempts to simulate the functions of the brain have not met with considerable success (which is not surprising given the complexity of that organ). Most simulations have been of the very basic, perceptual kind. It is interesting to speculate that a strong artificial intelligence position on the nature of simulating brain function would effectively result in the creation of a conscious computer. How likely do you think this is?

Learning in practice: being a student

So far, we have considered some of the important theories of learning that have made an impact on psychology and in applied contexts. Other elements of the learning process are covered in the next chapter on memory. The remainder of this chapter examines how various factors can affect academic learning and success. It explores how the use of different teaching methods can influence learning as might the type of material taught. It also considers how specific variables such as personality, learning style, group study and confidence can influence successful understanding of learned material.

Deep v. shallow learning

Perhaps the most consistently studied – and reliable – dichotomy in the psychology of learning is deep and shallow processing (or learning). In shallow learning, there is an emphasis on remembering facts, rather than on understanding them; in deep learning, there is an emphasis on knowing and understanding material, rather than on the straightforward process of remembering it.

For example, in the 1990s researchers suggested that learning could be conceptualised in five ways (Saljo, 1991; adapted from Hartley, 1998):

- 1 Learning is a means of acquiring knowledge.
- 2 Learning is a means of storing (remembering) information that could be used later.

- 3 Learning is the acquisition of facts, knowledge and methods.
- 4 Learning is the making sense of, or abstracting meaning from, material.
- 5 Learning is a process that assists the interpretation or understanding of reality.

Researchers found that those students who were classified as 'shallow' learners were most likely to adopt the first two of these learning strategies; 'deep' learners were more likely to adopt the last two. To examine whether 'depth' could be taught, Norton and Crowley (1995) studied the effect of incorporating workshops into a first-year psychology course on students' learning strategies. When the performance of those who attended all the workshops was compared with those who attended one or two or none, there was no increase in deep processing in the conscientious students. However, those who stayed with the workshops adopted a less shallow processing style as the course progressed. The results demonstrated that by encouraging students to think, to interpret and to discuss concepts and ideas – rather than asking them to learn their material by rote – this process could make them less shallow learners.

The idea was first proposed and demonstrated empirically in Sweden in the 1970s. Marton and Saljo (1976), for example, characterised deep learners as those who would agree with statements such as:

- I try to get the principal ideas.
- I try to find the main points of a chapter.

Whereas shallow learners were likely to agree with statements such as:

- I try to concentrate on remembering as much as possible.

That is, the deep learners tried to glean meaning from material whereas the shallow learners tried to remember the information. When a group of students was given a 1,400-word article on curriculum reform in Swedish universities and asked to summarise the author's main argument in one or two sentences, the results were – in light of what you now know – predictable. None of the students who were classified as shallow learners (based on their responses to a questionnaire) was able to do this; those classified as deep learners did this faultlessly.

In an article by Gibbs (1992) cited in Hartley (1998), the author lists factors which could encourage shallow processing and those which could foster deep learning. Here are some of those factors:

- Factors encouraging surface learning:
 - heavy workload;
 - excess course material;

- reduced opportunity to study a subject in depth;
- lack of choice in subject areas and methods of studying those subjects;
- assessment that is threatening and anxiety-provoking.
- Factors encouraging deep learning:
 - project work;
 - learning by doing;
 - problem-based learning;
 - work that does not rely solely on remembering;
 - work that allows reflection;
 - independent learning;
 - rewarding understanding and penalising memorisation;
 - involving students in the choice of assessment method.

So, the message that seems to be clear and consistent from research is: in the contexts studied, having a ‘deep’ approach to study is better than one driven by a need to remember.

Learning style

Psychologists have devised various ways of measuring students’ learning styles and investigating whether students on different courses learn in different ways. One of these measures is the Student Process Questionnaire (SPQ) (Biggs, 1987), a 42-item measure of a deep approach to learning (evaluating material critically; reading widely; engaging in discussion), a surface approach to learning (e.g. rote learning) and an achieving approach to learning (where the student has a strong intention to succeed and obtain high grades). In a study of how chemistry students’ learning style changes across their course

(Zeegers, 2001), the deep approach to learning was the one most closely related to good grade outcome but the achieving approach was the one most likely to undergo fluctuations across the course. Students expressed less achievement-driven behaviour as the course progressed, suggesting that striving for high grades became less important as their education progressed. The surface approach increased in the first year of study but stabilised thereafter. Older students were significantly more likely to engage in deep learning and also show high achievement motivation. These students also received higher grades and completed more units on their courses.

In a similar study, researchers from the universities of Leiden and Amsterdam investigated whether factors such as personality and learning style correlated with academic performance in 409 Dutch first-year psychology undergraduates (Busato *et al.*, 2000).

Intellectual achievement and the motivation to do well were, as expected, positively related to academic performance. There was a relationship between an undirected learning style and performance. Students who adopted this approach did significantly worse than did students who adopted other styles. The personality variable most closely related to academic success was conscientiousness. Interestingly, performance in the first exam at university was the most important predictor of academic success.

Changes in students’ views about their learning

The perception and understanding of material learned across a degree changes. A study at Princeton University found that the instructor’s way of expressing him/herself, information about the course and an absence of criticism about the course from others was significantly related to

Cutting edge – Personality and academic success

An analysis of 109 studies examining the relationship between psychosocial and study skill factors, grade success and student retention (how likely students are to stay on their course) has shown that there is a moderately significant relationship between remaining in college and (i) keeping academic goals, (ii) a person’s ability to assess the inability to succeed academically and (iii) good academic skills. The best predictors of grade success are motivation to achieve and the student’s ability to assess accurately his/her ability to succeed (Robbins *et al.*, 2004). The results seem to tally with those from the workplace where highly motivated employees and those capable of self-evaluation are those who are most successful.

However, personality may be a better predictor of academic performance than grades or other factors. Openness

to experience and agreeableness have been found to be significant predictors of academic success, but extraversion, neuroticism and conscientiousness have not (you will find a detailed description of these personality types in Chapter 14) (Farsides and Woodfield, 2003). Of all the variables studied, however, a non-personality factor – seminar attendance – was the strongest predictor of success. This said, a meta-analysis of studies exploring the relationship between personality and academic performance found that one personality variable in particular was important (Poropat, 2009). In a sample totaling over 70,000 participants from secondary and tertiary education the greatest correlation – it predicted performance better than did intelligence – was between performance and conscientiousness.

post-course evaluations in general (Babad *et al.*, 1999). The features that predicted evaluations at introductory level were not those that predicted evaluations at advanced 4. The only consistent feature was that workload and mark leniency were weak predictors of course selection.

For advanced courses, features which predicted evaluation were interesting readings, having an interesting course, and instructor's knowledge and expertise. None of the personality factors – such as the lecturer's sense of humour or approachability – predicted these students' evaluations of their course. Only for the introductory students was there a relationship between the instructor's humour and the post-course evaluation.

The study appears to show that as students progress through their degree, what they value in a course changes. They become more concerned with academic substance and less with 'lighter' features such as the instructor's sense of humour. At the beginning of their education, first year students are sampling the many different things that university or college has to offer. The instructor's sense of humour and expression was important to first year students, but advanced students valued the quality of their courses and teaching, such as the content of courses and how well they were taught and prepared. The authors argue that the respondents in their sample may not be representative (because Princeton undergraduates have different course structures to those of others) but suggest that the results could be generalised to similar institutions.

Chamorro-Premuzic *et al.* (2007) found that the personality characteristics of the lecturer interact with the students' own and these influence perceptions of teaching. Students tended to prefer lecturers with personalities similar to their own, unless they were neurotic. Particularly, they preferred lecturers who were emotionally stable and conscientious.

A study from the University of Missouri-Columbia found that by graduation, students placed less emphasis on extrinsic factors (such as earning money, gaining popularity and how they looked) and more on intrinsic factors (valuing community, intimacy and growth) (Sheldon, 2005). The greater the shift to intrinsic values, the greater the sense of psychological well-being students felt as they progressed through college. You might find that the findings of these studies mirror your own experience as a psychology student.

Confidence

One variable that might mediate the relationship between learning style and academic success is confidence. A small number of studies has shown that the relationship between a person's confidence in performing well and

actual performance, however, may not be that great. Studies of students have shown that those who do best are those that do not express over-generous levels of confidence: the more modestly self-assessed students performed best. Conversely, those who rate their confidence in their ability highly tend not to do as well as their self-image would predict. In one study of students from university courses in Israel, the Netherlands, Palestine, Taiwan and the USA, confidence ratings were seen to be nation-dependent in some cases (Lundeberg *et al.*, 2000).

Palestinian students expressed greatest confidence in their ability (whether they were actually correct or incorrect in answering questions). Taiwan students were the least confident but were better able to discriminate between their performance when they knew they were right and when they were wrong. That is, their confidence rating was higher when they got the answer right, and lower when they got the answer wrong. Other countries such as the USA, the Netherlands and Israel showed comparable performance and confidence scores. There was no significant difference between men or women in their confidence ratings and the relationship between this and performance.

There are aspects of learning that can be positively influenced by confidence, however. Participants who scored higher in conscientiousness and openness tend to be more confident about their reading and writing ability (Pulford and Sohal, 2006). Agreeableness and perfectionism predicted confidence in numeracy skills. People who expressed least confidence in speaking tended to be introvert, female, low on conscientiousness and were not especially motivated to be organised. Confidence in the ability to manage time was found in participants who were conscientious, extravert and motivated to be organised. All three personality traits predicted Grade Point Average in the first year (the greater the trait expressed, the higher the GPA).

The best way to understand a textbook

This textbook should provide you with enough basic information and further reading for you to understand important concepts, theories and findings in psychology research, to write your essays, sit your course exams or complete your course projects. But are there specific ways of reading this textbook that can maximise your learning?

According to research by Slotte and Lonka (1999), there is. They studied 226 high school students' methods of taking notes from a philosophical textbook, the content of which would be examined formally before students enrolled on a course. Half of the sample were asked to review their notes during note-taking; the other half were not given any explicit instructions. The quality

and quantity of the notes was then analysed and were correlated with exam performance.

They found that reviewing notes during essay writing was associated with good performance on questions that required comprehension of the text and deep, detailed knowledge. However, reviewing these notes did not help with drawing original conclusions about the text. Importantly, they note that students summarising the text in their own words with their own subheadings and structure performed better than those students who took verbatim notes or took notes in the exact order in which the material appeared in the text. This finding suggests that deeper understanding (and better performance) comes from having read and understood material in a text. The key to this is being able to express the text's ideas in your own words. If you have not done this, you haven't understood the text.

Is learning by note-taking from this book different from note-taking from a lecture? A recent meta-analysis suggests that the relationship between note-taking and encoding of information in a text or during a lecture is significant but modest (Kobayashi, 2005). Inexperienced students benefited more from note-taking than did experienced ones, possibly because the latter could perform successfully without substantial note-taking. Taking notes from a visual presentation was less effective than taking notes from an audio source, presumably because paying attention to the lecture together with meeting the mechanical demands of note-taking interfered with the writing.

Can the internet be used to teach successfully?

The past decade has seen an expansion in the use of the World Wide Web to facilitate teaching and research. One innovation that has potentially important implications for tutors and students is the development of online courses (Kinney, 2001; Carr-Chellman and Duchastel, 2000; Martin *et al.*, 2005; Schweizer, 1999; Waschull, 2001). One benefit of these courses is that they allow you greater autonomy. If the teaching materials are clear, interactive and engaging, you do not need to be physically in the classroom with the tutor. This idea is not novel. The Open University in the UK has based its peda-

gogy extensively on this approach, via the use of video-based interactive learning. There are now online versions of courses in health psychology (Upton and Cooper, 2001), social work (Stocks and Freddolino, 1998), nursing (Cravener, 1999), introductory psychology (Martin *et al.*, 2005; Waschull, 2001), child development (Graham, 2001) and research methods (Wang and Newlin, 2000), among others.

One study comparing the effectiveness of teaching an introductory psychology course via the Web with teaching via traditional lectures found that those who followed an online course showed greater knowledge of the content of the syllabus than did those who followed a lecture-based course (Maki *et al.*, 2000). Examination performance was also better in this group. Web-based courses were praised for their convenience but when both types of course were evaluated by the students, the lecture-based format received the most positive ratings, suggesting that learning and satisfaction with the course can be independent of each other: a format which yields better academic performance may not necessarily be the one that is regarded most positively.

There is also evidence that the more the students use online material, the better they perform. Upton and Cooper (2001) found that the grades of undergraduates in psychology were higher when they undertook an online health psychology course than when they followed a conventional lecture-based course, but improvement was related to the increased time spent on the learning materials.

One criticism of online courses is that students may not spend very long on them. One study found that the time spent on an online cognitive psychology course varied from 6.69 hours to 11.96 hours (Taraban *et al.*, 2001). When asked how long they spent on it, however, students overestimated the time they spent on the modules by 100 per cent (the computer tracked students' actual usage so tutors could compare self-reported use with actual use). One way of ensuring that students do spend time on these courses is by providing a comprehensive series of exercises where the student is expected to provide some form of reflective feedback (as part of the course assessment) or where the answers might be forwarded to their tutor.

Studying psychology – An international perspective

You might think that most psychology students study similar topics over similar periods of time across the world. In a sense, this is right but some countries teach psychology in different ways; some have only recently developed psychology degrees; some teach psychology to achieve a particular end such as training in educational psychology. How does the teaching of psychology differ across the world?

In Australia, psychology departments exist in almost all universities (only three do not have one) (Wilson and Provost, 2006). Like those in the UK, departments in the older universities evolved from philosophy departments in the early twentieth century. Again, like the UK, the 1980s saw an expansion of Australian institutes calling themselves universities and thus offering university psychology degrees (the parallel in the UK is the transmogrification of the polytechnics into universities in the early 1990s). Like the UK, courses are accredited by a professional organisation (the Australian Psychological Society). Psychology students in Australia can study three types of psychology degrees: a three-year degree that does not prepare the student to practise psychology; a four-year degree, which does and involves the writing of a thesis and the study of ethics; and graduate degrees.

Courses are slightly different in Italy. Here, students can study for a three-year degree, which qualifies them to practise as a 'psychological assistant' in a restricted range of areas (Prandini and McCarthy, 2006), or a five-year degree which involves an additional two years of study which qualifies the student to practise. The student then pursues a graduate programme in a specific area to specialise further. All public school teachers in Italy have to complete a postgraduate course which involves training in psychology (Prandini and McCarthy, 2006).

Surprisingly for a country that is the birthplace of modern psychology, Germany only established its first professional curriculum in psychology in 1941 (Hodapp and Langfeldt, 2006). In the 1960s, there were 18 universities offering psychology to 2,000 students taught by 31 professors. In the 1980s, there were 30 universities teaching 18,000 students. Currently, there may be around 43 universities with 450 professors teaching 32,000 students (Hodapp and Langfeldt, 2006). Approximately 70 per cent of students are women, a figure that is echoed in the UK. German universities are chang-

ing and as of 2004, a Diplom qualification now entitles students to work in a profession related to psychology. As with all the degrees mentioned so far, the emphasis in German education is on teaching skills that will enable students to apply scientific principles to human behaviour.

The large number of departments in Germany, and other countries, isn't seen elsewhere. Greece, for example, has four psychology departments offering two types of 'undergraduate' degree: a Ptychion (Bachelor's) degree, lasting four years, and a Master's degree (Metaptychiako Diploma) in an area such as clinical, school/educational or organisational psychology – this can last up to three years and involves internship at a relevant institution (Georgas, 2006).

The compactness of provision in Greece contrasts with Russia: 100 psychology departments have been established in the past decade (Karandashev, 2006). Students at Russian universities can study for four (Bachelor's degree) or five years (Specialist degree), in programmes regulated by the Ministry of Education (Karandashev, 2006). The four-year course trains students in general psychology; the five-year course prepares them for professional work. While Russia has divested itself of its communist shackles (partly), China has not. Psychology became an independent university discipline in China in 1960 but, following the 'Cultural Revolution' of 1966–76 and the resultant closure of all universities, psychology was attacked as pseudoscience (Zhang and Xu, 2006). Since 1980, however, psychology has clawed its way back into the university curriculum and is now one of the most popular science subjects (Zhang and Xu, 2006).

Finally, and interestingly given the politically fractious times in which we live, what of Iran? Iran was no academic late-developer: it was running courses in psychology in the 1920s. Currently, 19 universities offer psychology courses, with the BS (Bachelor of Science) degree being awarded after four years of study (Alipour, 2006). Unlike some other countries, the psychological associations in Iran do not accredit courses. Around 34,000 psychology students study in Iran and specialise in four fields: general, clinical, exceptional children and industrial psychology (Alipour, 2006). Very interestingly, in 2003, the Islamic Iranian parliament passed a law that granted equal status to medical and psychological counselling services.

Chapter review

Habituation and classical conditioning

- Habituation screens out stimuli that experience has shown to be unimportant. This form of learning allows organisms to respond to more important stimuli, such as those related to survival and reproduction.
- Classical conditioning occurs when a neutral stimulus occurs just before an unconditional stimulus (UCS) – one that automatically elicits a behaviour. The response that an organism makes in response to the unconditional stimulus (the UCR) is already a natural part of its behaviour; what the organism learns to do is to make it in response to a new stimulus (the conditional stimulus, or CS). When the response is made to the CS, it is called the conditional response, or CR.
- The relationship between the conditional stimulus and unconditional stimulus determines the nature of the conditional response. Acquisition of the conditional response is influenced by the intensity of the unconditional stimulus and the delay between the conditional stimulus and unconditional stimulus.
- Extinction occurs when the conditional stimulus is still presented but is no longer followed by the unconditional stimulus; the conditional response may show spontaneous recovery later, even after a delay.
- Generalisation occurs when stimuli similar to the conditional stimulus used in training elicit the conditional response.
- Discrimination involves training the organism to make a conditional response only after a particular conditional stimulus occurs.
- Classical conditioning can also establish various classes of stimuli as objects of fear (phobia) or of sexual attraction (fetishes). For classical conditioning to occur, the conditional stimulus must not only occur immediately before the unconditional stimulus, but it must also reliably predict the occurrence of the unconditional stimulus.

After behaviourism

- Hull's theory of learning reduced behaviour to numerical values; using these values Hull's system sought to predict behaviour.
- Tolman's theory of learning argued that stimulus–response models were too simplistic and suggested the concept of intervening variables – variables which mediated the relationship between a stimulus and the response to it. Tolman's research led to the coining of the term cognitive map to describe our ability to manipulate three-dimensional environments in the mind.

Operant conditioning

- The law of effect specifies a relation between behaviour and its consequences. If a stimulus that follows a response makes that

response become more likely, we say that the response was reinforced. If the stimulus makes the response become less likely, we say that it was punished. The reinforcing or punishing stimulus must follow the behaviour almost immediately if it is to be effective.

- The process of operant conditioning helps adapt an organism's behaviour to its environment.
- Skinner described the relation between behaviour and environmental events as a three-term contingency: in the presence of discriminative stimuli, a consequence will occur if and only if an operant response occurs.
- A reinforcer is an appetitive stimulus that follows an operant response and causes that response to occur more frequently in the future.
- A punisher is an aversive stimulus that follows an operant response and causes it to occur less frequently in the future.
- If an aversive stimulus is terminated after a response occurs, the response is reinforced through a process called negative reinforcement. The termination of an appetitive stimulus can punish a response through a process called response cost.
- Extinction occurs when operant responses are emitted but not reinforced, which makes sense because organisms must be able to adapt their behaviour to changing environments.
- Complex responses, which are unlikely to occur spontaneously, can be shaped by the method of successive approximations.
- Various types of schedule of reinforcement have different effects on the rate and pattern of responding. When a response is reinforced intermittently, it is more resistant to extinction, probably because an intermittent reinforcement schedule resembles extinction more than a continuous reinforcement schedule does.
- Discrimination involves the detection of essential differences between stimuli or situations so that responding occurs only when appropriate.
- Generalisation is another necessary component of all forms of learning because no two stimuli, and no two responses, are precisely the same. Thus, generalisation embodies the ability to apply what is learned from one experience to similar experiences.
- The major difference between classical conditioning and operant conditioning is in the nature of the contingencies: classical conditioning involves a contingency between stimuli (CS and UCS), whereas operant conditioning involves a contingency between the organism's behaviour and an appetitive or aversive stimulus. The two types of conditioning complement each other. The pairings of neutral stimuli with appetitive and aversive stimuli (classical conditioning) determine which stimuli become conditioned reinforcers and punishers.

Conditioning of complex behaviours

- Much behaviour is under the control of aversive contingencies, which specify particular behaviours that are instrumental in either escaping or avoiding aversive stimuli.

- In conditioned flavour aversions, there is a delay between tasting a poison and getting sick; the rule that a reinforcing or punishing stimulus must immediately follow the response cannot, therefore, apply.
- We are able to acquire both operantly and classically conditioned responses through observation and imitation; we can learn to modify and combine responses learned in other contexts to solve new problems. This is referred to as insight.
- Behaviour analysts argue that behaviour is governed by external causes, such as discriminative stimuli and environmentally based reinforcers and punishers; cognitive psychologists maintain that behaviour is controlled by internal causes, such as thoughts, images, feelings and perceptions.

Factors influencing learning in an academic context

- Research has shown that various factors can influence academic learning, including personality, learning style, group study, the type of learning materials and the style of teaching.
- Students normally begin courses by adopting superficial learning styles geared towards achieving grades and covering the basics; as they progress, learning becomes deeper and more thoughtful.
- While beginning students evaluate courses based on superficial factors, such as the lecturer's sense of humour, more advanced students value the lecturer's knowledge and the quality of the learning materials more.
- The key to understanding material in textbooks is to underline the parts that you consider relevant first and then to write these parts in your own words.
- Research on the use of the internet as a structured teaching tool suggests that it can bring academic benefits.
- Findings from studies that have compared students' performance on web-based courses and traditional classroom-based courses are mixed. Some show superior examination performance by the internet students but others report the opposite.

An excellent collection of links to behaviour analysis/operant conditioning sites.

Memory

Clive had no idea that Tuesday 26 March 1985 would be his last day of conscious thought. We weren't ready... By morning, he could not answer a simple question or remember my name. The doctor said it was 'flu and lack of sleep caused the confusion.

'I'm never ill,' Clive used to say. And he never was. Then, all of a sudden, he was. But instead of a normal illness the doctors had some chance of recognizing, this one is rare, sneaky. Nobody knew what was wrong with him. . .

'A sudden virus had caused holes in Clive's brain; memories fell out. But nothing could touch what was in his heart. He couldn't remember a thing that had ever happened to him; but he remembered me and knew that he loved me.'

Explore the accompanying videos, simulations, and animations on MyPsychLab. This chapter includes activities on: The phonological loop • Mnemonics • Experiencing the Stroop Effect • Interference – a theory of memory • Check your understanding and prepare for your exams using the multiple choice, short answer and essay practice tests also available.

WHAT YOU SHOULD BE ABLE TO DO AFTER READING CHAPTER 8

- Describe what is meant by 'memory' and describe the different types of memory process.
- Describe and understand theories of forgetting.
- Understand the term 'amnesia', be aware of different types of amnesia and understand the biological basis of the disorder.
- Distinguish between the processes of encoding and retrieval.
- Understand how memories are formed and can change over time (and how unreliable they can be).
- Be aware of the neural basis of learning and memory processes such as encoding and retrieval.
- Be aware of the practical applications of concepts from memory research and cognitive psychology.

QUESTIONS TO THINK ABOUT

- What do we mean when we refer to 'memory'?
- Are there different types of memory?
- Why do we forget?
- Can memories be manipulated, and if so, how?
- Would you expect the brain mechanisms that are responsible for memory acquisition also to be responsible for retrieval? Why?
- Is memory capacity finite?
- Without memory, do we have personality?
- Where, in the brain, are memories stored? Can they be stored?

Memory: an introduction

Memory is the process of encoding, storing and retrieving information. **Encoding** refers to the active process of putting stimulus information into a form that can be used by our memory system. The process of maintaining information in memory is called storage and the active processes of locating and using information stored in memory is called **retrieval**.

When psychologists refer to the structure of memory, they are referring to two approaches to understanding memory – a literal one and a metaphorical one. Literally, memory may reflect the physiological changes that occur in the brain when an organism learns. Metaphorically, memory is viewed as a store or a process made up of systems and subsystems. These divisions may not necessarily have neurological meaning but they are useful metaphorical shorthand for describing aspects of memory. They are a way of explaining aspects of memory.

Types of memory

Research suggests that we possess at least four forms of memory: sensory memory, short-term memory, working memory and long-term memory (Baddeley, 1996).

Sensory memory is memory in which representations of the physical features of a stimulus are stored for a very brief time, perhaps for a second or less. This form of memory is difficult to distinguish from the act of perception. The information contained in sensory memory represents the original stimulus fairly accurately and contains all or most of the information that has just been perceived. For example, sensory memory contains a brief image of a sight we have just seen or a fleeting echo of a sound we have just heard. Normally, we are not aware of sensory memory; no analysis seems to be performed on the information while it remains in this form. The function of sensory memory appears to be to hold information long enough for it to be transferred to the next form of memory, short-term memory.

Short-term memory (STM) refers to immediate memory for stimuli that have just been perceived. Its capacity is limited in terms of the number of items that it can store and of its duration. For example, most people who look at the set of numbers

1 4 9 2 3 0 7

close their eyes and recite them back, will have no trouble remembering them. If they are asked to do the same with the following set they might have a little more trouble:

7 2 5 2 3 9 1 6 5 8 4

Very few people can repeat 11 numbers. Even with practice, it is difficult to recite more than 7–9 independent pieces of information that you have seen only once. Short-term memory, therefore, has definite limits. However, there are ways to organise new information so that we can remember more than 7–9 items, but in such cases the items can no longer be considered independent.

Working memory is similar to short-term memory in that it involves short-term storage of information. But working memory is more than this in that it allows us to manipulate material in short-term memory. Remembering material while engaging in a different but related task, for example, illustrates working memory and you will find out more about this in a later section. If you had repeatedly recited the 11 numbers above until you had memorised them (rehearsal) you could have placed them in long-term memory. **Long-term memory (LTM)** refers to information that is represented on a permanent or near-permanent basis. Unlike short-term memory, long-term memory has no known limits and, as its name suggests, is relatively durable. If we stop thinking about something we have just perceived (that is, something contained in short-term memory), we may not remember the information later. However, information in long-term memory need not be continuously rehearsed. We can stop thinking about it until we need the information at a future time.

Some cognitive psychologists argue that no real distinction exists between short-term and long-term memory; instead, they see them as different phases of a continuous process. These psychologists object to the conception of memory as a series of separate units with information flowing from one to the next, as seen in Figure 8.1. Memory may be more complex than this model would have us believe, and the next sections explore the nature of sensory memory, STM, working memory, LTM and other types of memory process.

Sensory memory

Under most circumstances, we are not aware of sensory memory. Information we have just perceived remains in sensory memory just long enough to be transferred to short-term memory. In order for us to become aware of sensory memory, information must be presented very briefly so that we can perceive its after-effects. Although we probably have a sensory memory for each sense modality, research efforts so far have focused on the two most important forms: iconic (visual) and echoic (auditory) memory.

Figure 8.1 The information-processing model of human memory.:

Iconic memory

Visual sensory memory, called **iconic memory** (icon means ‘image’), is a form of sensory memory that briefly holds a visual representation of a scene that has just been perceived. To study this form of memory, Sperling (1960) presented visual stimuli to people by means of a tachistoscope, an apparatus for presenting visual stimuli for extremely brief durations. Sperling flashed a set of nine letters on the screen for 50 milliseconds (ms). He then asked people to recall as many letters as they could, a method known as the whole-report procedure. On average, they could remember only four or five letters, but they insisted that they could see more. However, the image of the letters faded too fast for people to identify them all.

To determine whether the capacity of iconic memory accounted for this limitation, Sperling used a partial-report procedure. He asked people to name the letters in only one of the three horizontal rows. Depending on whether a high, middle or low tone was sounded, they were to report the letters in the top, middle or bottom line (see Figure 8.2). When the participants were warned beforehand to which line they should attend, they had no difficulty naming all three letters correctly. But then Sperling sounded the tone after he flashed the letters on the screen. The participants had to select the line from the mental image they still had: they had to retrieve the information from iconic memory. With brief delays, they recalled the requested line of letters with perfect accuracy. For example, after seeing all nine letters flashed on the screen, they would hear the high tone, direct their attention to the top line of letters in their iconic memory, and ‘read them off’. These results indicated that their iconic memory contained an image of all nine letters.

Figure 8.2 The critical features of Sperling's iconic memory study.

Source: Adapted from Sperling, G., The information available in brief visual presentations, *Psychological Monographs*, 1960, 74, 1–29.

Sperling also varied the delay between flashing the nine letters on the screen and sounding the high, medium or low tone. If the delay was longer than 1 second, people could report only around 50 per cent of the letters. This result indicated that the image of the visual stimulus fades quickly from iconic memory. It also explained why participants who were asked to report all nine letters failed to report more than four or five. They had to scan their iconic memory, identify each letter and store each letter in short-term memory. This process took time, and during this time the image of the letters was fading. Although their iconic memory originally contained all nine letters, there was time to recognise and report only four or five before the mental image disappeared.

Echoic memory

Auditory sensory memory, called **echoic memory**, is a form of sensory memory for sounds that have just been perceived. It is necessary for comprehending many sounds, particularly those that constitute speech. When we hear a word pronounced, we hear individual sounds, one at a time. We cannot identify the word until we have heard all the sounds, so acoustical information must be stored temporarily until all the sounds have been received. For example, if someone says ‘mallet’, we may think of a kind of hammer; but if someone says ‘malice’, we will think of something entirely different. The first syllable we hear – ‘mal’ – has no meaning by itself in English, so we do not identify it as a word. However, once the last syllable is uttered, we can put the two syllables together and recognise the word. At this point, the word enters short-term memory. Echoic memory holds a representation of the initial sounds until the entire word has been heard; it seems to hold information for about four seconds (Darwin *et al.*, 1972).

Short-term memory

Short-term memory has a limited capacity, and most of the information that enters it is subsequently forgotten. Information in sensory memory enters short-term memory, where it may be rehearsed for a while. The rehearsal process keeps the information in short-term memory long enough for it to be

transferred into long-term memory. After that, a person can stop thinking about the information; it can be recalled later, when it is needed.

This simple story is actually inaccurate. First of all, information does not simply ‘enter short-term memory’. For example, most people who read the letters

P X L M R

and put them in short-term memory, have a number of strategies for achieving this. Some would have repeated the letters to themselves or would have whispered or moved their lips. We can say the names of these letters because many years ago we learned them. But that knowledge is stored in long-term memory. Thus, when we see some letters, we retrieve information about their names from long-term memory, and then we hear ourselves rehearsing those names (out loud or silently). The five letters above contain only visual information, their names came from long-term memory, which means that the information put into short-term memory actually came from long-term memory.

To illustrate this, try the following experiment. Study the symbols below, then look away from the book, and try to keep them in short-term memory.

ζ □ δ ρ □

This task is extremely difficult because few people will have learned the names of these symbols. Because of this, there is no way of recording them in short-term memory. Figure 8.3 may, therefore, be a better description of the memory process than is Figure 8.1.

Information can enter short-term memory from two directions: from sensory memory or from long-term memory. When we are asked to multiply 7 by 19, information about the request enters our short-term memory from our sensory memory. Actually performing the task, though, requires that we retrieve some information from long-term memory. What does ‘multiply’ mean? What is a 7 and a 19? At the moment of the request, such information is not being furnished through our senses; it is available only from long-term memory. However, that information is not recalled directly from long-term

memory. It is first moved into short-term memory and then enters conscious awareness.

Psychologists have long debated the number of memory stores that we have – some view humans as having a short-term memory store and a long-term memory store (the dual-store model), whereas others argue that the distinction between these two stores is blurred and that we have one flexible memory store that deals with short-term and long-term memory retrieval (single-store model). Dual-store models were (and are) based on a simple paradigm: participants recall items from a list; if they recall from the end of this list, these items were retrieved from STM; words recalled from the beginning of the list were retrieved from LTM.

To determine whether this distinction was supportable, Talmi *et al.* (2005) set up an fMRI experiment in which participants were asked to remember and then recognise words from a list, as their brain activation was measured. Recognition of items appearing early in the list was associated with activity in regions of the brain associated with LTM (the hippocampus and related structures); recognition of items appearing later in the list was not associated with activation in these areas, providing some neuroimaging support for the distinction between dual memory stores.

Working memory

The fact that short-term memory contains both new information and information retrieved from long-term memory has led some psychologists to prefer the term ‘working memory’ (Baddeley and Hitch, 1974; Baddeley, 1986). Working memory acts on material we have just perceived and allows us to manipulate this in the short-term. It allows us to keep a new telephone number ‘alive’ in memory long enough to dial it or allows us to perform that multiplication task mentioned in the earlier paragraph. In short, it represents our ability to remember what we have just perceived and to think about it in terms of what we already know (Baddeley, 1986; Logie, 1996). We use it to remem-

Figure 8.3 Relations between iconic memory, short-term memory and long-term memory. Letters are read, transformed into their acoustic equivalents and rehearsed as ‘sounds’ in the head. Information can enter short-term memory from both iconic memory and long-term memory. Visual information enters short-term memory from iconic memory, but what is already known about that information (such as names of letters) is moved from long-term memory to short-term memory.

ber whether any cars are coming up the street after looking left and then right, for example.

A widely used test of working memory is reading span (Daneman and Carpenter, 1980). One version involves asking people to read aloud and verify the truthfulness of sentences while, at the same time, trying to remember the last word of each sentence. This task, like many others of working memory, requires a person to maintain some information in memory (storage) while simultaneously manipulating other information (processing).

Another manipulation task in working memory might involve asking the participant to recite from memory a series of five letters forwards, backwards or in alphabetical order. After a delay, the participant is asked to match the number order of a given letter, according to the mental manipulation (e.g. forwards, backwards or alphabetical). So, if the letters B, M, T, E, I were presented and the participant was asked to alphabetise them, the number 4 (called a digit probe) should elicit the correct answer, M (because M is the fourth letter in the alphabetised string, B, E, I, M, T).

Although the terms 'short-term memory' (STM) and 'working memory' (WM) are sometimes used interchangeably, some psychologists make clear distinctions between them. Short-term memory has been referred to as information retained in long-term memory that is called on but not used in a sustained way. Working memory involves dual processing and actual manipulation of material in mental space, not simply the storage of material (Miyake, 2001). There is evidence that tests of working memory and STM measure different processes (Kail and Hall, 2001).

The components of working memory

Working memory was a model devised in the 1970s and later developed extensively by the British psychologists Alan Baddeley and Graham Hitch. They regarded this type of memory as having three components which allowed us to store temporarily verbal material and visuospatial material, and to coordinate the storage of this material. The component which stores verbal material was originally called the **articulatory loop** although this term has been superseded by the term **phonological loop** (Baddeley and Logie, 1992). The component that allows storage of visuospatial material is called the **visuospatial scratchpad** and the coordinating system is called the **central executive**. The working memory 'system' is illustrated in Figure 8.4 and is described next.

Phonological working memory

When we see a printed word, we say it, out loud or silently. If it is said to ourselves, circuits of neurons that

control articulation are activated. Information concerning this activity is communicated within the brain to circuits of neurons in the auditory system, and the word is 'heard'.

Information is then transmitted back to the articulatory system, where the word is silently repeated. The loop continues until the person's attention turns to something else or until it is replaced with new information.

This articulatory or phonological loop allows the retention of verbal phonetic information (so it acts as a phonological store) and operates like the loop of an audiotape (hence, the name). Lists of long words are remembered more poorly than lists of short words, for example, because there is less room on the loop for lists of long words (so the words 'encyclopaedia', 'constellation' and 'antediluvian' would be more difficult to recall than would the words 'clock', 'parrot' and 'daisy'). However, because the loop also allows the rehearsal of information by **subvocal articulation** (such as subvocally rehearsing a telephone number), the loss of information from the phonological store can be avoided. According to Baddeley *et al.* (1975), the capacity of the phonological loop is determined by how much material the participant can rehearse in two seconds. (Figure 8.5 illustrates how the phonological loop is represented in the brain.)

However, the operation of the loop can be defective under certain circumstances. For example, Salame and Baddeley (1982) found that irrelevant speech played in the background while participants learned visually presented

Figure 8.4 Logie's (1995) schematic drawing of the components of working memory.

Figure 8.5 The articulatory loop. A hypothetical explanation of phonological working memory.

words interfered with the recall of these words, but the length of the words to be remembered had no significant effect on recall. However, the closer the irrelevant speech was to the words to be remembered, the greater the interference, suggesting that there was some interference in learning words while attending to the sound (or phonology) of similar ones. There is also evidence that non-speech-related material can have the same effect: even background noise can disrupt recall of verbal and arithmetical material (Banbury and Berry, 1998, and see Chapter 9).

Visuospatial working memory

Much of the information we process is non-verbal. We recognise objects, perceive their locations and find our way around our environment. We can look at objects, close our eyes and then sketch or describe them. We can do the same with things we saw in the past. The visuospatial scratchpad contains visual information either obtained from the immediate environment by means of the sense organs or retrieved from long-term memory.

An example of the ability to manipulate visual information in working memory comes from a famous experiment by Shepard and Metzler (1971). They presented people with pairs of drawings that could be perceived as three-dimensional constructions made of cubes. The participant's task was to see whether the shape on the right was identical to the one on the left; some were, and some were not. Even when the shapes were identical, the one on the right was sometimes drawn

as if it had been rotated. For example, in Figure 8.6(a) the shape on the right has been rotated clockwise 80 degrees, but in Figure 8.6(b) the two shapes are different.

Shepard and Metzler found that people were accurate in judging whether the pairs of shapes were the same or different but took longer to decide when the right-hand shape was rotated. Participants formed an image of one of the drawings in their heads and rotated it until it was aligned the same way as the other one. If their rotated image coincided with the drawing, they recognised them as having the same shape. If they did not, they recognised them as being different. The data supported what the participants said – the more the shape was rotated, the longer it took for people to rotate the image of one of the shapes in working memory and compare it with the other one.

The central executive

The above elements – the phonological loop and the visuospatial scratchpad – do not work independently but have to be regulated and supervised, via the central executive subsystem (Baddeley, 1986). This central executive not only allocates mental resources to working memory tasks but also supervises the updating of what is in working memory.

Figure 8.6 The mental rotation task. (a) The shape on the right is identical to the one on the left but rotated 80 degrees clockwise. (b) The two shapes are different.

How does working memory work?

Apart from allowing us to do the activities mentioned in the previous sections, working memory is also important for cognitive functions such as reading comprehension, academic ability and mathematics (Ashcraft and Kirk, 2001; Daneman and Hannon, 2001). Performance on a working memory span task involving numbers, for example, is a good predictor of spatial task performance (Kane *et al.*, 2001). WM performance is also a good predictor of reading comprehension or verbal ability if the working memory span tests involve verbal or numerical material (Daneman and Hannon, 2001; Hitch *et al.*, 2001; Shah and Miyake, 1996; see Chapter 10).

According to the ‘resource sharing model’ of Daneman and Carpenter (the name given to it by Hitch *et al.*, 2001), a reading span task measures how flexibly we can allocate mental resources to the processing and storage of material. In practical terms, if a person is a good reader, reading sentences for their truthfulness uses up very few cognitive resources and, therefore, frees up more ‘cognitive space’ for other activities (in this example, storage of the last word in the sentences). If readers are poor, on the other hand, the opposite pattern is seen and they, therefore, show poor working memory performance (Yuill and Oakhill, 1991). Working memory capacity is thought to be one factor which determines good reading comprehension ability, although this view has been challenged – some psychologists argue that working memory deficits occur with language impairment, rather than causing it (Nation and Snowling, 1998, 1999). They note that even poor readers can remember as many one-, two- or three-syllable words as good readers.

Daneman and Carpenter’s view of working memory (1980) has attracted much support and has been the dominant, explanatory view of working memory. An alternative model of working memory, however, argues that it is our control of attention that leads to successful working memory performance (Engle *et al.*, 1999). What counts is how much information can be stored, and this is determined by attention capacity. Thus, you should be able to predict people’s performance on attention tasks from their working memory reading span tasks and there is some evidence to support this link.

A final alternative explanation argues that working memory depends on a person’s ability to ignore irrelevant information rather than on their limited capacity to process information (Hasher and Zacks, 1988). In order to achieve this goal, there must be good inhibition of irrelevant information and a focus on only relevant material. It is a persuasive argument. Performance on working memory tasks depends on, among other factors, the ability to inhibit the interference produced by items encountered in early experimental trials (Lustig *et al.*,

2001). It appears to be one of the keys to successful working memory performance.

Primacy and recency effects

When individuals are asked to listen to a long list of words spoken one at a time and then write down as many as they can remember (a free recall task), most participants will remember the words at the beginning and the end of the list and forget the words in between. The tendency to remember the words at the beginning of the list is called the **primacy effect**; the tendency to remember words at the end of the list is called the **recency effect**. Two factors may account for these effects.

The primacy effect appears to be due to the fact that words earlier in a list have the opportunity to be rehearsed more than do words in the other parts of a list. This makes good sense – the first words get rehearsed more because, at the experiment’s outset, these are the only words available to rehearse. The rehearsal permits them to be stored in long-term memory. As more and more words on the list are presented, short-term memory becomes fuller so that words that appear later in the list have more competition for rehearsal time. Because the first words on the list are rehearsed the most, they are remembered better.

As Atkinson and Shiffrin (1968) point out, because the words at the end of the list were the last to be heard, they are still available in short-term memory. Thus, when you are asked to write the words on the list, the last few words are still available in short-term memory even though they did not undergo as much rehearsal as words at the beginning of the list.

A way of testing this would be to create a delay between the presentation of the last stimulus and its recall. Postman and Phillips (1965), for example, inserted a delay of 15 seconds between the last item and recall and had their participants engage in another task. The effect was to abolish the recency effect because STM was occupied and was not allowed to rehearse the last items in the list. When the delay involved no intervening activity, and so STM was unoccupied by another task, the recency effect remained intact (Baddeley and Hitch, 1977). However, the abolition of both recency and primacy effects seems to depend on the nature of the intervening task. If people are told to count backwards for 20 seconds after the presentation of a word list, primacy and recency effects are still shown (Tzeng, 1973). The instructions given to people are also important. If people are instructed to repeat the list in the order they heard the words, the recency effect is abolished (Tulving and Arbuckle, 1963). If they are allowed to recall the list spontaneously, the recency effect remains.

Recency (and primacy) effects extend beyond the recall of artificial word lists. They have been reported for the

recall of parking positions (Pinto and Baddeley, 1991), operas attended over a quarter of a century (Sehulster, 1989) and names of American presidents (Roediger and Crowder, 1976; Healy *et al.*, 2000). Baddeley and Hitch (1977) found that when rugby players were asked to recall the teams they played, they named the most recently played teams first and with greater accuracy. Maylor (2002) asked 27 Methodist churchgoers and 27 non-churchgoers to place six verses of various hymns that were not carols and did not have a narrative, in the correct order. If serial positioning occurs in semantic memory, Maylor predicted, people would be better at identifying the first and last verses but would do less well in arranging the order of verses two to five. This is exactly what she found. Even practised participants showed the serial positioning effect. Serial positioning occurs when people remember more of the end or the beginning of a list of items they are asked to remember. It suggests that items are better recalled from the beginnings and ends of lists because they are temporally distinctive: nearby items are more likely to be confused with each other than are items that are widely separated.

The primacy and recency effects are important because they demonstrate that memory is not a random process. Information is not just plucked from the environment and stored away randomly in the brain. Instead, the processing of information is much more orderly; it follows predictable patterns and is dependent on the contributions of rehearsal and short-term memory.

The limits of short-term and working memory

How long does information remain in short-term or working memory? The answer may lie in a classic study by Lloyd and Margaret Peterson (Peterson and Peterson, 1959). The experimenters presented participants with a stimulus composed of three consonants, such as JRG. With rehearsal, the participants easily recalled it 30 seconds later. The Petersons then made the task more challenging: they prevented participants from rehearsing. After they presented the participants with JRG, they asked them to count backwards by three from a three-digit number they gave them immediately after they had presented the set of consonants. For example, they might present participants with JRG, then say, ‘397’. The participants would count out loud, ‘397... 394... 391... 388... 385’, and so on until the experimenters signalled them to recall the consonants. The accuracy of recall was determined by the length of the interval between presentation of the consonants and when recall was requested (see Figure 8.7). When rehearsal was disrupted by backward counting – which prevented individuals from rehearsing information in

short-term memory – the consonants remained accessible in memory for only a few seconds. After a 15–18-second delay between the presentation of the consonants and the recall signal, recall dropped to near zero.

What, then, is the capacity of short-term memory? Miller (1956), in a famous article entitled ‘The magical number seven, plus or minus two’, demonstrated that people could retain, on average, seven pieces of information in their short-term memory: seven numbers, seven letters, seven words or seven tones of a particular pitch. If we can remember and think about only seven pieces of information at a time, how can we manage to write novels, design buildings or even carry on simple conversations? The answer comes in a particular form of encoding of information that Miller called chunking, a process by which information is simplified by rules which make it easily remembered once the rules are learned.

A simple demonstration illustrates this phenomenon. Read the ten numbers printed below and see whether you have any trouble remembering them.

1 3 5 7 9 2 4 6 8 0

These numbers are easy to retain in short-term memory because we can remember a rule instead of ten independent numbers. In this case, the rule concerns odd and even numbers. The actual limit of short-term memory is seven chunks, not necessarily seven individual items. Thus, the total amount of information we can store in short-term memory depends on the particular rules we use to organise it.

Figure 8.7 Limits of recall from working memory. Percentage correct recall of the stimulus as a function of the duration of the distractor task used in the study by Peterson and Peterson.

Source: Adapted from Peterson, L.M. and Peterson, J.M., Short-term retention of individual verbal items. *Journal of Experimental Psychology*, 1959, 58, 193–98.

In life outside the laboratory we are rarely required to remember a series of numbers. The rules that organise our short-term memories are much more complex than those that describe odd and even numbers. The principles of **chunking** can apply to more realistic learning situations. If we look at the following words:

along got the was door crept locked slowly he until
passage the he to which

and try to remember them, the task is difficult; there is too much information to store in short-term memory. If we repeat the process for the following group of words:

He slowly crept along the passage until he got to the
door, which was locked.

we would be much more successful. Once the same fifteen words are arranged in a sequence that makes sense, they are not difficult to store in short-term memory.

The capacity of short-term memory for verbal material is not measured by the number of letters, syllables or words it can retain but by how much meaning the information offers: this is working memory and long-term memory working together. The first set of words above merely contains fifteen different words. However, when the items are related, we can store many more of them. We do not have to string fifteen words together in a meaningless fashion but can let the image of a man creeping down a passage towards a locked door organise the new information.

Loss of information from short-term memory

The essence of short-term memory is its transience; hence, its name. Information enters from sensory memory and from long-term memory, is rehearsed, thought about, modified and then leaves. Some of the information controls ongoing behaviour and some of it causes changes in long-term memory, but ultimately, it is lost from short-term memory. What causes it to leave? The simplest possibility is that it decays, it fades away. Rehearsal allows us to refresh information indefinitely, thus preventing the decay from eliminating the information.

However, the most important cause appears to be displacement. Once short-term memory has reached its capacity, either additional information will have to be ignored or some information already in short-term memory will have to be displaced to make room for the new information.

One of the best examples of displacement of information in short-term memory comes from an experiment conducted by Waugh and Norman (1965). The people in this study heard lists of sixteen digits. The last digit, accompanied by a tone, was called the probe digit. When people heard it, they had to think back to the previous occurrence of the same digit and tell the experimenter the digit that followed that one.

Look at the sequence of numbers listed below. The last one, a 9, was accompanied by a tone, which told the person that it was the probe. If you examine the list, you will see that the earlier occurrence of a 9 was followed by a 4. Thus, the target, or correct, response was 4.

2 6 7 5 1 3 7 2 6 3 9 4 5 8 1 9

Notice that the 4 is separated from the second 9 by three numbers (5, 8 and 1). Waugh and Norman presented many different lists in which the location of the correct response varied. The distance between the target and the probe ranged from one to twelve items.

The study had two conditions. In one, the lists were presented rapidly, at four digits per second. In the other, they were presented slowly, at only one digit per second. The reason for this manipulation was to determine whether any effects they observed were caused by the mere passage of time rather than by displacement. They found that the more items that came between the target and the probe, the less likely it was that the target would be remembered. The critical variable seemed to be the number of items between the target and the probe, not the time that had elapsed (see Figure 8.8).

Figure 8.8 Displacement of information in short-term memory. The graph shows the percentage of correct responses as a function of intervening items presented at two different rates of time.

Source: Adapted from Waugh, N.C. and Norman, D.A., Primary memory. *Psychological Review*, 1965, 72, 89–104.

The results indicate that new information displaces old information in short-term memory. But at the longest delays (six or more intervening items), subjects performed more poorly when the items were presented slowly. Perhaps information in short-term memory does decay, but the effect is much less important than displacement.

Learning and encoding in long-term memory

What allows memory to move from short-term to long-term memory? Memory involves both active and passive processes. Sometimes, we use deliberate strategies to remember something (encode the information into long-term memory), for example, rehearsing the lines of a poem or memorising famous dates for a history exam. At other times, we simply observe and remember without any apparent effort, as when we tell a friend about an interesting experience we had. And memories can be formed even without our being aware of having learned something. What factors determine whether we can eventually remember an experience?

The consolidation hypothesis

The traditional view of memory is that it consists of a two-stage process (not counting sensory memory). Information enters short-term memory from the environment, where it is stored temporarily. If the material is rehearsed long enough, it is transferred into long-term memory. This transfer of information from short-term memory into long-term memory has been called consolidation (Hebb, 1949). Through rehearsal (for example, by means of the articulatory loop), the neural activity responding to sensory stimulation can be sustained; and if enough time passes, the activity causes structural changes in the brain. These structural changes are more or less permanent and solid (hence, the term ‘consolidation’), and are responsible for long-term memory.

The **consolidation** hypothesis makes several assertions about the learning process. It asserts that short-term memory and long-term memory are physiologically different, and few investigators doubt that information that has just been perceived is stored in the brain in a different way from information that was perceived some time ago. However, some other features of the original consolidation hypothesis have been challenged. First, the hypothesis asserts that all information gets into long-term memory only after passing through short-term memory. Secondly, it asserts that the most important factor determining whether a particular piece of information reaches long-term memory is the amount of time it spends in short-term memory.

Levels of processing

Craik and Lockhart (1972) have pointed out that the act of rehearsal may effectively keep information in short-term memory but does not necessarily result in the establishment of long-term memories. They suggested that people engage in two different types of rehearsal: maintenance rehearsal and elaborative rehearsal. **Maintenance rehearsal** is the rote repetition of verbal information – simply repeating an item over and over. This behaviour serves to maintain the information in short-term memory but does not necessarily result in lasting changes. In contrast, when people engage in elaborative rehearsal, they think about the information and relate it to what they already know. **Elaborative rehearsal** involves more than new information. It involves deeper processing: forming associations, attending to the meaning of the information, thinking about that information, and so on. Thus, we elaborate on new information by recollecting related information already in long-term memory. We are more likely to remember information for an examination by processing it deeply or meaningfully; simply rehearsing the material to be tested will not be effective.

Craik and Tulving (1975) gave participants a set of cards, each containing a printed sentence including a missing word, denoted by a blank line, such as ‘The _____ is torn’. After reading the sentence, the participants looked at a word flashed on a screen, then pressed a button as quickly as possible to signify whether the word fitted the sentence. In this example, ‘dress’ will fit, but ‘table’ will not. The sentences varied in complexity. Some were very simple:

She cooked the _____.

The _____ is torn.

Others were complex:

The great bird swooped down and carried off the struggling _____.

The old man hobbled across the room and picked up the valuable _____.

The sentences were written so that the same word could be used for either a simple or a complex sentence: ‘She cooked the chicken’ or ‘The great bird swooped down and carried off the struggling chicken’. All participants saw a particular word once, in either a simple or a complex sentence.

The experimenters made no mention of a memory test, so there was no reason for the participants to try to remember the words. However, after responding to the sentences, they were presented with them again and were asked to recall the words they had used. The experimenters found that the participants were twice as likely to remember a word if it had previously fitted into a sentence of medium or high complexity than if it had fitted

into a simple one. These results suggest that a memory is more effectively established if the item is presented in a rich context – one that is likely to make us think about the item and imagine an action taking place.

Craik and Lockhart (1972) suggested that memory is a by-product of perceptual analysis. A central processor, analogous to the central processing unit of a computer, can analyse sensory information on several different levels. They conceived of the levels as being hierarchically arranged, from shallow (superficial) to deep (complex). A person can control the level of analysis by paying attention to different features of the stimulus. If a person focuses on the superficial sensory characteristics of a stimulus, then these features will be stored in memory. If the person focuses on the meaning of a stimulus and the ways in which it relates to other things the person already knows, then these features will be stored in memory. For example, consider the word:

tree

This word is written in black type, the letters are lower case, the bottom of the stem of the letter ‘t’ curves upwards to the right, and so on. Craik and Lockhart referred to these characteristics as surface features and to the analysis of these features as shallow processing. Maintenance rehearsal is an example of **shallow processing**. In contrast, consider the meaning of the word ‘tree’. You can think about how trees differ from other plants, what varieties of trees you have seen, what kinds of foods and what kinds of wood they provide, and so on. These features refer to a word’s meaning and are called semantic features. Their analysis is called **deep processing**. Elaborative rehearsal is an example of deep processing. According to Craik and Lockhart, deep processing generally leads to better retention than does surface processing (see Figure 8.9). As you saw in Chapter 7, a deep approach to learning also improves a student’s performance.

Automatic versus effortful processing

Our retrieval of material from memory is enhanced by the extent to which we practise or rehearse information. Practising or rehearsing information, through either shallow or deep processing, is called **effortful processing**. As a student, you know that the more you concentrate on your studies, the more likely it becomes that you will do well in an exam. But your experience also tells you that you have stored information in memory that you had never rehearsed in the first place. Somehow, without any effort, information becomes encoded into your memory. This formation of memories of events and experiences with little or no attention or effort is called automatic processing.

Information that is automatically processed includes frequency (how many times have you read the word ‘encode’ today?), time (when did you experience your first kiss?), and place (where in the textbook is the figure of Sperling’s data located?). Automatic processing helps us to

Figure 8.9 Shallow versus deep processing. Mean number of words recalled after performing tasks that required analysis of surface features or analysis of semantic features.

Source: Based on Craik, F.I.M. and Lockhart, R.S., Levels of processing: A framework for memory research. *Journal of Verbal Behavior*, 1972, 11, 671–84.

learn things with relative ease, which makes life a lot less taxing than having continually to process information effortfully. Unfortunately, perhaps because of its complexity, most textbook learning is effortful, not automatic.

Encoding specificity

Encoding specificity refers to the principle that the way in which we encode information determines our ability to retrieve it later. For example, suppose that someone reads you a list of words that you are to recall later. The list contains the word ‘beet’, along with a number of terms related to music, such as ‘melody’, ‘tune’ and ‘jazz’. When asked if the list contained the names of any vegetables, you may report that it did not. Because of the musical context, you encoded ‘beet’ as ‘beat’ and never thought of the tuberous vegetable while you were rehearsing the list (Flexser and Tulving, 1978). Many experiments have made the point that meaningful elaboration during encoding is helpful and probably necessary for the formation of useful memories.

Mnemonics

When we can imagine information vividly and concretely, and when it fits into the context of what we already know, it is easy to remember later. **Mnemonic systems** (from the Greek

mnemon, meaning ‘mindful’) – special techniques or strategies consciously used to improve memory – make use of information already stored in long-term memory to make memorisation an easier task.

Mnemonic systems do not simplify information but make it more elaborate. More information is stored, not less. However, the additional information makes the material easier to recall. Mnemonic systems organise new information into a cohesive whole so that retrieval of part of the information ensures retrieval of the rest of it.

Method of loci

In Greece before the sixth century BC, few people knew how to write, and those who did had to use cumbersome clay tablets. Consequently, oratory skills and memory for long epic poems (running for several hours) were highly prized, and some people earned their livings by using them. Because people could not carry around several hundred pounds of clay tablets, they had to keep important information in their heads. To do so, the Greeks devised the **method of loci**, a mnemonic system in which items to be remembered are mentally associated with specific physical locations (*locus* means ‘place’ in Latin).

To use the method of loci, would-be memory artists had to memorise the inside of a building. In Greece, they would wander through public buildings, stopping to

study and memorise various locations and arranging them in order, usually starting with the door of the building. After memorising the locations, they could make the tour mentally, just as you could make a mental tour of your house to count the rooms. To learn a list of words, they would visualise each word in a particular location in the memorised building and picture the association as vividly as possible. For example, for the word ‘love’ they might imagine an embracing couple leaning against a particular column in a hall of the building. To recall the list, they would imagine each of the locations in sequence, ‘see’ each word, and say it. To store a speech, they would group the words into concepts and place a ‘note’ for each concept at a particular location in the sequence.

For example, if a person wanted to remember a short shopping list without writing it down and the list consists of five items: cheese, milk, eggs, soy sauce and lettuce, the person might first think of a familiar place, perhaps their house. Next, they would mentally walk through the house, visually placing different items from the list at locations – loci – in the house: a lump of cheese hanging from a coat rack, milk dripping from the kitchen tap, eggs lying in the hallway, a bottle of soy sauce on a dining chair, and a lettuce on the sofa (see Figure 8.10). Then, in the supermarket, the person mentally retraces his or her path through the house and notes what he or she has stored at the different loci.

Figure 8.10 The method of loci. Items to be remembered are visualised in specific, well-known places.

Figure 8.11 The peg-word method. Items to be remembered are associated with nouns that rhyme with numbers ('one' is a bun, etc.).

Peg-word method

A similar technique, the **peg-word method**, involves the association of items to be remembered with a set of mental pegs that are already stored in memory (Miller *et al.*, 1960). As with the method of loci, the goal involves visually associating the new with the familiar. One example is to take the numbers from one to ten and rhyme each number with a peg-word; for example, one is a bun, two is a shoe, three is a tree, four is a door, five is a hive, and so on. Returning to your grocery list, you might imagine the package of cheese in a hamburger bun, a shoe full of milk, eggs dangling from a tree, soy sauce on a door, and the lettuce on top of a bee hive (see Figure 8.11). In the supermarket, you review each peg word in order and recall the item associated with it. At first, this technique may seem silly, but there is ample research suggesting that it works (Marshark *et al.*, 1987).

Narrative stories

Another useful aid to memory is to place information into a **narrative**, in which items to be remembered are linked together by a story. Bower and Clark (1969) showed that even inexperienced people can use this method. The investigators asked people to try to learn twelve lists of ten concrete nouns each. They gave some of the people the following advice (p. 181):

A good way to learn the list of items is to make up a story relating the items to one another. Specifically, start with the first item and put it in a setting which will allow other items to be added to it. Then, add the other items to the story in the same order as the items appear. Make each story meaningful to yourself. Then, when you are asked to recall the items, you can simply go through your story and pull out the proper items in their correct order.

Here is a typical narrative, described by one of the subjects (list words are italicised):

A lumberjack darted out of the forest, *skated* around a *hedge* past a colony of *ducks*. He tripped on some *furniture*, tearing his *stocking* while hastening to the *pillow* where his *mistress* lay.

People in the control group were merely asked to learn the lists and were given the same amount of time as the people in the 'narrative' group to study them. Both groups could remember a particular list equally well immediately afterwards. However, when all the lists had been learned, recall of all 120 words was far superior in the group that had constructed narrative stories.

Cutting edge – Something to chew over

Of all the pressing issues psychologists could study, you wouldn't think that chewing gum was up there with mental illness, prejudice and the reduction of smoking. But some evidence suggests that chewing gum can improve memory, specifically, improvements in immediate and delayed word recall. Functional MRI evidence suggests increased blood flow when people chew gum and psychophysicologists report increased heart rate during the same.

But the picture is inconsistent. For each study showing positive effects of mastication, there is at least another showing no effect. Some researchers have even suggested that it is not the act of chewing that produces these supposed improvements, but the mint flavour released by the gum during mastication. The very immediate effect of chewing on cognitive performance – which may be due to an increase in

alertness/arousal – could be mediated by the perception of the peppermint/spearmint that is immediately released on chewing (and which dissipates the longer it is chewed).

To examine whether it is the flavour of the gum rather than the act of chewing which produces memory improvements, Johnson and Miles (2008) had participants either chew flavourless gum or taste mint-flavoured strips during the learning and recall of 15 nouns.

They found that chewing gum at encoding and retrieval or tasting mint strips during the same was no more likely to improve recall than conditions where no gum/strips were present at learning/recall or one was present at encoding/retrieval and the other was not.

Which suggests that this is another myth that is best spat out rather than digested.

Not all information can be easily converted to such a form, however. For example, if you were preparing to take an examination on the information in this chapter, figuring out how to encode it into lists would probably take you more time than studying and learning it by more traditional methods.

Long-term memory: episodic and semantic memory

Long-term memory contains more than exact records of sensory information that has been perceived. It also contains information that has been transformed – organised in terms of meaning. For example, the type of information that is personally meaningful to us (such as what we had for breakfast this morning or what we were doing last night) appears to be different from the type of information that is based on general knowledge (such as knowing the capitals of the world or the order in which Shakespeare wrote his plays). These two types of memory have been termed episodic and semantic memory, respectively, and the distinction was originally made by Tulving (1972). **Episodic memory** (or **autobiographical memory**) provides us with a record of our life experiences. Events stored there are autobiographical and there appears to be cross-cultural agreement on when such memories are acquired (even though cultures differ in terms of the type of memory encoded) (Conway *et al.*, 2005). **Semantic memory** consists of conceptual information such as general knowledge; it is a long-term store of data, facts and information. Our knowledge of what psychology is, the names of the authors of this book, the components of the human

sensory systems and how neuroimaging has helped localise the process of working memory should form part of your semantic memory. Semantic memories can, of course, interact with episodic ones.

The distinction between episodic and semantic memory reflects the fact that we make different uses of things we have learned: we describe things that happened to us, or talk about facts we have learned. Tulving (1983, 1984) revised his original views of the two systems, suggesting that episodic memory is a part of semantic memory, not a separate, independent system, so the debate is ongoing.

One way of determining a distinction between them would be to show that brain regions involved in one are not as involved in the other. Studies of brain injury have highlighted the involvement of the left prefrontal cortex in the retrieval of words in response to a cue (such as another word or a letter) and the temporal lobe in object naming and the retrieval of information about an object's characteristics (Martin and Chao, 2001). The processing of semantic information appears to involve a network of regions including the left prefrontal, parietal and posterior temporal cortex. When people are allowed to generate words to visually or auditorily presented cues, the posterior temporal cortex is activated regardless of whether the words are generated from the participants' native language or from their second language (Klein *et al.*, 1999; Tatsumi *et al.*, 1999).

Perhaps the most controversial data supporting the notion of semantic memory concerns stimulus specificity, the notion that one region of the brain is more involved than others in the perception or retrieval of certain categories of object. Well-known examples of this, as you saw in Chapter 6, are face recognition and the naming of inanimate and animate objects (Warrington, 1975; Warrington and Shallice, 1984; Warrington and

Autobiographical Memory – An international perspective

There seem to be real differences in the content of the autobiographical memories of people from different cultures. European Americans tend to recall their own roles in events and the feelings those events generated, whereas Asian Americans tend to recall details of social/group activities (Wang, 2004; Wang and Ross, 2005). One explanation for this is that American culture – at the most general level – is highly individualistic and emphasises and rewards autonomy and self-drive, whereas Asian cultures emphasise interdependence and the importance of social interaction/dependence.

To test this hypothesis, Wang (2008) asked Asian American to focus either on their American or their Asian background prior to recalling autobiographical memories. Those primed by the American condition recalled memories that were more self-focused and less social than were those whose Asian-ness had been primed. Participants who were not primed either way recalled the two types of content about equally.

McCarthy, 1987). Warrington's patients showed evidence of a dissociation between knowledge for living and non-living things. They were able to name non-living things but had considerable difficulty in naming living things, whether the stimuli to be named were verbal or non-verbal. In a later study, Warrington and Shallice (1984) interpreted their findings by suggesting that the two types of object-naming depended on different processing mechanisms. Living things would be processed primarily according to perceptual and visual features such as their size, colour, shape and so on, whereas non-living things would be processed according to their function.

Neuroimaging data have generally supported the proposition that certain brain regions are specifically activated by specific stimuli, but do not explain why. Pictures of tools have been found to generate more brain activity in the left posterior temporal cortex than do pictures of other objects and animals (Martin *et al.*, 1996; Chao *et al.*, 1999). An area of the brain called the fusiform gyrus, as you saw in Chapter 6, is activated during face recognition but is not as consistently or significantly activated by other types of stimuli. Other stimuli which selectively activate certain brain regions are buildings and houses (Epstein and Kanwisher, 1998).

Explicit and implicit memory

Another distinction is made between explicit and implicit memory. **Explicit memory** refers to memory for information we were aware of learning. A simple example would be our recollection of the 12 times table: this is a task that most of us were instructed to remember explicitly. Recognition and recall of material in explicit memory require active recollection of material that has been studied (McBride and Doshier, 1997). For example, we might ask participants to recall freely as many words as they can after being presented with a long list of them, or to indicate which stimuli from an array of visual stimuli were previously seen. Under these conditions, participants are explicitly instructed to recall or to recognise.

Implicit memory, however, does not appear to rely on conscious awareness. Instead, it is memory for information that is incidentally or unintentionally learned and which does not rely on the recognition or recall of any specific learning episode (Schacter, 1987; Cleermans, 1993). It is sometimes referred to as being synonymous with procedural memory, the memory for knowing how to do things (like riding a bike, operating a computer keyboard, or playing a musical instrument). There is some question, however, over whether implicit and procedural memory are truly synonymous. Procedural memory implies that some conscious effort has been made towards learning a skill such as riding a bike or playing a musical instrument; implicit memory would assume that skills were learned without such conscious effort, which seems highly unlikely. Also, there seems to be little procedural input to performing a stem-completion task (described below), which taps implicit memory. There continues to be debate about the number of memory systems, and whether these memory systems are separate or different forms of the same system.

The acquisition of specific behaviours and skills is probably the most important form of implicit memory. Driving a car, turning the pages of a book, playing a musical instrument, dancing, throwing and catching a ball, sliding a chair backwards as we get up from the dinner table – all these skills involve coordination of movements with sensory information received from the environment and from our own moving body parts. We do not need to be able to describe these activities in order to perform them. We may not be aware of all the movements involved while we are performing them. Implicit memory may have evolved earlier than explicit memory.

A good example of learning without awareness is provided by an experiment conducted by Graf and Mandler (1984). These investigators showed people a list of six-letter words and had some of them engage in a task that involved elaborative processing: they were to think about each word and to decide how much they liked it. Other people were given a task that involved processing superficial features: they were asked to look at the words and

decide whether they contained particular letters. Later, their explicit and implicit memories for the words were assessed. In both cases the basic task was the same, but the instructions to the subjects were different. People were shown the first three letters of each word. For example, if one of the words had been 'define', they would have been shown a card on which was printed 'def' (this is called a word-stem completion task). Several different six-letter words besides define begin with the letters 'def', such as 'deface', 'defame', 'defeat', 'defect', 'defend', 'defied' and 'deform', so there are several possible responses. The experimenters assessed explicit memory by asking people to try to remember the words they had seen previously, using the first three letters as a hint. They assessed implicit memory by asking the people to say the first word that came to mind that started with the three letters on the card.

Deliberate processing (shallow or deep processing) had a striking effect on the explicit memory task but not on the implicit memory task. When people used the three letters as cues for deliberate retrieval, they were much more successful if they had thought about whether they liked the word than if they simply paid attention to the occurrence of particular letters. However, when people simply said the first word that came to mind, the way they had studied the words had little effect on the number of correct words that 'popped into their heads' (see Figure 8.12).

There is some evidence, however, that the distinction between implicit and explicit memory may not be gen-

uinely dissociable. Buchner and Wippich (2000) suggest that these differences in test performance reflect nothing more than test demands. That is, that there are differences between measures of implicit and explicit memory (apart from the fact that they measure implicit and explicit memory) that produce these differences between groups. They note that whereas explicit measures are reliable, tests of implicit memory are relatively unreliable. The unreliability of implicit measures, therefore, may account for the lack of group differences that are reliably seen when explicit measures are used.

In one experiment, Buchner and Wippich required participants either (1) to recognise from a list of new and old words, words that had been previously seen, or (2) to complete word stems using words that had previously been seen. This last implicit task was used in a famous study of amnesics' memory and no differences were found between amnesics and controls. When the researchers analysed the reliability of these measures, the implicit measure was significantly less reliable than was the recognition measure. The study raises important questions about experiments which claim to show differences in memory performance based on implicit measures: it suggests that such differences may be due to methodological, rather than conceptual, reasons.

However, another study adopting a different method provides a different view. It puts forward the possibility that tests of explicit and implicit memory are dissociable because explicit tasks involve conceptual processing whereas implicit tasks involve perceptual processing. If both types of test are made conceptual, people may perform no differently on them (Brooks *et al.*, 2001).

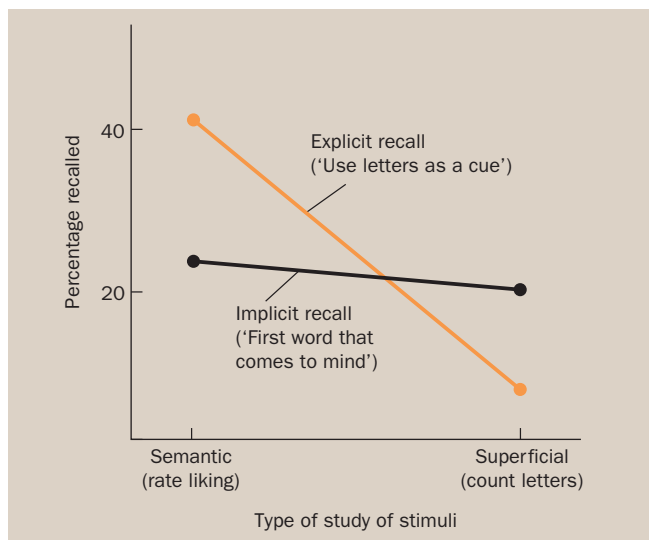

Figure 8.12 Explicit versus implicit memory. The graph shows the percentage of words recalled as a function of the type of study procedure. Deliberate processing improved performance of the explicit memory task but had little effect on the implicit memory task.

Source: Based on data from Graf, P. and Mandler, G., Activation makes words more accessible, but not necessarily more retrievable. *Journal of Verbal Learning and Verbal Behavior*, 1984, 23, 553–68.

Remembering

Remembering is an automatic process. The word 'automatic' means 'acting by itself'. But this definition implies that no special effort is involved. What is automatic is the retrieval of information from memory in response to the appropriate stimulus. What sometimes requires effort is the attempt to come up with the thoughts (the internal stimuli) that cause the information to be retrieved. In psychology experiments, retrieval can be measured in two basic ways: participants either recall material they have learned unprompted (free recall) or they are asked to identify material they had previously seen; this material is presented amongst stimuli that had not been seen (this is called a recognition memory paradigm).

The retrieval of implicit memories is automatic: when the appropriate stimulus occurs, it automatically evokes the appropriate response. Explicit memories can be retrieved automatically. Whisper your name to yourself. How did you manage to remember what your name is? How did

you retrieve the information needed to move your lips in the proper sequence? Those questions cannot be answered by introspection. The information just leaps out at us when the proper question is asked (or, more generally, when the appropriate stimulus is encountered).

Reading provides a particularly compelling example of the automatic nature of memory retrieval. When an experienced reader looks at a familiar word, the name of the word occurs immediately, and so does the meaning. In fact, it is difficult to look at a word and not think of its name. Figure 8.13 contains a list of words that can be used to demonstrate a phenomenon known as the Stroop effect (Stroop, 1935; MacLeod, 1992). Look at the words in Figure 8.13 and, as quickly as you can, say the names of the colours in which the words are printed; do not read the words themselves.

Most people cannot completely ignore the words and simply name the colours; the tendency to think of the words and pronounce them is difficult to resist. The **Stroop effect** indicates that even when we try to suppress a well-practised memory, it tends to be retrieved automatically when the appropriate stimulus occurs.

But what about the fact that some memories seem to be difficult to recall? For most people, remembering information is effortless and smooth. It is something we do unconsciously and automatically – most of the time. Occasionally, though, our memory of a name or a place or something else fails. The experience is often frustrating because we know that the information is ‘in there somewhere’ but we just cannot seem to get it out. This is known as the **tip-of-the-tongue phenomenon** (you encountered the olfactory analogue, the tip-of-the-nose phenomenon, in Chapter 5). It was first studied carefully during the 1960s (Brown and McNeill, 1966), and since then we have learned a great deal about it (Jones, 1989; A.S. Brown, 1991). It is a common, if not universal, experience; it can occur about once a week and increases with age; it often involves proper names and knowing the first letter of the word; and is solved during the experience about 50 per cent of the time.

The active search for stimuli that will evoke the appropriate memory, as exemplified in the tip-of-the-tongue phenomenon, has been called **recollection** (Baddeley, 1982). Recollection may be aided by contextual variables, including

Figure 8.13 The Stroop effect. Name the colour in which the words are printed as quickly as you can; you will find it difficult to ignore what the words say.

physical objects, suggestions, or other verbal stimuli. These contextual variables are called **retrieval cues**. The usefulness of these retrieval cues often depends on encoding specificity.

Remember from the previous section that the encoding specificity principle states that information can only be retained if it has been stored and the way in which it is retrieved depends on how it was stored. One famous example is that of encoding and retrieving material above and under water. Godden and Baddeley (1975) asked skilled scuba divers to learn lists of words either under water or on land. The divers’ ability to recall the lists was later tested in either the same or a different environment. The variable of interest was where subjects learned the list: in or out of the water. When lists were learned under water, they were recalled much better under water than on land, and lists learned on land were recalled better on land than in the water. The context in which information is learned or processed, therefore, influences our ability to recollect that information.

Psychology in action – Using odour to retrieve memories

One of the most celebrated examples of the use of odour as a memory prompt is that of Marcel Proust. In *À la recherche du temps perdu*, he recounts how the experience of dipping a cake into tea provoked a long autobiographical reverie

because the memorable aroma percolating from the tea-soaked madeleine transported him back to his childhood. But, literary licence aside, is there sound evidence for the ability of odour to provoke genuine autobiographical memories?

Psychology in action – Continued

The evidence for the beneficial effects of odour on behaviour is mixed: some studies show strong positive effects, others show no effect of odour while still others show that exposure to pleasant scents can impair performance. Of the positive studies, exposure to a pleasant odour has been found to increase charitable behaviour (Baron, 1997), facilitate anagram formation (Baron and Thomley, 1994), create more favourable impressions of a casually dressed female job candidate but a less favourable one of a formally dressed candidate (Baron, 1983), enhance recall of verbal material when odour is presented at encoding and recall (Herz, 1997), generate more emotional memories than can words or sights (Herz and Cupchik, 1992), increase genital arousal in women exposed to male cologne during a specific stage of the menstrual cycle (Graham *et al.*, 2000), increase brain electrical activity associated with relaxation or lack of attention (Martin, 1998), and reduce anxiety in women waiting for dental surgery (Lehrner *et al.*, 2000). Exposure to a pleasant, relaxing odour can also impair vigilance (Gould and Martin, 2001) and mental arithmetic performance (Ludvigson and Rottman, 1989) and worsen pain perception (Martin, 2006) but can leave some tasks unaffected (Knasko, 1992).

In the field of memory, however, accurate recall of memories of events experienced years previously has been found when the odours present at those events are re-presented some time later (Aggleton and Waskett, 1999; Chu and

Downes, 2000), illustrating a form of state-dependent learning. Cann and Ross (1989) reported that the presence of a pleasant perfume at the presentation of a series of photographic slides led to better recognition if it was also presented at recall. Schab (1990) found that participants who learned and recalled in the presence of an ambient chocolate odour recalled more antonyms than did a control group or a group presented with an odour at encoding but not retrieval. In a subsequent experiment, odour-related words were no better recalled than neutral words although there was benefit to having the same odour present at encoding and recall. But the recall of memories may depend on the emotional nature of the odour. People report more unhappy memories in the presence of an unpleasant odour, for example, than they do in a pleasant one, and happier memories in the presence of a pleasant odour (Ehrlichman and Halpern, 1988).

In a real-life study, Aggleton and Waskett (1999) asked participants to recall memories of their visit to the Viking Museum in York, England, during exposure to no odour or to odours that accompanied the exhibits at the museum. Participants who recalled memories in the presence of the odours they had previously been exposed to, remembered significantly more about the exhibits and about their visit than did those participants who received no such olfactory cues. This seems to confirm what Proust described at the beginning of the last century: odour may be an effective retrieval cue.

Reconstruction: remembering as a creative process

Much of what we recall from long-term memory may not be an accurate representation of what actually happened previously. One view of memory is that it is a plausible account of what might have happened or even of what we think should have happened. An early experiment by Bartlett (1932) drew attention to this possibility. This was Bartlett's view (p. 213):

Remembering is not the reexcitation of innumerable fixed, lifeless and fragmentary traces. It is an imaginative reconstruction, or construction, built out of the relation of our attitude towards a whole active mass of organised past reactions or experience and to a little outstanding detail which commonly appears in image or in language form. It is thus hardly ever really exact, even in the most rudimentary cases of rote recapitulation, and it is not at all important that it should be so.

Bartlett had people read a story or essay or look at a picture. Then he asked them on several later occasions to retell the prose passage or to draw the picture. Each time, the people 'remembered' the original a little differently. If the original story had contained peculiar and unexpected sequences of events, people tended to retell it in a more coherent and sensible fashion, as if their memories had been revised to make the information accord more closely with their own conceptions of reality. Bartlett concluded that people remember only a few striking details of an experience and that during recall they reconstruct the missing portions in accordance with their own expectations.

Many studies have confirmed Bartlett's conclusions and have extended his findings to related phenomena. Spiro (1977, 1980) found that people will remember even a rather simple story in different ways, according to their own conceptions of reality. Two groups of people read a story about an engaged couple in which the man was opposed to having children. In one version, the woman was upset when she learned his opinion because she wanted to have children. In the other version, the woman also did not want to have children. After reading the story,

people were asked to fill out some forms. While collecting the forms, the experimenter either said nothing more about the story or ‘casually mentioned’ that the story was actually a true one and added one of two different endings: the couple got married and have been happy ever since, or the couple broke up and never saw each other again.

Two days, three weeks or six weeks later, the participants were asked to recall the story they had read. If at least three weeks had elapsed, people who had heard an ending that contradicted the story tended to ‘remember’ information that resolved the conflict. For example, if they had read that the woman was upset to learn that the man did not want children but were later told that the couple was happily married, people were likely to ‘recall’ something that would have resolved the conflict, such as that the couple had decided to adopt a child rather than have one of their own. If people had read that the woman also did not want children but were later told that the couple broke up, then they were likely to ‘remember’ that there was a difficulty with one set of parents. In contrast, people who had heard an ending that was consistent with the story they had read did not remember any extra facts; they did not need them to make sense of the story. For example, if they had heard that the couple disagreed about having a child and later broke up, no new ‘facts’ had to be added.

People were most confident about details that had actually not occurred but had been added to make more sense of the story. Thus, a person’s confidence in the accuracy of a particular memory is not necessarily a good indication of whether the event actually occurred.

However, some researchers have criticised Bartlett’s findings and some have even argued that Bartlett himself drew conclusions that were not warranted (Ost and

Costall, 2002). Edwards and Middleton (1987), for example, have argued that the studies reported by Bartlett, – these studies reported a form of memory called serial reproduction – did not assess the normal, everyday process of remembering. For example, participants in Bartlett’s experiments wrote down alone what they could remember of a story read to them (rather than being retold to them, as you might expect in most everyday contexts). Others, such as Roediger *et al.* (2000), have argued that the material to be remembered was not particularly ecologically valid. One of the stories to be recalled, *The War of the Ghosts*, was quite exotic and unusual and not like everyday prose (Wynn and Logie, 1998; Roediger *et al.*, (2000), which made connections between parts of the story difficult to form. Bartlett did use more familiar material and found that participants made the typical reconstruction of the story. Bartlett’s story is reproduced in Table 8.1, together with two recalled versions. Note the differences, and types of differences, between the actual story and the remembered one.

In an experiment in which the material to be remembered was relevant, Wynn and Logie (1998) quizzed undergraduates at two-month intervals about an incident at the beginning of the academic year and asked them to recall memories from that time. They found that memories were very resistant to change over time. However, although the study found that some distinctive memories could be accurately recalled, recent research suggests that memories can be very manipulable to the extent that false information introduced at recall can lead to this false information being incorporated into memory. The context in which memory and acquisition takes place can also influence our recall of events, as the next section shows.

Table 8.1 Three examples of *The War of the Ghosts* story. The first (a) is the original story; the second (b) is a version by a participant after 20 hours’ delay; the third (c) is the same person’s version of the story after eight days

(a) *The War of the Ghosts*

One night two young men from Egulac went down to the river to hunt seals, and while they were there it became foggy and calm. Then they heard war-cries, and they thought: ‘Maybe this is a war-party.’ They escaped to the shore, and hid behind a log. Now canoes came up, and they heard the noise of paddles, and saw one canoe coming up to them. There were five men in the canoe, and they said: ‘What do you think? We wish to take you along. We are going up the river to make war on the people.’

One of the young men said: ‘I have no arrows.’

‘Arrows are in the canoe,’ they said.

‘I will not go along. I might be killed. My relatives do not know where I have gone. But you,’ he said, turning to the other, ‘may go with them.’

So one of the young men went, but the other returned home.

And the warriors went on up the river to a town on the other side of Kalama. The people came down to the water, and they began to fight, and many were killed. But presently the young man heard one of the warriors say: ‘Quick, let us go home: that Indian has been hit.’ Now he thought: ‘Oh, they are ghosts.’ He did not feel sick, but they said he had been shot.

So the canoes went back to Egulac, and the young man went ashore to his house, and made a fire. And he told everybody and said: ‘Behold I accompanied the ghosts, and we went to fight. Many of our fellows were killed, and many of those who attacked us were killed. They said I was hit, and I did not feel sick.’

He told it all, and then he became quiet. When the sun rose he fell down. Something black came out of this mouth. His face became contorted. The people jumped up and cried.

He was dead.

Table 8.1 Continued

- (b) *The War of the Ghosts*
Two men from Egulac went fishing. While thus occupied by the river they heard a noise in the distance. 'It sounds like a cry,' said one, and presently there appeared some men in canoes who invited them to join the party on their adventure. One of the young men refused to go, on the ground of family ties, but the other offered to go. 'But there are no arrows,' he said. 'The arrows are in the boat,' was the reply. He thereupon took his place, while his friend returned home. The party paddled up the river to Kaloma, and began to land on the banks of the river. The enemy came rushing upon them, and some sharp fighting ensued. Presently someone was injured, and the cry was raised that the enemy were ghosts. The party returned down the stream, and the young man arrived home feeling none the worse for his experience. The next morning at dawn he endeavoured to recount his adventures. While he was talking something black issued from his mouth. Suddenly he uttered a cry and fell down. His friends gathered round him. But he was dead.
- (c) *The War of the Ghosts*
Two young men from Egulac went fishing. While thus engaged they heard a noise in the distance. 'That sounds like a war-cry,' said one, 'there is going to be some fighting.' Presently there appeared some warriors who invited them to join an expedition up the river. One of the young men excused himself on the ground of family ties. 'I cannot come,' he said, 'as I might get killed.' So he returned home. The other man, however, joined the party, and they proceeded on canoes up the river. While landing on the banks the enemy appeared and were running down to meet them. Soon someone was wounded, and the party discovered that they were fighting against ghosts. The young man and his companion returned to the boats, and went back to their homes. The next morning at dawn he was describing his adventures to his friends, who had gathered round him. Suddenly something black issued from his mouth, and he fell down uttering a cry. His friends closed around him, but found that he was dead.

Psychology in action – How long does memory last?

In 1885, Hermann Ebbinghaus reported the results of the first experiment to determine the duration of memory. Using himself as a participant, Ebbinghaus memorised 13 nonsense syllables such as 'dax', 'wuj', 'lep' and 'pib'. He then studied how long it took him to relearn the original list after intervals varying from a few minutes up to 31 days. Figure 8.14 shows what he found. Much of what he learned was forgotten very quickly – usually within a day or two. But even after 31 days, he could still recall some of the original information.

Ebbinghaus's research dealt with remembering nonsense syllables and began a fruitful line of enquiry for psychologists interested in the length of time we can reasonably retain information before we begin to forget. For example, for how long might you remember the important experiences of your childhood? Or the information in this book? Or a well-known public event?

Schmolck *et al.* (2000) looked at the effect of **retention interval** – the period between encoding and retrieval – on memory for the O.J. Simpson trial verdict, announced on 3 October 1995. College students were asked about how they heard the news about the verdict three days after the result, 15 months later and 32 months later. There was a significant difference between recall at 15 and at 32 months. After 15 months, about 50 per cent of recollections were accurate and only 11 per cent

Figure 8.14 Ebbinghaus's (1885) forgetting curve.

contained major errors; at 32 months, only 29 per cent of the recollections were accurate and 40 per cent contained major distortions. Figure 8.15 shows you how memory became distorted in these participants over time. There may be some value

Psychology in action – Continued

Figure 8.15 The degree of memory distortion (none, minor and major) for the O.J. Simpson trial verdict seen in Schmolck *et al.*'s study after 15 and 32 months.

Source: Schmolck, H., Buffalo, E.A. and Squire L.R., Memory distortions develop over time: Recollections of the O.J. Simpson trial verdict after 15 and 32 months. *Psychological Science*, 2000, 11(1), 39–45, reprinted by permission of Blackwell Publishers Ltd.

to this. There is neuroimaging evidence to suggest that the process of forgetting frees up regions of the brain: the forgetting of material that competes with more important information that we need to remember is associated with a decline in the activation of the prefrontal cortex, for example (Kuhl *et al.*, 2007).

In a well-known study, Bahrick *et al.* (1975) investigated how much information about their classmates (such as faces or names) graduates would remember 25 years after graduation. Bahrick found that the ability to recall classmates' names and to generate a name from a photo declined over time. The longer the retention interval (RI), the greater the decline. Recognition of faces and names and the matching of names to faces, however, was fairly robust. Ninety per cent of responses were correct over the first 15 years (although accuracy, again, declined when the RI became longer). Bahrick (1984) also reported that retention for Spanish learned at school declined in the first six years after graduating, stabilised for the next 35 years and then declined thereafter (see Figure 8.16).

Bahrick argued that the period of stability from 6 to 35 years represents a 'permastore'; this was a store of knowledge that was resistant to forgetting and which must have been learned deeply. An alternative interpretation, however, was suggested by Neisser (1984). He suggested that individuals have a schematic representation of a 'knowledge domain', that is, specific knowledge is not stored in a permanent way, but ways of representing that knowledge allow the retrieval of information. On the basis of this view, conceptual knowledge should be better retained (and retrieved) than would, say, straightforward facts.

Figure 8.16 The forgetting curve for Spanish vocabulary.

Source: Adapted from Bahrick, H.P., Semantic memory content in permastore: Fifty years of Spanish learned in school. *Journal of Experimental Psychology: General*, 1984, 113, 1–29.

Conway and co-workers (Conway *et al.*, 1991; Cohen *et al.*, 1992), measured students' retention of knowledge of cognitive psychology over twelve years (between 1978 and 1989) and found that memory declined in the first 36 months, then stabilised. However, the recall and recognition of proper names declined more rapidly than did memory for concepts. Why? If you accept Neisser's position, conceptual information should be better retained because memory is organised in such a way as to facilitate the retention of this type of information. Cohen (1990) further suggested that proper names lacked the semantic depth necessary for encoding concepts. Proper names did not need to be represented in abstract form and do not fall within a scheme of knowledge. In a follow-up study, Conway *et al.* (1992) found that coursework was a better predictor of retention than was exam performance because the learning for the former was distributed across the term whereas learning for the exam was, arguably, massed (being crammed).

In a separate study of how much first-year students thought they knew, guessed or remembered answers on a multiple choice examination on a range of psychology lecture courses, Conway *et al.* (1997) found the better students seemed to 'remember' more of the answers. For research methods courses, the same students 'knew' more, indicating that a **remember-to-know shift (R–K shift)** had occurred. Why, then, did better students not 'know' more after their lecture courses? One reason may be that the lecture courses contained more topics and that there was, therefore, greater variability in the types of knowledge domain to be learned

Psychology in action – Continued

(Conway *et al.*, 1997). Also, the research methods courses involved a large degree of repetition (as research methods courses do) and problem-solving is integral to the course: these factors might promote the R–K shift.

People's memory for their grades also declines with time (Baird *et al.*, 2008). One to 54 years after graduating, 276 participants were able to recall 3,025 of 3,967 grades. The better students made fewer errors. Of those who recalled their marks incorrectly, 81 per cent inflated the grade.

So, what can we conclude about long-term retention of knowledge? Non-schematic knowledge (such as the names of psychologists) declines more greatly than schematic knowledge (such as conceptual information). Better students also remember more of non-research methods psychology lecture courses and know more from research methods courses as well as recall grades more accurately. One reason for this is that there is a shift from remembering to knowing, from episodic to semantic memory.

The malleability of memory

An experiment takes place in which participants are asked to read short passages of text and then, one day later in a telephone conversation, are asked questions about the content of the text and the context in which the reading occurred. Six weeks later, they are asked the same questions and also whether they remembered answers given in their telephone conversation. This experiment by Loftus and her colleagues (see Joslyn *et al.*, 2001) found that while participants were remarkably good at remembering the correct answers they gave, they were significantly poor at remembering the questions they answered incorrectly. Perhaps the correct answers generated a positive mood or represented a more coherent memory.

This is one of several studies that indicate that our subjective beliefs about the context of content of memory can influence the recall of events. Research from social psychology and cognitive psychology shows how we can be misled into saying things or doing things we believe to be incorrect or which we are not sure about. The studies of Solomon Asch (described in Chapter 15) and Elizabeth Loftus (described below) show how malleable human behaviour can be, especially when we are faced with the pressure to conform.

Roediger *et al.* (2001) investigated whether conformity was simply a 'public' behaviour where a person wants to be seen to behave correctly and yet knows that their response is wrong, or a 'private' one, where the conversion in their belief is genuine. Studies of social psychology have shown that conformity is greater when participants make decisions in the company of others than when alone. Would the presence of another person who falsely claimed that an object had been in a room lead a participant also to claim that they remembered seeing an object in a room when no such object was present?

In one condition, a participant and a confederate watched slides of six household scenes featuring common household objects for either 15 or 60 seconds. In a collaborative recall task in which both individuals tried to recall as many objects in the scenes as they could, the

confederate made occasional mistakes such as recalling items that were not in the slides. Some of these items were consistent with some of the items in the scene and other were not. After a short delay, the participant was asked to recall as many items from the scenes as they could. In a second condition, a similar experiment was carried out but no erroneous suggestions were made.

Participants in the company of those confederates who recalled objects that were not in the scenes recalled significantly more erroneous objects than did those in the control condition. This effect was magnified if people were exposed to the scenes for 15 seconds (presumably, reflecting the fact that such a short period leaves little time to monitor the scene and leads you to believe that there were objects presented that were not actually there). Participants who recalled these erroneous items were also more likely to report that they 'knew' the objects were in the scene rather than report they remembered seeing them.

Why were the participants influenced in this way? The authors interpret the results in terms of Johnson's source monitoring framework (Johnson *et al.*, 1993). This argues that because we receive information from many sources, we can recall this material but misattribute it to earlier events. The collaborative recall part of the experiment may be an example of an early event acting as a source of memory interference where more recent memories interfere with current retrieval. The more consistent the confederates' recall is with that of the event or scene, the stronger the social contagion will be; the more distinctive the recall, the less likely social contagion is to occur.

This susceptibility has significant consequences for important areas of life, especially those which can have serious repercussions, such as eyewitness testimony.

Eyewitness testimony

On 4 October 1992, an El Al plane lost its engine after take-off from Amsterdam Schiphol Airport. It returned to the airport but lost height and crashed into an 11-storey apartment building. Ten months

later, Crombag *et al.* (1996) questioned 193 individuals about the crash. The event was widely reported in the news but was not actually filmed. When individuals were asked if they saw the plane hit the building, 55 per cent said that they had (they had not been present at the time of the accident); 59 per cent said that the fire started immediately on impact. In a follow-up study, 68 per cent said they had seen the crash and 67 per cent of participants said that they saw the plane hit the building horizontally (in fact, it hit the building vertically).

This experiment and those of Loftus and her colleagues (Loftus, 1997) suggest that our recollections of events may not be infallible. Loftus, for example, has reported that the kinds of questions used to elicit information after an event has been experienced can have a

major effect on what people remember. Loftus's research shows that even subtle changes in a question can affect people's recollections. For example, Loftus and Palmer (1974) showed people films of car accidents and asked them to estimate vehicles' speeds when they 'contacted/ hit/bumped/collided/smashed' each other. People's estimates of the vehicles' speeds were directly related to the force of the impact suggested by the verb, such as 'hit', that appeared in the question (see Figure 8.17). That is, the more expressive and dramatic the verb, the greater the estimated speed. In a similar experiment, people were asked a week after viewing the film whether they saw any broken glass at the scene (there was none). People in the 'smashed' group were most likely to say yes. Thus, a leading question that encouraged them to remember the vehicles going faster also encouraged them to remember that they saw non-existent broken glass. The question appears to have modified the memory itself.

Even very subtle leading questions can affect people's recollections. Loftus and Zanni (1975) showed people short films of an accident involving several vehicles. Some people were asked, 'Did you see a broken headlight?'; others were asked, 'Did you see the broken headlight?' The particular question biased the people's responses: although the film did not show a broken headlight, twice as many people who heard the article 'the' said that they remembered seeing one.

These are not the only examples of the ways in which memories can be altered. Individuals can be misled into thinking that a 'stop' sign was a 'give way' sign (Loftus *et al.*, 1978) and that a bare-handed thief wore gloves (Zaragoza and Mitchell, 1996). This misinformation effect is much stronger in older people (Jacoby *et al.*, 2005).

Experiments such as these have important implications for eyewitness testimony in courts of law. Wells and Seelau (1995) illustrate this point with the following examples:

Figure 8.17 Leading questions and recall. Mean estimated speed of vehicles as recalled by people in the study of Loftus and Palmer (1974).

Source: Based on data from Loftus, E.F. and Palmer, J.C., Reconstruction of automobile destruction: An example of the interaction between language and memory. *Journal of Verbal Learning and Verbal Behavior*, 1974, 13, 585–89.

In 1984, Frederick Rene Dange was identified from a set of photographs and served 10 years in a Californian prison for rape, kidnapping, robbery and murder he did not commit. Dange was released in 1994 after a DNA test proved his innocence. In 1980, James Newsome was convicted of murder on the basis of eyewitness evidence. Fifteen years later, he was released after his fingerprints were submitted to new computer technology that implicated someone else as the murderer.

In a review of 205 cases of wrongful arrest, Rattner (1988) found that 52 per cent of these cases were associated with mistaken eyewitness testimony. In 1996, the National Institute of Justice found that 28 people had been wrongfully convicted based on eyewitness testimony (DNA evidence had exonerated the accused). Consequently, in 1998, the American Psychological Association issued a new series of rules and procedures designed to reduce errors made in considering eyewitness identification (Wells *et al.*, 1998).

Eyewitness identification

In a famous, historical case, *Frye v. The United States* (1923), the court ruled that scientific evidence was admissible only if it was generally accepted by the relevant scientific community. The judgment in a case called *Daubert v. Merrell Dow Pharmaceuticals, Inc.* 70 years later, however, ruled that judges would be the gatekeepers of scientific reliability in the US – they would judge the rel-

evance, validity and reliability of scientific evidence. This makes the quality of evidence very important. Laypeople regard eyewitness reports, crime scene reports and police procedures as important contributions to their evaluation of testimony (Shaw *et al.*, 1999). They also regard the eyewitness's vision, knowledge of the suspect and emotional state during the crime as well as lighting at the crime scene and the time of day as being the factors which most frequently influence the accuracy of testimony. Do these lay views correspond to the views of professional psychologists who have studied these processes? And how much agreement is there between psychologists?

According to one study (Kassin *et al.*, 2001) experts in eyewitness identification agreed on the following:

- 98 per cent thought that testimony could be influenced by the way in which questions are worded
- 98 per cent thought that police line-up instructions could affect identification.
- 92 per cent agreed that the eyewitness's attitudes and expectations about the event could influence testimony.
- 87 per cent thought that eyewitnesses' confidence in their judgement is poorly correlated with the accuracy of the testimony.
- 83 per cent thought that memory loss is greatest immediately after witnessing the event.
- 81 per cent thought that the less time an eyewitness has to observe an event, the less well it will be remembered.
- 45 per cent thought that hypnosis improved testimony accuracy.
- 80 per cent thought that eyewitness confidence is malleable and influenced by factors unrelated to accuracy, that exposure to a mugshot increases the likelihood of the face in the mugshot being selected from a later line-up, that children are more susceptible than adults to leading questions, and that eyewitnesses are better at recognising perpetrators of their own race.

According to forensic psychologists Gary Wells and Amy Bradfield (1999), 'There is increasing evidence that mistaken eyewitness identifications from line-ups and photospreads are the most frequent cause of juries convicting innocent persons.' They examined how information given to a witness before and after making a line-up identification affected the witness's confidence in making the correct identification. Giving positive post-identification feedback (such as telling the witness they identified the right suspect when they had not) inflates confidence in their identification, but also makes them think that their view of the suspect was better, that they identified the suspect more quickly and that they paid more attention when they witnessed the suspect.

What do these famous lines have in common? 'Beam me up, Scotty', 'Me Tarzan, you Jane', 'You dirty rat', 'Play it again, Sam', 'Elementary, my dear Watson'? Their fame, yes. But none of these lines was actually said. This highlights how our memory can be very malleable.

Source: Paramount Television/The Kobal Collection.

In a twist to this type of experiment, Wells and Bradfield asked witnesses to think privately about how certain they were about their identification, how good their view was, how long they took to identify the suspect before being given false positive feedback. Another group of participants was given these instructions after receiving feedback and another was not instructed to think about its decision. In each case, the eyewitness had identified the wrong suspect.

The researchers found that when eyewitnesses were instructed to think about the decision prior to feedback, they were relatively unaffected by the false positive feedback. Those who were not instructed to think about their decision or were instructed to think after being given feedback, showed a significant inflation in their confidence which also extended to other aspects of their testimony.

'The solution to preventing feedback,' say Wells and Bradfield, 'is apparent from the argument that a properly conducted line-up is like a properly conducted experiment.' They suggest that the person with whom the witness communicates the decision about line-up identification should be unaware of who the suspect is and that confidence measures should be taken prior to the witness being told whether the suspect had been correctly identified. If not, false identification will be confounded by a false sense of inflated confidence.

Cutting edge – Unbelievable accents

Can your accent affect your plausibility as an eyewitness? We make assumptions about people based on little psychological information – from the way they look and dress to their voice and accent. A study from the US has found that eyewitnesses who used an accent (German, Mexican and Lebanese) were judged to be significantly less credible, accurate and prestigious and more deceptive than an American accent by

US-born participants (Frumkin, 2007). The Lebanese accent was rated least favourably.

The study suggests that testimony delivered by a non-native speaker may be interpreted negatively by native speakers. The finding should make prosecutors and defence lawyers aware that seemingly trivial factors – such as a person's accent – can have serious effects on their plausibility.

The experiments reviewed in this section indicate that learning new information and recalling it later are active processes – information is not placed in a mental filing cabinet and picked up later. We organise and integrate information in terms of what we already know about life and have come to expect about particular experiences. Thus, when we recall the memory later, it may contain information that was not part of the original experience.

At first, this phenomenon may appear to be maladaptive because it means that eyewitness testimony cannot be regarded as infallible, even when a witness is trying to be truthful. However, it probably reflects the fact that information about an episode can be more efficiently stored by means of a few unique details. The portions of an episode that are common to other experiences, and hence resemble information already stored in long-term memory, need not be retained. If every detail of every experience had to be encoded uniquely in long-term memory, perhaps we would run out of storage space. Unfortunately, this process sometimes leads to instances of faulty remembering.

Interference

Although long-term memory is durable, it may also be susceptible to interference. The finding that some memories may interfere with the retrieval of others is well established. An early study by Jenkins and Dallenbach (1924) showed that people are less likely to remember information after an interval of wakefulness than after an interval of sleep, presumably because of new memories that are formed when one is awake (see Figure 8.18).

Subsequent research soon showed that there are two types of interference in retrieval. Sometimes we experience **retroactive interference**: when we try to retrieve information, other information, which we have learned more recently, interferes. You may have a hard time recalling your old telephone number because a new one has replaced it. When memories that interfere with retrieval are formed after the learning that is being tested, we experience retroactive interference.

At other times, retrieval is impaired by **proactive interference**, in which our ability to recall new information is reduced because of information we learned previously. Figure 8.19 illustrates the experimental procedure used to examine the effects of proactive interference.

In this procedure, the experimental group learns the words in both list A and list B. The control group learns only the words in list B. Both groups then experience a retention interval before they are asked to recall the words in list B. If the experimental group recalls fewer words in list B during the test than does the control group, proactive interference is said to have occurred.

As reasonable and intuitive as the principle of interference may be, it has not gone unchallenged. Researchers agree that interference can affect retrieval, but some argue that the kinds of recall task people are asked to perform in the laboratory are most likely to be affected by interference. In real life, such effects may not be so powerful. For

Figure 8.18 Interference in memory retrieval. The mean number of nonsense syllables recalled after sleeping or staying awake for varying intervals of time.

example, meaningful prose, such as the kind found in novels, is resistant to interference. That said, however, a recent study demonstrated that when participants watched either a violent, sexually explicit or neutral television show featuring nine adverts, recall of the advertisements immediately after the exposure and 24 hours later was poorer in the violent and sexual television conditions (Bushman and Bonacci, 2002). The effect was robust whether the television programme was liked or disliked and whether the participant was male or female. It seems as if some stimuli are powerful or exciting enough to interfere with our memory, even outside the laboratory.

State-dependent memory: the effect of mood on recall

Research suggests that recall of memory is better when people’s moods or emotional states match their emotional states when they originally learned the material. This phenomenon is called **state-dependent memory**. The experimental procedure used in tests of state-dependent memory usually requires the manipulation of a person’s mood by hypnosis (Bower, 1981), through drugs (Eich *et al.*, 1975), or, more commonly, by the alteration of the environmental context, as exemplified by the scuba diver study described earlier (Godden and Baddeley, 1975). Next, the person is given a list of items to memorise. Later, when the person may or may not be experiencing the same mental or emotional state, they are asked to recall the items on the list. If the states match, recall is better.

Mood-dependent memory describes a context in which the person’s mood at encoding and retrieval can affect the successful execution of these two processes (such as a well-liked song provoking memories of events experienced when the song was first heard). Although replications in which positive effects in mood-dependent memory are

rare (Bower and Mayer, 1989), Eich (1995) suggests that when participants in these experiments experience strong/stable moods and are responsible for generating memory cues, mood-dependent memory is robust.

In one experiment, participants were asked to generate specific memories for events from autobiographical memory in response to common words (Eich *et al.*, 1994). Two to three days later, participants were allowed to free recall the memories generated in the experiment. Eich *et al.* found that more events were recalled when the mood matched the mood at testing. In another set of experiments, Eich (1995) found that the transfer of information from one environment to another is better if these environments feel similar. However, changes in the environment are not important if the moods at acquisition and reinstatement are the same. There is also evidence to suggest that individuals with mood disorders have a greater ability to discriminate between old and new stimuli if their moods at exposure and testing match (Eich *et al.*, 1997).

Does this evidence suggest that mood-dependent memory is genuinely robust? Smith (1995) and Eich himself (1995) suggest that mood-dependent memory effects may be explained by other factors. Smith, for example, suggests that active memories or pre-existing mood generated at the time of acquisition could have cued a representation of the initial context of the original event.

State-dependent memory may be related to **place-or context-dependent memory**, illustrated by the Godden and Baddeley experiment above. The demonstration of place-dependent memory (PDM) depends on the event to be remembered, the nature of encoding and retrieval, the ease by which people can mentally reinstate themselves, and the retention interval (Smith, 1979, 1988; McDaniel *et al.*, 1989; Wilhite, 1991). Reinstatement is important to PDM and refers to the process whereby the individual is placed in the same environment or is experiencing the same mood as when they originally encoded or generated information.

Because all of the factors listed above are important to PDM, the evidence for the phenomenon is mixed but generally supportive. In a meta-analysis of context-dependent memory studies in which retrieval and encoding were dependent on the explicit processing of aspects of the experimental environment, Smith and Vela (2001) found that context effects were very reliable. However, when people were encouraged to use non-contextual cues during encoding of material and its retrieval, the effects of environmental cues were reduced.

Flashbulb memories

For British sports fans, it was a blessing; for those bored with wall-to-wall sport and physical activity involving sticks and running around in circles, it was a prompt for a collective groan. On 6 July 2005, the United Kingdom was told that London's bid to hold the 2012 Olympic Games was successful. Scenes of celebration ensued in Singapore and in London. The morning after, one of the authors was listening to the BBC's News and Sports radio station where the regular phone-in turned to discussing the logistics of holding the games and whether the capital would be up to it. At 9.50 a.m., the presenter, Michael Bannister, was about to introduce a guest when he read out an announcement from London Transport indicating that Liverpool Street underground station in the financial district of London had been closed, due to a technical problem. Probably electrical, he said. This seemed unusual but, after 11 September 2001, nothing could be that unusual. The association with the 11 September attack was prescient. It later transpired that bombs had been detonated in two London underground stations. A bus travelling near Tavistock Square, the home of the British Medical Association, had its roof blown off by another bomb. A total of 53 people were murdered on 7 July 2005, including all of the British-born bombers.

The above recollection is an example of a **flashbulb memory** – the remembering of an event that is personally or socially important, novel, unexpected, vivid and has major long-term consequences. You will often hear people say that they knew exactly what they were doing when Kennedy was assassinated (Winograd and Killinger, 1983) in the same way that the author knew exactly where he was and what he was doing when news of the first of the 7 July London bombs exploding was heard.

The name 'flashbulb memories' was coined by Brown and Kulik (1977) to describe the vivid recollections from black and white respondents of the assassinations of Martin Luther King and President Kennedy. According to Brown and Kulik, the memory has a "live" quality that is almost perceptual. . . like a photograph' (p. 74). Since Brown and Kulik's landmark paper was published, flash-

bulb memories have been reported for the death of the King of Belgium (Finkenauer *et al.*, 1998), the death of spectators at the Hillsborough football stadium, England (Wright, 1993; Wright *et al.*, 1998), the resignation of Margaret Thatcher as British prime minister (Conway *et al.*, 1994; Wright *et al.*, 1998), the Gulf War (Weaver, 1993), the assassination of Olaf Palme, the Swedish prime minister (Christianson, 1989), the 1986 American space shuttle disaster (Bohannon, 1988), the experience of being in an earthquake (Neisser *et al.*, 1996b), the fall of the Berlin Wall, by East and West Germans (Bohn and Bernsten, 2007), and the death of Diana, Princess of Wales (Hornstein *et al.*, 2003).

According to Christianson (1992), 'people remember. . . public negative emotional events better than ordinary events that occurred equally long ago', suggesting that these events are not only more salient than others but also more accurate. Recently, there has been some debate on whether flashbulb memories are genuinely different from other types of memory. According to Brown and Kulik, flashbulb memories are of surprising or consequential events which are stored in the brain 'unchanged'; they also operate via a mechanism that is different from that which allows the formation of other types of memory. Wright (1993; Wright *et al.*, 1998), however, has conducted an extensive study of memories of the Hillsborough disaster and the resignation of Margaret Thatcher and suggests that flashbulb memories do not require a special mechanism. Furthermore, memories for these events may not even be vivid.

Wright *et al.* (1998) considered three assumptions behind flashbulb memories: (1) that they are 'collective' in nature (i.e. most of us will experience them when encountering a surprising and important event); (2) that the subjective characteristics of memories are reliable (would changing the order of questions in the study alter recollective ability, for example, especially if certain orders cued memories better?); and (3) that flashbulb memories are actually vivid. The researchers looked at memories for the Hillsborough disaster – where 96 spectators were crushed to death at an English FA football semi-final – and the resignation of Margaret Thatcher on 22 November 1990. Memory for the resignation was more vivid than for Hillsborough but the Hillsborough event was considered more important. Twelve per cent of the sample had vivid recollections of the resignation whereas nine per cent had vivid recollections of Hillsborough. This contrasts markedly with the 86 per cent reported by Conway *et al.* (1994) for Thatcher's resignation. Perhaps age, or even a lack of interest in politics, could have accounted for the difference in the later study.

A problem with previous flashbulb memory research has been the absence of a 'control' group of memories: researchers have measured memories for flashbulb events over time but have not compared them with memories for

Flashbulb memories are thought to be generated by events that are important, unusual and personally meaningful. The attack on the World Trade Center (**a**), the destruction of the space shuttle Challenger (**b**), the car crash involving Dodi Fayed and Diana, Princess of Wales (**c**), and the London bombings of 7 July 2005 (**d**) are examples of such events.

Source: © Press Association Images.

other events experienced roughly at the same time or before the memorable event. Addressing this problem, Talarico and Rubin (2003) examined undergraduates' recall of events when first hearing about the 11 September 2001 attack on the World Trade Center, and of other everyday memories on 12 September. There is some debate in the flashbulb memory literature concerning the accuracy of recall of important events. Talarico and Rubin returned to the students 1, 6 or 32 weeks later to test the accuracy and consistency of memory. There was a decline in the consistency of detail given for both types of event across time. Recall declined for both types of memory but flashbulb memories were recalled in a more narrative and coherent way. Emotion was unrelated to the consistency of recall but the more emotional the response, the greater the confidence in recalling details surrounding the event. The results suggest that while flashbulb memories are inconsistently recalled, their emotional impact makes people more confident about the perceived accuracy of their recall.

In another study, 145 Danes aged between 72 and 89 were asked to indicate when they heard about the invasion (April 1940) and liberation (May 1945) of Denmark during the Second World War. Recollection was compared against objective accounts (e.g. what the weather was like; the day of the week, the time of the announcement). All participants reported memories for the invasion and liberation and those closely linked to the resistance movement had more vivid, detailed and accurate memories.

Theories of flashbulb memories

What theory or theories can best account for flashbulb memories? Finkenauer *et al.* (1998) put the theories of Brown and Kulik (1977), and their own (called the emotional-integrative model) to the test by examining memories of the death of the King of Belgium on 13 August 1993. The experimenters' own model suggests that the appraisal of the event as novel and important leads to surprise. Surprise and the importance of the event to the person determine the intensity of the emotion experienced.

Finkenauer *et al.* noted that all the theories agreed that surprise and consequentiality are necessary for flashbulb memories. The degree of consequentiality influenced the degree of completeness and explicitness of the memory. Rehearsal of the memory for the event (thinking and talking about it) is also important. However, although the photographic model suggested that importance and feeling state were important determinants of flashbulb memories, these factors did not predict flashbulb memories.

Conway *et al.*'s (1994) model suggests that surprise and emotional feeling are determinants of flashbulb memories. However, Christianson and Engelberg's study (1999) of 203 participants' recall of the Estonia ferry disaster of September 1994 – in which 900 passengers died –

found that fewer than one-third of respondents consistently reported their emotional state at the time of hearing of the disaster, suggesting that the recollection of emotional state is not a good predictor of memory consistency. This is consistent with Finkenauer *et al.*'s (1998) review of flashbulb memory models.

Finkenauer *et al.* suggest that the appraisal of an event as novel causes surprise; this then leads to the formation of a flashbulb memory. Appraisal of an event as important determines the intensity of the emotional response but this response does not directly affect the formation of flashbulb memories. Instead, the data suggest that emotional state triggers the rehearsal of remembered events which, in turn, strengthens memory.

The emotional-integrative model is a persuasive way of accounting for the factors necessary to determine a flashbulb memory. Because it is explicit, it is testable: you can generate hypotheses from the model and test them empirically. The evidence at the moment, however, suggests that flashbulb memories may not be special. Events may be memorable but they may not be memorable for the reasons originally given by the authors of flashbulb memories. Also, it seems as if the length of time since the flashbulb event was experienced is important to the amount of detail recalled.

The biological basis of memory

Psychologists agree that long-term memory involves more or less permanent changes in the structure of the brain (Fuster, 1995; Horn, 1998). Much of what we know about the biology of human memory has been derived from studies of people who suffer from memory loss – amnesia – or from studies of animals in which amnesia is surgically induced to learn more about the specific brain mechanisms involved in memory (Parkin, 1996). But with the development of neuroimaging techniques, psychologists and neuroscientists have begun to outline the regions of the healthy brain that are active during the various memory processes of encoding, retrieval and working memory. Before reviewing this material, however, we need to go back to the beginning. To learning.

Before memory: learning

Before material can be remembered (and forgotten), it must first be learned. Learning involves three basic processes: the acquisition of material, its consolidation and its retrieval. Retrieval can involve free recall, where the participant is asked to remember previously presented stimuli, unaided by cues (or recognition) where the partic-

ipant has, for example, to determine which of two stimuli had been previously presented (where one stimulus is a distractor and not experienced before and the other is the stimulus previously seen/heard/etc.).

As you saw in Chapter 7, during instrumental learning the organism identifies a link between a stimulus and the response. It learns that by making a certain number of behavioural responses or making these responses at certain intervals it will be rewarded (or reinforced; the reward reinforces the behaviour and encourages it to be repeated to achieve the same outcome). In classical conditioning, the organism learns that if two previously unassociated stimuli are paired often enough, then the response normally elicited by the first will also be elicited by the other (although before they were paired it would not have done this).

Learning seems to involve a strengthening of connections between neurons. The theory was proposed by Hebb (1949) in his famous book, *The Organization of Behaviour*. Hebb proposed that each psychologically important event is conceived of as the flow of activity in a neuronal loop. This loop is made up of the interconnections between dendrite, cell body and the synapses on these structures. The synapses in a particular path become functionally connected to form what Hebb called a cell assembly. The assumption he made was that if two neurons are excited together, they become linked functionally. If the synapse between two neurons is repeatedly activated as the postsynaptic neuron fires, then the structure or chemistry of the synapse changes. This change strengthens the connection between neurons.

Hebb proposed that short-term memory resulted from reverberation of the closed loops of the cell assembly; long-term memory is the more structural, lasting change in synaptic connections. This long-term change in structure is thought to reflect **long-term potentiation (LTP)**, a term which describes the strengthening of neuronal connections via repeated stimulation (Lomo, 1966). Lomo found that if the axonal pathway from the entorhinal cortex to the dentate gyrus was repeatedly, electrically stimulated, then there was a long-term increase in the size of potentials generated by the postsynaptic neurons. LTP, therefore, was produced by the activation of synapses and the depolarisation of postsynaptic neurons. Psychologists agree that long-term memory involves more or less permanent changes in the structure of the brain (Fuster, 1995; Horn, 1998). But where and how?

Where are long-term memories formed?

Long-term potentiation seems to predominate in the **hippocampus**. If the hippocampus is stimulated, long-term

physical changes are observed (Bliss and Gardner-Medwin, 1973). The entorhinal cortex provides inputs to the hippocampus. The axons from the entorhinal cortex pass through a part of the subcortex called the perforant path and form synapses with cells in the dentate gyrus, a part of the hippocampal formation.

The hippocampal formation itself is composed of two distinct structures: Ammon's horn (often referred to as the hippocampus) and the dentate gyrus. Ammon's horn comprises the substructures CA1, CA2 and CA3. CA1 is sometimes referred to as 'Sommer's sector'. There is also significant hippocampal output to the mammillary body via a tract called the fornix. Damage to each of these structures is sometimes associated with memory loss although the evidence for the involvement of the fornix is mixed (Calabrese *et al.*, 1995).

Translating this process into the behaviour seen in classical conditioning, the unconditioned stimulus (the puff of air) makes strong synaptic connections with the neurons which produce the unconditioned response (the blink). Presenting the conditioned stimulus (the tone) alone, generates weak synapses. But pairing the tone with the unconditioned stimulus, leads to the conditioned stimulus forming very strong synaptic connections. The more often the pairing is made, the stronger the connection becomes. For this type of classical conditioning to occur, a functioning hippocampus appears to be necessary and the involvement of the structure would appear to be that of acquiring conscious knowledge of the relationship between the conditioned and unconditioned stimulus. The hippocampus is also involved in learning the relationship between the unconditioned and conditioned stimulus when there is a delay between the presentation of each, a process called trace conditioning (Clark and Squire, 1998).

The consolidation of memory seems to be time-dependent. For example, the initial period and the few hours after the learning of UCS and CS pairings appears to be the moment when memory is consolidated. Therefore, interruption of the process at these times will impede consolidation (Bourtchouladze *et al.*, 1998). The first period of consolidation may be dependent on a different neurotransmitter system to that involved in the second. These are the NMDA and dopaminergic systems, respectively.

Chemical modulation of long-term potentiation

The most important excitatory neurotransmitter in the nervous system is glutamic acid or glutamate. One subtype of glutamate, N-methyl-D-aspartate (NMDA) appears to be important for producing long-term potentia-

tion (LTP) (Abel and Lattal, 2001). NMDA receptors are found in the CA1 sector of the hippocampus; blocking activity in NMDA receptors prevents long-term potentiation in CA1 and the dentate gyrus. Blocking activity does not prevent or reverse LTP that has already occurred. The key process is the entry of calcium ions through ion channels, a phenomenon mediated by NMDA receptors.

When calcium enters an ion channel, changes in the structure of the neuron are produced by an enzyme, called a calcium-dependent enzyme, CDE (Lynch *et al.*, 1988). One CDE is called calpain which breaks down proteins in the spines of dendrites. Without this entry of calcium, LTP does not occur. Weak synapses, resulting from weak activation, do not lead to depolarisation that allows calcium ions to enter ion channels. Strong synapses that are activated do lead to this depolarisation, suggesting that the NMDA receptor is vital for the process of learning acquisition (Steele and Morris, 1999).

However, LTP can occur in other parts of the brain, apart from the hippocampus, and not all forms of LTP involve the NMDA receptors. So, although the hippocampus and the NMDA receptors seem to be prime mechanisms for LTP, they may not be the only ones. There are structures such as the amygdala, for example, that are involved in the conditioning of fear. Temporarily inactivating part of the amygdala, for example, can impair an organism's ability to learn to fear whereas inactivating the same area after conditioning has taken place, still results in a fear response in the organism (Wilensky *et al.*, 1999). This finding suggests that this part of the amygdala may be involved in the acquisition, but not consolidation, of memory. The topic of fear conditioning is explored in more detail in Chapter 13.

One of the most important findings in the physiology of memory in recent decades has been that the hippocampal formation is essential for the formation or learning of new memories but it may not be involved in the long-term retention or retrieval of memory (Shors, 2004). What is unclear is why this dissociation should be.

Lee *et al.* (2004) have discovered that a type of gene, called *zif268*, is needed for the reconsolidation of context-dependent fear memory but another factor (called BDNF) is needed for initial consolidation. This shows how different physiological processes are involved in different aspects of memory formation: one type of factor is needed for immediate consolidation (but not reconsolidation) and another is involved in reconsolidation (but not immediate consolidation). The retrieval of fear memory also appears to recruit *zif268* but in another region of the brain – the anterior cingulate cortex (Frankland *et al.*, 2004). Frankland *et al.* found that remote memory for fear was associated with anterior cingulate involvement in mice. Both the studies report changes in the brain during fear conditioning.

Studies of memory in animals have now associated around 47 specific genes with good memory performance. In research with human participants, genetic clusters were examined in participants who learned a series of semantically-unrelated words for immediate free recall and then completed an unexpected delayed free-recall test 5 minutes later (de Quervain and Papassotiropoulos, 2006). The genes that encoded a certain protein (ADCY8), and five others, were related to better memory performance and with greater activation in those brain regions involved in autobiographical memory and delayed recall (areas described below).

Amnesia

Damage to particular parts of the brain can permanently impair the ability to form new long-term memories while leaving language and perception intact (Warrington and Weiskrantz, 1968). The inability to form new memories is called **anterograde amnesia**. The impairment in the ability to retrieve memories from before the brain injury is called **retrograde amnesia**. The brain damage can be caused by the effects of long-term alcoholism, severe malnutrition, stroke, head trauma or surgery (Parkin, 1996). In general, people with anterograde amnesia can still remember events that occurred prior to the damage. They can talk about things that happened before the onset of their amnesia, but they cannot remember what has happened since. They never learn the names of people they subsequently meet, even if they see them daily for years.

One of the most famous cases of anterograde amnesia was patient HM (Scoville and Milner, 1957; Milner, 1970; Corkin *et al.*, 1981). HM's case is interesting because his amnesia was both severe and relatively pure, being uncontaminated by other neuropsychological deficits. At the age of nine, HM suffered a head injury after a bicycle accident which left him epileptic. In 1953, when HM was 27 years old, a neurosurgeon removed part of the temporal lobe on both sides of his brain because the drugs used to treat his epilepsy were not effective. The surgery cured the epilepsy, but it caused anterograde amnesia (this type of operation is no longer performed). HM died in 2009.

HM could carry on conversations and talk about general topics not related to recent events. He could also talk about his life prior to the surgery. However, he could not talk about anything that had happened since 1953. He lived in an institution where he could be cared for and spent most of his time solving crossword puzzles and watching television. HM was aware that he had a memory problem. For example, here is his response to a researcher's question:

Every day is alone in itself, whatever enjoyment I've had, and whatever sorrow I've had ... Right now, I'm wondering. Have I done or said anything amiss? You see, at this moment everything looks clear to me, but what happened just before? That's what worries me. It's like waking from a dream; I just don't remember.

Source: Quoted in Milner, 1970, p. 37.

Clearly, HM's problem lay in his ability to store new information in long-term memory, not in his short-term memory. His verbal short-term memory was normal; he could repeat seven numbers forwards and five numbers backwards, which is about average for the general population. At first, investigators concluded that the problem was in memory consolidation and that the part of the brain that was destroyed during surgery was essential for carrying out this process. But subsequent evidence suggests that the brain damage disrupts explicit memory without seriously damaging implicit memory.

Recently, however, psychologists have questioned whether HM had a pure memory deficit, that is, one that prevents the acquisition or consolidation of new information for explicit recall but leaves other cognitive abilities (such as the ability to produce and comprehend language) intact (Mackay *et al.*, 1998). Mackay *et al.* cite studies in which participants described two meanings of ambiguous sentences presented visually (such as 'they talked about the problem with the mathematician') and compared these participants' performance with those of HM. HM's descriptions were 'less clear and concise and more repetitive than controls'. Independent judges also rated HM's descriptions as less grammatical and comprehensible.

Other investigators have found that people with anterograde amnesia can learn to solve puzzles, perform visual discriminations, and make skilled movements that require hand-eye coordination (Squire, 1987). Clearly, their brains are still capable of undergoing the kinds of change that constitute long-term memory, but the people fail to remember having performed the tasks previously. For example, they may learn the task on one occasion. When, the next day, the experimenter brings them to the experimental apparatus and asks if they have ever seen it before, they say no. They have no explicit, episodic memory for having spent some time learning the task. But then they go on to perform the task well, clearly demonstrating the existence of implicit long-term memory.

Graf and Mandler (1984) showed lists of six-letter words to amnesic and non-amnesic people and asked them to rate how much they liked them. They then admin-

istered two types of memory test. In the explicit memory condition, they asked people to recall the words they had seen. In the implicit memory condition, they presented cards containing the first three letters of the words and asked people to say the first word that started with those letters that came into their minds. The amnesic people explicitly remembered fewer words than the non-amnesic people in the control group, but both groups performed well on the implicit memory task (see Figure 8.20).

Amnesia is not an all-or-nothing phenomenon, however. Severe amnesia, for example, can leave facial familiarity recognition, the acquisition of school knowledge or knowledge of the meaning of words intact. The fact that amnesic patients can remember facts and describe experiences that occurred before the brain injury indicates that their ability to recall explicit memories acquired earlier is not severely disrupted. Of those parts of the brain necessary for establishing new explicit memories, the most important part seems to be the hippocampus, a structure located deep within the temporal lobe, and which forms part of the limbic system.

Figure 8.20 Explicit and implicit memory of amnesic patients and non-amnesic people. The performance of amnesic patients was impaired when they were instructed to try to recall the words they had previously seen but not when they were asked to say the first word that came into their minds.

Psychology in action – Memory at the movies . . .

Common sense, as you saw in Chapter 1, may be common but does not make much sense in psychology. Sometimes people's misunderstandings of psychology, and science in general, can have serious consequences, such as distorting how mental illness and the mentally ill are viewed (see Chapter 18). In more light-hearted contexts, the misperception can seem comical. Films, television and novels exploit artistic licence to bend scientific facts sometimes to breaking point. An episode of the American sci-fi television programme, *The X Files*, had a protagonist confuse a technique used for measuring brain structure with one used for measuring brain activity. This protagonist was the medically qualified one. Even as this passage was being written, a journalist on a 24-hour television news channel is describing football supporters' reaction to a national football team manager as 'Pavlovian', thus misunderstanding Pavlov and, probably, football supporters.

Perhaps nowhere is artistic licence more vigorously exploited than in films. In an article in the *British Medical Journal*, Sallie Baxendale (2004), a clinical neurologist from the National Hospital for Neurology and Neurosurgery in London, has reviewed how films interpret and portray an important human phenomenon: memory loss. *The Bourne Supremacy*, *Total Recall*, *Memento*, *Men in Black*, *The Eternal Sunshine of the Spotless Mind*. . . several recent films have used amnesia as the hook with which to draw in cinema-goers and the hook is not new. At least ten silent movies released before 1926 featured amnesic characters.

Amnesia is an organic disorder with a neurological or psychiatric basis. Fugue states (where people experience lack of consciousness but appear conscious and wander around oblivious to their condition, ending up in, for example, a bus depot) or states where people believe they are someone else (dissociative disorders) are rare, as are changes in personality and identity. Amnesic patients have normal intelligence, normal attention span but show a severe inability to process new information. The most common causes of amnesia are neurosurgery, infection or stroke. Many films routinely flout these known facts in the cause of entertainment and Baxendale highlights a few of these.

In terms of causes of amnesia, she finds that many movies attribute memory loss to car crashes and assault. When Santa falls from a sleigh in the film *Santa Who?* he loses his identity and autobiographical memory. This cause and effect, as Baxendale suggests, is highly unlikely. Everyday memory difficulties are also rarely seen (although they should be one of the defining features of the disorder) and amnesic characters pursue new careers and social networks, unimpeded by their cinematic affliction. Trained assassins are especially prone to developing this trait, as seen in *The Bourne Identity* and *The*

Long Kiss Goodnight. (Although in an unusual and knowing twist, *The Bourne Identity Crisis* features a protagonist who forgets he is gay and becomes a trained assassin.)

Two other films, best forgotten, are *Clean Slate* and *50 First Dates*. In the former, the hero is able to form new memories while awake but, after sleeping, forgets all he has learned. In the latter, Adam Sandler attempts to seduce Drew Barrymore who forgets each meeting they have had. As Baxendale pointedly notes, 'Some viewers might envy Ms Barrymore's ability to forget her romantic encounters with Mr Sandler, but her affliction seems to be the result of a head injury rather than the unconscious suppression of traumatic memories.' Cinematic forgetfulness reaches its zenith – humorously and deliberately – in *Groundhog Day* where Bill Murray's character exists in a world in which he perpetually relives the previous day.

In terms of recovery, Baxendale notes how television and movies are enamoured of the 'two are better than one' philosophy of head injury – a bang on the head can produce memory loss but a second bang can restore it. This happens in the Tom and Jerry cartoons and films such as *Tarzan the Tiger* and *Singing in the Dark*. In real life, a second blow does not make an effective rehabilitation strategy.

There are some honourable exceptions to this filmic hall of dishonour. Christopher Nolan's innovative film *Memento*, for example, features a character played by Guy Pierce who has severe anterograde amnesia and tries to recall the events leading to his wife's death. This is relayed in a narrative played backwards, as the character tries to piece together clues to his life. The character does not suffer retrograde amnesia, does not lose his identity and suffers severe everyday memory problems (like HM who, apparently, inspired the story). He writes every detail he thinks is important, and which may help him understand the past, in a clearly visible place such as his body (if he used a notebook, he would forget about it and forget what he wrote in it).

Ironically, the film that does portray amnesia in the most realistic form, according to Baxendale, does not feature humans at all. It is *Finding Nemo* and the fish, Dory, has severe difficulty in learning and remembering new information, recalling names and knowing where she is going and why. 'Although her condition is often played for laughs,' Baxendale writes, 'poignant aspects of her memory loss are also portrayed, when she is alone, lost, and profoundly confused.' This reflects real-life, human amnesia.

Does the accurate or inaccurate portrayal of amnesia in films matter? After all, we don't always go to the cinema to confront a mirror raised to real life. We go to suspend disbelief. We go to see fish, toys and ants talking, to see a man in an unlikely, figure-hugging suit swinging from buildings by

Psychology in action – Continued

(a) Leonard Shelby, played by Guy Pierce in the film *Memento*, is one of the few successful cinematic portrayals of amnesia. The most successful, however, appears to be Dory (b), in *Finding Nemo*.

sticky strings spurting from his wrists, to cheer for a group of hobbits, to boo an asthmatic, black-helmeted villain, or to see a boy in spectacles racing on a broom in a flying contest. Reality becomes important, however, if the reality is meant to be accurately portrayed. Dustin Hoffman's character in *Rain Man*, for example, although an extreme example, is an

attempt at a serious portrayal of the social debilitation experienced by a person with Asperger's Syndrome. (The man who inspired the Hoffman character appears in Chapter 12.)

The general lesson, however, is this: don't go to the movies expecting to learn much about psychology. In fact, as this section demonstrates, you might as well forget it. . .

The role of the hippocampus in memory

The hippocampus, like many structures of the brain, is not fully mature at birth. In fact, it is not until a child is 2–3 years old that most of these structures are fully developed. As a result, many cognitive activities, such as the formation of semantic memories, are not particularly well developed until this age (Liston and Kagan, 2002). One reason that few people remember events that occurred during infancy may be the immaturity of the hippocampus.

The hippocampus receives information from all association areas of the brain and sends information back to them. In addition, the hippocampus has two-way connections with many regions in the interior of the cerebral hemispheres. Thus, the hippocampal formation is in a position to 'know' – and to influence – what is going on in the rest of the brain (Gluck and Myers, 1995). Presumably, it uses this information to influence the establishment of explicit long-term memories.

The structure appears to be very important for navigating or exploring our way around a spatial environment or in forming representations of the locations of objects (O'Keefe and Nadel, 1978). Morris *et al.* (1982), for example, placed rats in a pool of milky water that contained a platform just underneath the water.

In order to avoid swimming constantly, the rats had to find the platform hidden beneath the milky water.

Eventually, through trial and error, the rats would find the platform. Then, the researchers performed a series of experimental ablations. One group of rats received lesions to the hippocampus, another received lesions to the cerebral cortex and another received no lesion. When the rats were then allowed into the pool, the pattern of behaviour seen in Figure 8.21 was observed. Notice how those rats with the hippocampus lesion had extremely poor navigation compared with the cortex lesion and control group. Similarly, when rats had learned that there was a platform under water and were then allowed to explore the water with the platform removed, those with an intact hippocampus would spend longer in the part of the maze where the platform had been previously positioned. Those rats with hippocampal lesions, however, did not engage in this 'dwell time' in the quadrant where the platform once was (Gerlai, 2001). This suggests an important role for the hippocampus in spatial learning.

Both rodents and primates show deficits in what has been called spatial memory (Redish and Touretzsky, 1997). Spatial memory, the ability to encode and retrieve information about locations and routes is, like memory itself, not a unitary function. Kessels *et al.* (2001), for example, note that there is a difference between memory

Figure 8.21 The effects of damaging a rat's hippocampus on its ability to find a platform in opaque water after having initially been trained to locate the platform successfully.

Source: Reprinted by permission from Macmillan Publishers Ltd: *NATURE*, Place navigation impaired in rats with hippocampal lesions, 182(297), pp. 681–683 (Morris, R.G.M. et al. 1982), Copyright 1982.

for routes and paths and the knowledge of spatial layouts which enables a person to find an object or a location. The role of the hippocampus in aspects of spatial memory have been well documented in animals, but O'Keefe and Nadel's view (1978) of hippocampal function has not gone unchallenged. Olton *et al.* (1979), for example, argued that the hippocampus was not exclusively responsible for spatial memory but was more involved in working memory. Tasks used in spatial memory tasks were, according to the theory, tests of short-term or working memory rather than spatial memory: all required the organism to keep information in mind while they engaged in another behaviour that used such information and this is the feature that was disrupted by damage.

In a meta-analysis of 27 studies that reviewed the consequences of hippocampal dysfunction, Kessels *et al.* (2001) found that whereas mild or moderate impairments were found on tasks requiring integration of information or navigation around a maze, there was little effect on spatial working memory. There was, however, a large impairment on tests of positional memory such as locating Xs in an array of letters. The lesions in patients showing mild to severe impairment were invariably to the right hippocampus, a finding that is consistent with O'Keefe and Nadel's hypothesis (1978) that the right hippocampus is specialised for mapping spatial information.

Neuroimaging and memory

Although much of our knowledge about the brain mechanisms that underlie memory has been derived from animal studies or from studies of individuals with brain injury, neuroimaging studies provide evidence from healthy individuals, and suggest that different regions of the brain are more involved than others in performing different types of memory task (Cabeza and Nyberg, 2000; Fletcher and Henson, 2001). As Horn

(1998) asked, 'If memory consists of a mark made in the brain by a particular experience, where is the mark and what is its nature?'

Spatial navigation

Maguire and her colleagues set up a novel and unusual experiment to see whether the hippocampus was active during spatial navigation (Maguire *et al.*, 1997). In their study, 11 London taxi drivers each with at least 14 years' experience of driving described the shortest legal route between two locations in London as a positron emission tomography (PET) scanner observed brain activity study. You can see a map of the route in Figure 8.22.

The taxi drivers were also asked to recall famous London landmarks (an examination of topographical memory). The activation during these tasks was compared with that during the recall of sequences from famous films. When the drivers described the route from one location to another, significant activation of the right hippocampus was found (but was not found with the landmark or film conditions), as Figure 8.23 illustrates.

This finding suggests that the right part of the hippocampus is important to retrieval of information that involves recall of movement in complex environments. In another PET experiment, participants were asked to navigate their way around a familiar but complex virtual town, using a pair of virtual reality goggles (Maguire *et al.*, 1998). Activation of the right hippocampus was again associated with knowing accurately where places were located and with navigating between them. The speed with which individuals navigated their environment was associated with right caudate nucleus activity. Also activated, however, were the right inferior parietal and bilateral medial cortices, which suggests, as many imaging studies do, that memory performance is not exclusively dependent on one region or structure.

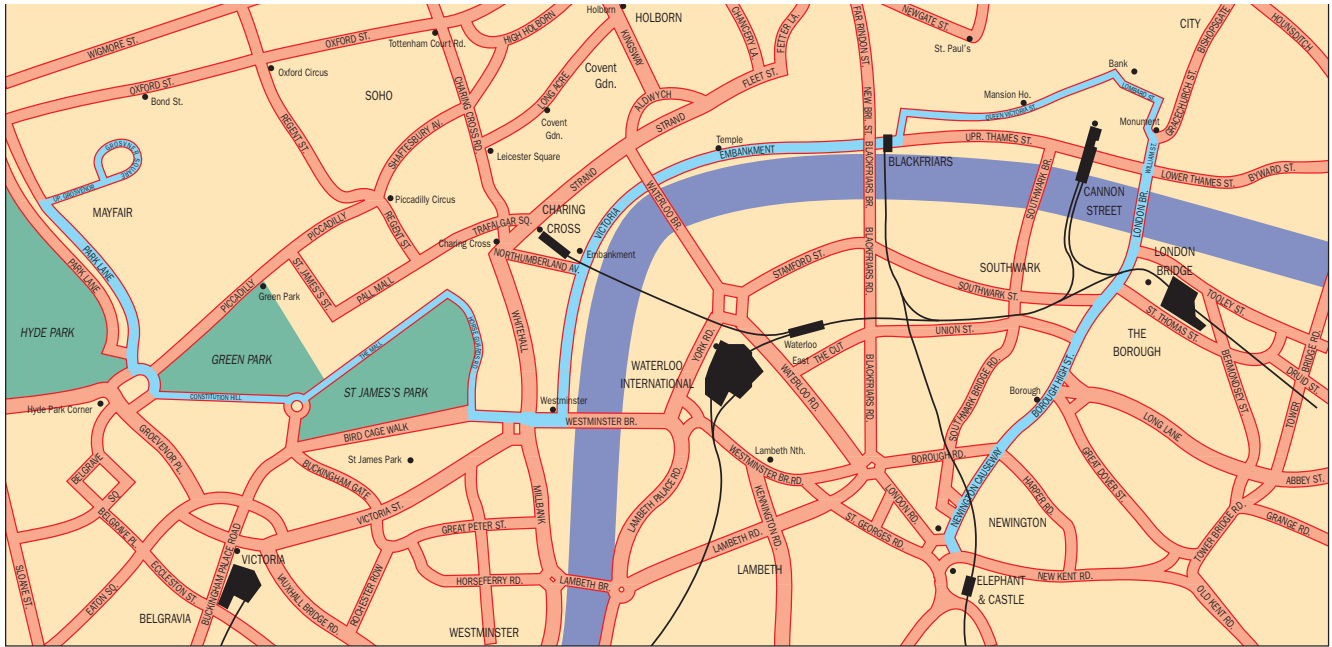

Figure 8.22 The route (in blue) that Maguire's taxi drivers had to describe.

Source: Maguire, E.A., Frackowiak, R.S.J. and Frith, C.D., Recalling routes around London: Activation of the right hippocampus in taxi drivers. *Journal of Neuroscience*, 1997, 17, 7103. © Society for Neuroscience.

Experienced taxi driving is one thing, but day-to-day navigation is another. A recent study, however, examined untrained people's ability to navigate (drive) their way around a virtual London, as fMRI measured brain activation to see which regions of the brain were recruited during this type of task (Spiers and Maguire, 2007). Starting, turning and stopping were associated with activation in the premotor, parietal and cerebellar regions of the brain. Swerving and avoiding collisions were associated with occipital and parietal, as well as premotor and insula activation. The right prefrontal lobe was especially active when observing road traffic rules, supporting other studies you read about in Chapter 4 (and will read about further in Chapter 13) that these regions play a role in moral reasoning.

The picture is not consistent, however. Rosenbaum *et al.* (2005) noted that Maguire *et al.*'s data showed that activation was actually seen in the parahippocampal gyrus, not the hippocampus. They also describe results from their own fMRI study which found that participants who were engaged in the recall of well-rehearsed knowledge about a city's topography showed greatest activation in the parahippocampal gyrus (there was slight activation in the hippocampus) (Rosenbaum *et al.*, 2004).

A case study, reported by Rosenbaum *et al.* (2005), provides another source of evidence against the involvement of the hippocampus in topographical memory. They studied SB, a patient with probable Alzheimer's disease who had been a taxi driver in Toronto, Canada, for 40 years. His remote memory for spatial locations in Toronto was compared with two other retired taxi drivers (with different illnesses) and a healthy control group. His ability to spatially navigate between various Toronto landmarks was comparable to the other participants. His most pronounced deficit was an inability to distinguish between Toronto landmarks and unknown buildings (an impairment that extended to world-famous landmarks). While the hippocampus may be necessary for the acquisition and retrieval of spatial information in the short-term, these results suggest that its role in long-term memory for old environments is much less certain.

This and the earlier study, together with those of amnesics who can recall the topography of the neighbourhood in which they grew up (e.g. Teng and Squire, 1999), provides a challenge to the view that the hippocampus is

Figure 8.23 Areas of the brain activated by the recall of routes. Note the activation of the right hippocampus.

needed for the acquisition and retrieval of long-term topographical memories. However, Maguire *et al.* (2006) investigated the effects of brain injury on recall of routes in London in a taxi driver with damage to the hippocampus, the area which was active during route recall in the earlier imaging study. In the experiment, the driver and a matched control navigated their way through a virtual version of the city of London, along streets they had encoded 40 years ago.

They found that the injury did not affect the driver's ability to orientate himself around the city, his knowledge of landmarks and the spatial relationships between them or his ability to navigate the town. However, the driver did have difficulty when navigating routes that were not A-roads (major road arteries). It was as if complex routes were more problematic for him. It is possible, therefore, that coarse recall of topography is not affected by the hippocampus but recall of detailed, complex spatial relations might be.

Working memory

The ability to manipulate information in memory over a short space of time seems to be the primary responsibility of the frontal lobes (Fletcher and Henson, 2001), regions which, apparently contrarily, also become active during the retrieval of material that has been retained over long periods. Fletcher and Henson (2001) distinguish between two types of measures in working memory tasks: maintenance and manipulation. Working memory maintenance tasks involve measuring the process of keeping information in mind; working memory manipulation tasks involve measuring the reorganisation of material that is kept in mind.

A typical maintenance task involves presenting a participant with between three and nine stimuli and asking them to indicate whether a single stimulus presented subsequently formed part of the original array. The letter-based version of this task is usually associated with significant increases in activation in the left hemisphere, especially the ventrolateral frontal cortex, parietal lobe and premotor area (Awh *et al.*, 1996). When the task involves information about spatial relations or objects rather than words, activity is greater in the right hemisphere. Often, the same regions activated by letters or words in the left hemisphere are also activated in the right by spatial/object stimuli (Smith *et al.*, 1996).

Remember from earlier that one type of working memory manipulation task involves presenting the participant with a series of five letters and then asking them to recite the letters forwards, backwards or in alphabetical order, in mind. After a delay, the participant is asked to match the number order of a given letter, according to the mental manipulation (e.g. forwards, backwards or alphabetical). During the delay, there is usually activation seen

in the ventrolateral and dorsolateral frontal cortex; during the reordering part of the task, activation is seen more in the dorsolateral part (D'Esposito *et al.*, 1999; Postle *et al.*, 1999).

In tasks that involve the generation of words, left dorsolateral activation is observed but not if words simply have to be repeated (Frith *et al.*, 1991). Word generation is a common 'frontal lobe' test: people with frontal lobe injury are poor at generating words from a given first-letter, for example.

Encoding and retrieval in episodic and semantic memory

Given that encoding and retrieval of information are two different cognitive tasks relating to the same function, you would expect these processes to have different underlying neural substrates. The left prefrontal cortex is activated when we learn and encode material whereas the right side is activated when we try to recall this material (Tulving *et al.*, 1994; Nyberg *et al.*, 1996; Fletcher *et al.*, 1998a, b).

The encoding of episodic memory is associated with activity in regions including the prefrontal and medial-temporal cortex and the cerebellum (Cabeza and Nyberg, 2000). Studies have usually found left-sided activation during episodic memory encoding, especially during the encoding of verbal material. The encoding of non-verbal material tends to be associated with bilateral activity in the frontal cortex. The role of the left prefrontal cortex in memory may be one of organising information: this part of the brain is responsible for our ability to group items on the basis of some characteristic or attribute.

Fletcher *et al.* (1998a) conducted a PET study in which participants listened to words that were either semantically organised, or disorganised but had to be put into categories. As expected, the condition in which the list was already organised produced the least amount of left prefrontal cortex activation whereas the task requiring the participant to generate an organisational structure resulted in greatest activation. A distractor task reduced activation during the organisation task but not during any other encoding task, suggesting that the organisational, executive role of the left prefrontal cortex can be disrupted.

Retrieval of episodic memory is consistently associated with prefrontal activation, sometimes in both cerebral hemispheres but usually in the right, although other regions are also activated depending on the type of material retrieved (Nyberg *et al.*, 1996; Fletcher *et al.*, 1996). Furthermore, there is evidence that the amygdala and the hippocampus contain neurons that encode our ability to recognise something and also when/where this something was originally seen. In one experiment, participants were asked to remember as many of 12 unique items, presented on a computer screen, as possible and also remember

where on the screen they had seen them. The stronger the neurons' responses in these regions, the better the recall (Rutishauser *et al.*, 2008).

Remembering and long-term memory

Neuroimaging studies of long-term memory involve presenting the participants with several items that they are told to memorise (or given no memorisation instructions), and then asking them to recall the presented material some time later. Usually, the participant is asked to recognise the presented stimulus from a range of target and distractor stimuli. The process involves encoding and retrieval and neuroimaging research has highlighted the different brain regions involved in each type of process. If encoding is intentional or incidental, it is associated with left frontal cortex activation, as we have already seen. Simple retrieval of information is also associated with left frontal lobe activation (Fletcher and Henson, 2001).

If encoding and retrieval is successful, would greater brain activation be seen during encoding for those stimuli that were successfully encoded or for all stimuli regardless of how well they were retrieved? There is evidence from EEG studies that a specific type of electrical activity, called EEG theta, is greater during the encoding of successfully retrieved words than unsuccessfully retrieved ones (Klimesch *et al.*, 1997). In one neuroimaging study, Brewer *et al.* (1998) found that greater right frontal cortex activity was associated with successful encoding. Individuals were asked to view a series of indoor or outdoor scenes and decide whether each scene depicted outdoors or indoors. Thirty minutes later, they were given a recognition test and asked to indicate whether they remembered the scene, thought the scene was familiar but not well remembered or was forgotten. Memory for the scenes was predicted by frontal and parahippocampal activation with greater activation found for the remembered images.

Lateralisation of memory processes

A model called the HERA model has been proposed to account for the differences in brain activation seen during memory encoding and retrieval. HERA stands for Hemispheric Encoding-Retrieval Asymmetry, and the model argues that greater left than right frontal cortex activation is seen during episodic encoding whereas greater right than left frontal cortex activation is seen during episodic retrieval (Tulving *et al.*, 1994). The evidence reviewed above and more extensively in Fletcher and Henson (2001) and Cabeza and Nyberg (2000) suggests strong support for the model. In general, verbal encoding is associated with left frontal activation whereas right activation is more common during retrieval but, as

we have seen, such areas as well as others can be bilaterally active during encoding and retrieval. Why?

Fletcher and Henson (2001) put forward some interesting possibilities. Two are statistical and methodological and hinge on (1) the type of statistical parameters a study sets for statistical significance in neuroimaging research (different studies may set different parameters) and (2) the small number of samples used in neuroimaging research. A further reason may be the lack of clarity over the precise definition of cognitive processes in memory studies. Setting aside questions regarding what is verbal and what is non-verbal (and whether these two categories could be considered unitary), there are also questions regarding the nature of encoding and retrieval. Not all studies use the same measures of encoding or retrieval; perhaps the inconsistencies in findings can, therefore, be attributed to these different methodological approaches.

The nature of the model is challengeable, however. Dobbins and Wagner (2005) presented participants with various stimuli and then presented three images (two of which had been seen before) and asked them three different questions about each. The questions were 'Was this bigger before?' (the participant had to indicate whether an image previously seen had been bigger), 'Was it pleasant in the previous task?' (the participant was asked to indicate which of the stimuli was rated as pleasant or unpleasant in the previous task) and 'Is there a new item?' (participant was asked to identify the image that had not been seen before). Two areas of the left prefrontal cortex (specifically, the ventromedial/orbitofrontal cortex) were active in each of the retrieval conditions. There was greater activation in the anterior part of this region when participants retrieved conceptual information (pleasant condition) and in the posterior region during retrieval of conceptual and perceptual information (see Figure 8.24).

Figure 8.24 Domain-general and domain-sensitive prefrontal mechanisms.

Memory-enhancing drugs

In recent years, pharmaceutical companies have become excited at the possibility that drugs may help improve memory or reduce the decline in memory performance

seen with normal ageing or in people with probable Alzheimer's disease, the major cause of dementia (and a topic described on page 462 in Chapter 11). But do these drugs work? The Controversies in Psychological Science box sifts through some of the evidence.

Controversies in Psychological Science – Do 'smart drugs' work?

The issue

SHOULD WE JUST SAY NO TO SMART DRUGS?

All across India school children are popping little green and yellow pills – and claiming better grades as a result. Balding executives insist they are regaining lost hair as their memories improve. The country's Science Minister only half-jokingly prescribes the capsules for all members of Parliament. This new wonder drug, launched nationwide in January, is called Memory Plus, a compound derived from the brahmi plant found in India's marshlands. Memory Plus is just one of hundreds of so-called 'smart drugs' available around the world, either in the form of over-the-counter herbal mixtures or synthetic prescription formulas. Though these potions vary widely in composition, effectiveness and toxicity, they are all intended to enhance memory by stimulating neural activity.

This extract from *Time* magazine was not a one-off. 'Scientists boost memory power', proclaimed the BBC Health website; 'Smarten up your act', advised the *Sydney Morning Herald*; 'The making of a genius', declared the India Express News Service, hopefully.

What unites these stories is a fascination with a relatively new development in pharmacology: so-called smart drugs. Smart drugs are non-prescription pharmaceuticals that claim to improve memory, restore neural function or generally enhance intellectual function. The increase in the number of people getting older, together with the knowledge of the devastating consequences of Alzheimer's disease, suggests that there may be a large market for these drugs. But do they live up to their claims? Do they reverse memory decline and improve thinking?

The evidence

Drugs that claim to improve intellectual function have been called *nootropics* (from the Greek, *noos*, 'mind', and *tropein*, 'towards'). Although the word was used to describe a specific drug that increased neurotransmitter activity (Nicholson, 1990), it is now used to refer to any drug that claims to improve cognitive function or protect neurons from injury or insult. These drugs are not excitants, tranquillisers or antipsychotics and they have few side effects (Gabryel and Trzeciak, 1994).

Much of the excitement surrounding the use of memory-enhancing drugs in humans was based on findings from animal studies in which the animals' brains were found to respond positively to various drugs. Improvements in neural activity or memory performance in these animals led to trials with human participants. Many models of Alzheimer's disease, for example, are based on studies of neuronal degeneration in animals and so such research can be very useful. But could the animal findings be replicated in humans?

In a major review of every available peer-reviewed, systematic study of the effect of non-prescription compounds on memory enhancement, McDaniel *et al.* (2002) conclude that the evidence provides little scientific support for the drugs' claims. However, they concede that it is possible that such drugs may be effective in certain circumstances.

The six drugs which McDaniel *et al.*'s review investigated are listed in Table 8.2 together with the putative mechanisms for their action.

Phosphatidylserine (PS)

The drug phosphatidylserine (PS) has been found to reduce the neurobiological effects of ageing in animals and to restore memory function that has been lost. Its effects on humans, however, are less clear-cut. For example, McDaniel *et al.* found that the drug had no positive effect on the memory performance of people with probable Alzheimer's disease. However, people demonstrating cognitive decline associated with ageing showed some improvement in memory, especially in the ability to recall word lists. There were hardly any significant effects found on other memory tests.

Choline compounds

Drugs such as phosphatidylcholine (PC) and citicoline are called choline compounds because the chemical, choline, forms their basis. These drugs are thought to help with neurotransmitter activity associated with memory performance, although the few studies of PC on the memory performance of people with probable Alzheimer's disease have produced non-significant results. McDaniel *et al.* conclude that the efficacy of PC in improving memory in people without neuronal degeneration is also open to question because there are no studies of this drug in normally ageing individuals. Although there are

Controversies in Psychological Science – Continued

Table 8.2 A list of the major drugs claimed to improve memory, and the proposed mechanisms for their effects

Drug	Mechanism
Phosphatidylserine (PS)	<ul style="list-style-type: none">• Maintains neuron membrane• Increases number of neuronal receptors• Helps the branching of dendrites• Stimulates neurotransmitter release
Citicoline	<ul style="list-style-type: none">• Maintains neuron membrane• Increases availability of neurotransmitter, acetylcholine• Promotes activity in the dopamine neurotransmitter system
Piracetam	<ul style="list-style-type: none">• Facilitates activity in the dopaminergic, cholinergic and noradrenergic systems• Protects neurons from toxins
Vinpocetine	<ul style="list-style-type: none">• Increases blood flow to brain• Increases the uptake of glucose• Increases the availability of neurotransmitter, acetylcholine
Acetyl-L-carnitine	<ul style="list-style-type: none">• Increases production of energy in neurons• Protects neurons from toxins• Maintains neurons' receptors• Increases the availability of acetylcholine
Antioxidants (e.g. Vitamins E, C)	<ul style="list-style-type: none">• Protects neurons from toxins

Source: Adapted from McDaniel M.A., Maier, S.F. and Einstein, G.O., 'Brain-specific' nutrients: A memory cure? *Psychological Science in the Public Interest*, 2002, 3 (1), 12 –38.

hardly any studies investigating the effects of citicoline, the one double-blind study has found a significant increase in the accurate recall of stories in ageing individuals with no neuronal degeneration.

Piracetam

This drug is thought to improve the efficiency of neurons, increase the activity of neurotransmitters and combat the age-related decrease in the number of neuronal receptors. As with the other two drugs, McDaniel *et al.* found that piracetam did not produce memory improvement in patients with Alzheimer's disease or in old people whose memory was deteriorating.

Vinpocetine

Like many of the other drugs in this section, vinpocetine has been shown to have significant and positive effects on the neurobiology of animals. For example, studies have observed

increases in blood flow and a reduction in the cell loss that results from blood flow loss in animals that were administered the drug. McDaniel *et al.* note that there is some evidence for the efficacy of the drug in humans. They cite three studies showing that administration of the drug to older adults with memory problems resulted in improvements in performance on tests measuring attention, concentration and memory when compared with a similar group that received a placebo drug. The effects of vinpocetine on episodic memory, however, were negligible.

Acetyl-L-carnitine

In animals, this drug has been found to reduce the number of receptor membranes that are lost through normal ageing; it is also thought to remove toxins from the brain. In humans, the drug has been found to increase performance on some memory tests performed by people with Alzheimer's disease but, according to McDaniel *et al.*, there are few significant differences between groups receiving the drug and groups receiving a placebo.

Antioxidants

As organisms age, the appearance of free radicals increases. Free radicals are not helpful to the organism; in fact, they are dangerous and they damage tissue wherever they exist. Antioxidants are drugs that combat the effects of free radicals and the thinking behind their use in studies of memory is that their administration will prevent the damage that these free radicals inflict on neurons. Antioxidants, such as vitamin E, however, have not been associated with any significant or consistent memory improvement in Alzheimer's disease or Parkinson's disease.

McDaniel *et al.* have found that although some studies appear to show positive benefits of drug administration on memory, closer observation of the data shows a more specific pattern of efficacy. A study of the drug Ginkgo-ginseng found an improvement in memory four weeks after drug administration to adults with normal memory (Wesnes *et al.*, 2000). This improvement was sustained for two weeks after the 12-week study. Scores on the memory tests, however, showed that the drug seemed to work only at a certain time of day. McDaniel *et al.* found that there was little difference in memory performance between the placebo and pill groups at 7.30 a.m. but there was a large and robust difference at 2.30 p.m. For almost all tests, performance in the pill group was better in the afternoon. Why?

McDaniel *et al.* suggest that two explanations could account for this improvement. It is well documented that the preference for the morning increases with increasing age. Older people's memory performance is worse in the afternoon than it is in the morning. It is possible, therefore, that in the

Controversies in Psychological Science – *Continued*

Wesnes *et al.* study, the drug helped halt the decline in memory seen in older people in the afternoon. It is also possible, however, that repeated testing resulted in proactive interference for tests completed later in the session. If this hypothesis were correct, you would expect the last test to show the poorest performance. In fact, this was the pattern found in both groups but the pill group outperformed the placebo group. This suggests that an alternative mechanism for the drug may be a reduction in the degree of proactive interference. Both of these explanations are plausible and future studies need to eliminate one or the other. This analysis of one study, however, shows that closer examination of data can reveal more specific patterns of behaviour than those originally presented.

Conclusion

The evidence reviewed by McDaniel *et al.* indicates that the results of studies examining the effects of smart drugs on

memory performance in people with Alzheimer's disease, or older people with impaired memory performance, are patchy but suggestive. As each of the drugs examined claims to exert a specific effect on neuronal structure and function, perhaps it is unrealistic to administer just one of these drugs in the hope of achieving memory benefits; perhaps a combination would be more appropriate. One marketed drug, 'Memory 2000' manufactured by Natural Balance and mentioned in the *Time* magazine piece, already does this. McDaniel *et al.* (p. 35) conclude that the evidence, while not scientifically strong, lays open the possibility that drugs might be effective given in the right context in well-controlled environments. 'The current data', they say, 'do not allow strong scientifically based recommendations for any of these memory nutrients . . . [however,] the data do not allow us to conclude that these nutrients are ineffective in boosting memory.' Given the evidence you have read about the efficacy of 'smart drugs', would you recommend them? Why?

Chapter review

Sensory memory

- Memory is the process of encoding, storing and retrieving information. It exists in three forms: sensory, short-term/working and long-term. The characteristics of each differ, which suggests that they differ physiologically as well.
- Sensory memory provides temporary storage of information until the newly perceived information can be stored in short-term memory.
- Information in sensory memory lasts for only a short time. The partial-report procedure shows that when a visual stimulus is presented in a brief flash, all of the information is available for a short time (iconic memory). If the viewer's attention is directed to one line of information within a few hundred milliseconds of the flash, the information can be transferred into short-term memory. Echoic memory – sensory memory for sound – appears to operate similarly.

Short-term and working memory

- Short-term memory and working memory contain a representation of information that has just been perceived, such as a person's name or telephone number. Although the capacity of short-term memory is limited, we can rehearse the information as long as we choose, thus increasing the likelihood that we will remember it indefinitely.
- Information in short-term memory is encoded according to previously learned rules. Information in long-term memory determines the nature of the encoding.
- Working memory is different from short-term memory in that it allows the short-term storage and manipulation as opposed to simple storage of material in memory.
- Working memory comprises a phonological loop – a store of phonetic, verbal information – a visuospatial scratchpad – a store of spatial information and memories for movement – and a central executive responsible for supervising and updating the content of working memory.
- Short-term memory lasts for about 20 seconds and has a capacity of about seven items. We often simplify large amounts of information by organising it into 'chunks' of information, which can then be more easily rehearsed and remembered.
- When presented with a list of items, we tend to remember the items at the beginning of the list (the primacy effect) and at the end of the list (the recency effect) better than items in the middle of the list.
- The primacy effect occurs presumably because we have a greater opportunity to rehearse items early in the list and thus store them in long-term memory. The recency effect occurs because we can retrieve items at the end of the list from short-term memory.

- The existence of acoustical errors (rather than visual ones) in the task of remembering visually presented letters suggests that information is represented phonologically in short-term memory.
- Loss of information from short-term memory appears to be primarily a result of displacement; new information pushes out old information. However, a small amount of simple decay may also occur.

Learning and encoding in long-term memory

- Long-term memory refers to the very long-term retention of information and appears to consist of physical changes in the brain – probably within the sensory and motor association cortex.
- Consolidation of memories is likely caused by rehearsal of information, which sustains particular neural activities and leads to permanent structural changes in the brain.
- Short-term memories probably involve neural activity (which can be prolonged by rehearsal), whereas long-term memories probably involve permanent structural changes.
- Elaboration is important to learning. Maintenance rehearsal, or simple rote repetition, is usually less effective than elaborative rehearsal, which involves deeper, more meaningful processing.
- Encoding of information to be stored in long-term memory may take place automatically or with effort. Automatic processing of information is usually related to the frequency, timing and place (location) of events. Textbook learning entails effortful processing, most likely because of its complexity.
- Encoding specificity states that the way in which material is stored depends on how the material is retrieved. The most durable and useful memories are encoded in ways that are meaningful.
- Some psychologists have argued that shallow processing is a less effective way of encoding information than is deep processing (levels of processing, therefore, determine the success of retrieval). Critics, however, point out that shallow processing sometimes produces very durable memories, and the distinction between shallow and deep has proved to be impossible to define explicitly.
- Mnemonic systems are strategies used to enhance memory and usually employ information that is already contained in long-term memory and visual imagery. These are useful for remembering lists of items but are less useful for more complex material, such as textbook information.

The organisation of long-term memory

- Episodic memory refers to memories of events and people that are personally meaningful to us; it is synonymous with autobiographical memory.
- Semantic memory refers to memory for knowledge and facts.
- Most psychologists believe that episodic and semantic memories are parts of different systems although this is controversial.
- Explicit memory refers to recollection of information that was deliberately encoded and retrieved; implicit memory refers to memory for information that is unintentionally learned.

Remembering

- Remembering is an automatic process, although we may sometimes work hard at generating thoughts that will help this process along.
- Forgetting information occurs primarily in the first few years after it is learned and the rate of forgetting decreases slowly thereafter. Once we have learned something and retained it for a few years, the chances are that we will remember it for a long time afterwards.
- Recalling a memory of a complex event entails a process of reconstruction that uses old information.
- Our ability to recall information from episodic memory is influenced by retrieval cues, such as the questions people are asked in courts of law to establish how an event occurred. Sometimes, the reconstruction introduces new ‘facts’ that we perceive as memories of what we previously perceived.
- Remembering is strongly influenced by contextual variables involving mood and emotion. Some evidence suggests that remembering is easier when an individual’s mood during the attempt to recall information is the same as it was when that information was originally learned; this is called state-dependent memory.
- We also tend to remember the circumstances that we were in when we first heard of a particularly emotional event such as the death of a famous person, a natural disaster, or an invasion of one country by another; these are called flashbulb memories.
- Sometimes recollecting one memory is made more difficult by the information contained in another memory, a phenomenon known as interference.
- In retroactive interference, recently learned information interferes with recollection of information learned earlier.
- In proactive interference, information learned a while ago interferes with recently learned information.
- Although interference has been demonstrated in the laboratory, interference may not operate so obviously in real life. Prose and other forms of everyday language appear to be more resistant to interference than are the nonsense syllables that people who participate in memory experiments are often required to learn.

Biological basis of memory

- Much of what we have learned about the biological basis of memory comes from studies involving humans with brain damage, from laboratory studies in which animals undergo surgical procedures that produce amnesia, and from neuroimaging studies of memory in healthy individuals.
- Learning seems to involve a strengthening of connections between neurons.
- Hebb proposed that short-term memory resulted from reverberation of the closed loops of the cell assembly; long-term memory is the more structural, lasting change in synaptic connections. This long-term change in structure is thought to reflect long-term potentiation (LTP), a term which describes the strengthening of neuronal connections via repeated stimulation.

- LTP is thought to originate in the hippocampus although it can occur elsewhere in the brain.
- A subtype of glutamate, N-methyl-D-aspartate (NMDA), appears to be important for producing long-term potentiation. NMDA receptors are found in the CA1 sector of the hippocampus; blocking activity in NMDA receptors prevents long-term potentiation in CA1 and the dentate gyrus.
- Anterograde amnesia refers to an inability to learn new memories after brain injury; these individuals can learn to perform many tasks that do not require verbal rules, such as recognising fragmentary pictures. Retrograde amnesia refers to the inability to retrieve remote memories.
- Patient HM showed an inability to store new information in long-term memory as a result of damage to the temporal lobes in general and the hippocampus in particular.
- The hippocampus is important for the learning of new material and for spatial navigation.
- The frontal cortex is involved in working memory and in the encoding and retrieval of material.
- Some recent studies have suggested that ‘smart drugs’ can improve memory function in people with poor memory. Evidence, however, is mixed with most studies showing no significant, positive effects on memory.

Consciousness

Court told of sleep deprivation clue in Selby train case

The man accused of causing the deaths of 10 people in the Selby rail crash had ‘insufficient’ sleep before setting off on his journey to work, a court heard today.

Professor James Horne, from Loughborough University, told a jury at Leeds Court he believed Gary Hart could not have maintained alert driving as he made his way along the M62 towards Great Heck, North Yorkshire. Mr Hart had only had a short nap in the previous 24 hours. [Prof. Horne] added: ‘There is no doubt about it, it was insufficient.’

The prosecution claims that Mr Hart fell asleep at the wheel after chatting for five hours to Kristeen Panter, a woman he had met on the Internet.

Prof. Horne said that drivers were particularly prone to falling asleep at the wheel between 2am and 6am. They were most likely to fall asleep on dull and boring roads where there was little stimulation for the driver, such as the stretch of the M62 ahead of the crash site.

WHAT YOU SHOULD BE ABLE TO DO AFTER READING CHAPTER 9

- Describe what psychologists and philosophers mean by consciousness.
- Understand the problems of studying consciousness.
- Be familiar with theories explaining consciousness.
- Understand the concept of selective and divided attention and give examples of it.
- Describe hypnosis and the reasons for hypnotically induced behaviour.
- Describe the behavioural and psychophysiological stages of sleep.
- Understand theories of sleep.
- Describe the symptoms of sleep disorders and their possible causes.

QUESTIONS TO THINK ABOUT

- What is consciousness?
- Can we measure it?
- Is consciousness unitary?
- How do we manage to attend to some stimuli in the environment while ignoring others?
- What is hypnosis and how does it work?
- How do we selectively attend to information in our environment?
- Why do we sleep?
- What are the effects of sleep deprivation on behaviour?

Explore the accompanying videos, simulations, and animations on MyPsychLab. This chapter includes activities on: Background noise • Split brain • Hypnosis • Sleep and circadian rhythms • Check your understanding and prepare for your exams using the multiple choice, short answer and essay practice tests also available.

Consciousness: an introduction

Consciousness poses the most baffling problems in the science of the mind. There is nothing that we know more intimately than conscious experience, but there is nothing that is harder to explain. *Source: Chalmers, 1995.*

Why are we aware of ourselves, of our thoughts, our perceptions, our actions, our memories and our feelings? Is some purpose served by our ability to realise that we exist, that events occur, that we are doing things and that we have memories? According to James (1890), ‘all people unhesitatingly believe that they feel themselves thinking. This belief is the most fundamental of all postulates of Psychology.’

Philosophers have puzzled over the questions raised above for centuries without finding a convincing answer (Block *et al.*, 1997). Psychologists, however, had generally neglected the problem of consciousness. Early behaviourists, as you saw in Chapter 1, denied that there was anything to explain and argued that the only subject matter for psychological investigation was behaviour, not consciousness. Several psychologists continue to believe that consciousness is a side effect of what we do – an epiphenomenon – that is not intrinsically interesting as a research question or a psychological topic. To illustrate psychology’s lack of interest in this topic, consider the fate of one paper written by the influential neuro-psychologist, Jeffrey Gray. Over three decades ago, Gray (1971) published a paper outlining what he regarded as the hard problems of consciousness. Gray (1998) noted that in the ten years following the publication of the article, he received just two requests for a copy of the paper.

Recent years, however, have seen a revival in the scientific study of consciousness, with philosophers, neuroscientists, mathematicians and psychologists contributing ideas and theories to this area (Penrose, 1989; Dennett, 1991; Crick, 1994; Pinker, 1997; Gray, 1998; Blackmore, 2010).

Once the bane of behaviourists, consciousness is now provoking new research and concepts from psychologists, particularly those who seek the neural basis of consciousness. Popular accounts of theories of consciousness, such as Daniel Dennett’s *Consciousness Explained* and Francis Crick’s *The Astonishing Hypothesis*, reflect a renewed interest in the topic. This chapter reviews current thinking about consciousness and, more importantly, research findings in this complex area.

Philosophical approaches to consciousness

Historically, people have taken three philosophical positions about the nature of consciousness (Block *et al.*, 1997). The first and earliest position is that consciousness

is not a natural phenomenon: it is not subject to the laws of nature that all scientists attempt to discover, laws involving matter and purely physical forces. This position states that consciousness is something supernatural and miraculous, not to be understood by the human mind.

The second position is that consciousness is a natural phenomenon but, for various reasons, we cannot understand it. Consciousness exists because of the nature of the human brain, but just how this occurs is not known. We can never understand consciousness because our brains are simply not capable of doing so; it would take a more complex brain than ours to understand the biology of subjective awareness. An alternative but related view is that everything can be explained, including all aspects of the human brain, but that consciousness is a vague, poorly operationally defined term (Wilkes, 1988; McGinn, 1989).

The third position is that people are indeed conscious, that this consciousness is produced by the activity of the human brain, and that there is every reason for us to be optimistic about our ability to understand this phenomenon (Crick, 1994).

The meaning of ‘consciousness’

Although the word ‘consciousness’ is a noun, ‘consciousness’ itself does not exist. What exists are humans having the ability to do something that we describe as ‘being conscious’. So, then, what does it mean to be conscious? Allport (1988) reported that, ‘I find that I have no clear conception what people are talking about when they talk about consciousness or “phenomenal awareness”, nor, for that matter, when they talk about its linguistic-conceptual Siamese twin, the conscious self.’ Consciousness is a private experience, which cannot be shared directly. We experience our own consciousness but not that of others. We conclude that other people are conscious because they are like us and because they can tell us that they, too, are conscious. This, inevitably, has a subjective quality which makes consciousness difficult to study scientifically.

According to Chalmers (1995), consciousness investigators face easy problems and a hard problem. The easy problems include the ability to discriminate, categorise and react to stimuli, to integrate information by using a cognitive system, to report mental states and to access internal states, to control behaviour deliberately and to differentiate between wakefulness and sleep. All of these features are associated with consciousness but, according to Chalmers, they are the relatively easy topics of consciousness because they primarily involve the contents of consciousness; these features refer to functions or abilities. Understanding (or discovering) the neural correlates of consciousness is also an easy problem, according to Chalmers. A mental state is said to be conscious when this

state can be verbally reportable or internally accessible; the organism is able to be conscious of some information, react to it and explain it. This is another easy problem. But this is only one side of the story. The hard problem lies in studying the experience of these mental events.

When we report these mental events we have an experience of reporting these mental events. Over and above this ability, we have the experience itself. There must be something ‘that it is like’ to be conscious (Nagel, 1974); there is a subjective quality about it and because of this, it poses a difficult problem. These conscious experiences are sometimes referred to as phenomenal consciousness or ‘qualia’. In summary, the easy problems are understanding the functions and neurophysiology of consciousness; the hard problem is explaining why we have the experience of consciousness in the first place. The distinction between easy and hard problems is a controversial one and you yourself would probably challenge the notion that the understanding of the neural correlates of consciousness, for example, represents an easy problem. In the next section, we will consider some of the theories that have been proposed to account for the ‘easy’ and ‘hard’ aspects of consciousness.

Theories of consciousness

Neurobiological theories

Recent years have seen an increased interest from scientists in explaining the nature of consciousness neurobiologically (Gray, 1998). In fact, Chalmers (1998) has listed over twenty proposed neural correlates of consciousness (NCC).

The essence of the neurobiological approach is that consciousness arises from the neural activity of the brain. Neurobiological approaches diverge, however, when they begin to specify which parts or elements of the brain give rise to the activity that is meant to represent consciousness. Neurobiological theories of consciousness derive their data from a number of sources, such as those described in Chapter 4 – neuroimaging and brain damage – and other branches of natural science, such as mathematics and quantum physics. Each type of study has yielded a different perspective on the NCC and some of the most important or influential of these theories are reviewed below.

Consciousness and brain damage

Brain damage can alter human consciousness. Patients with anterograde amnesia, for example, are unable to form new verbal memories but can learn some kinds of

tasks. However, they remain unaware that they have learned something, even when their behaviour indicates that they have. The brain damage does not prevent all kinds of learning, but it does prevent conscious awareness of what has been learned.

As you saw in Chapter 6, there are individuals who, if they have damaged the posterior parts of their brain, show a lack of awareness of stimuli presented to their visual field. Brain damage which impairs the perception of visual stimuli seems also to impair the ability. Blindsight patients have damage to the primary visual cortex and, although they are able to perform some visual perception tasks, they report being unaware of the task stimuli that had been presented in their visual field. Remember from Chapter 6 that individuals with certain types of agnosia are unable to recognise objects or may be unable to ascribe meaning to such objects. Another form of agnosia is characterised by the inability to identify familiar faces by using facial cues alone. All of these disorders involve some lack of awareness and may help us to understand the regional contribution of the brain to conscious awareness.

Blindsight patients have damage to an area called V1, the primary visual cortex. This is the region in the brain to which information from the retina travels. Does the activity of V1 reflect conscious awareness of visual stimuli? Crick and Koch (1995) have proposed the controversial idea that it does not. They argue that it is not involved in conscious visual perception because V1 does not directly project to the frontal cortex (which integrates information from other parts of the cortex); the areas surrounding V1, however – the extrastriate cortex – do, and it is the activity of these areas which may reflect conscious processing. Crick and Koch (1995) admit that this is a subtle and speculative proposal and have not undertaken an empirical test of this hypothesis. It remains an intriguing hypothesis.

Another form of brain damage, this time a surgical procedure designed to eliminate the symptoms of intractable epilepsy, gives rise to what has become known as the **split brain** or **callosal syndrome** (Bogen, 1993). Individuals who suffer epilepsy which cannot be controlled by drugs, experience violent storms of neural activity which begin in one hemisphere and shift to the other via the corpus callosum, the large bundle of axons that connect one cerebral hemisphere to another. This causes an epileptic seizure. These seizures can occur many times each day, preventing the patient from leading a normal life. Neurosurgeons discovered that by severing the corpus callosum, thereby ‘splitting’ the brain, they could reduce the frequency of these seizures (Sperry *et al.*, 1969). This is illustrated in Figure 9.1.

Roger Sperry and Michael Gazzaniga and their associates (Gazzaniga, 1970, 1998; Gazzaniga *et al.*, 1996;

Figure 9.1 The split-brain operation. Holes are drilled in the top of the skull and a cutting device is introduced between the left and right cerebral hemispheres, severing the corpus callosum.

Sperry, 1966) pioneered research into the psychological consequences of **split-brain surgery**. Sperry won the Nobel Prize in 1981 for his work on neurosurgery. Their work, initially with cats, demonstrated that the cerebral cortex of the left and right hemispheres normally exchange information via the corpus callosum. With one exception (described later), each hemisphere receives sensory information from the opposite side of the body and controls muscular movements on that side, as we saw in Chapters 4 and 6. The corpus callosum allows these activities to be coordinated, so that each hemisphere ‘knows’ what is going on in the other hemisphere (Hoptman and Davidson, 1994; Banich, 1995).

When the two hemispheres are disconnected after split-brain surgery, they appear to operate independently; their sensory mechanisms, memories and motor systems no longer appear to exchange information. The effects of these disconnections are not obvious to a casual observer, for the simple reason that only one hemisphere – in most people, as we will see in the next chapter, the left – controls speech. The right hemisphere of an epileptic person with a split brain allows the patient to understand speech reasonably well, but it is poor at reading and spelling. Because Broca’s speech area is located in the left hemisphere, the right hemisphere is totally incapable of producing speech.

Given that only one side of the brain can ‘talk about’ what it is experiencing, a casual observer will not detect the independent operations of the right side of a split

brain. Even the patient’s left brain has to learn about the independent existence of the right brain. One of the first things that these patients say they notice after the operation is that their left hand seems to have a mind of its own. This is called **alien hand** (‘la main étrangère’). For example, patients may find themselves putting down a book held in the left hand, even if they are reading it with great interest. At other times, they surprise themselves by making obscene gestures with the left hand. Because the right hemisphere controls the movements of the left hand, these unexpected movements puzzle the left hemisphere, the side of the brain that controls speech. One hypothesis suggests that the inhibition of actions organised elsewhere, but originating in the frontal cortex, is lost in split-brain patients, hence the appearance of unusual, uninhibited behaviour in one hand. Another, different phenomenon is **intermanual conflict**. This refers to the apparently contradictory activity of the left and right hands; one might do up a set of buttons on a shirt, for example, while the other might undo them (Akelaitis, 1944/45).

If a patient with a split brain tries to use their right hand to arrange blocks to duplicate a geometrical design provided by the experimenter, the hand will hopelessly fumble around with the blocks. Often, the left hand (controlled by the right hemisphere) will brush the right hand aside and easily complete the task. It is as if the right hemisphere gets impatient with the clumsy ineptitude of the hand controlled by the left hemisphere.

The effects of cutting the corpus callosum suggest that consciousness depends on the ability of speech mechanisms in the left hemisphere to receive information from other regions of the brain. If such communication is interrupted, then some kinds of information can never reach consciousness.

There is still some controversy over whether split-brain patients are genuinely unable to perform the tasks that psychologists set them (see Martin, 2006, for a review). The degree to which split-brain patients can make decisions about stimuli presented to the left or right of their visual field may depend on the part of the corpus callosum damaged: normally, not all of the corpus callosum is cut, only parts of it (Sergent, 1987, 1990, 1991). In one study, two out of three patients when presented with circles in each hemifield could indicate which was bigger (Sergent, 1987). There are also other connections between the hemispheres, in addition to those made by the corpus callosum. Some neuropsychologists, such as Sergent, have argued that split-brain patients who do not show the typical split-brain profile are so because these channels of communication are intact – there is still some way in which the hemispheres can transfer information (Seymour *et al.*, 1994).

Crick's astonishing hypothesis

Other neurobiological models of consciousness specify more exact regions and neural elements which give rise to consciousness. Crick's theory (Crick, 1994), for example, suggests that consciousness is the result of the activity of collections of neurons called neural assemblies (this is the astonishing hypothesis). The behaviour of neurons is represented by 35–75 Hz oscillations in the cortex; these oscillations form the basis of consciousness and correlate with awareness in different sensory modalities. According to the theory, oscillation represents the way in which the information we process is bound. The concept of binding is important in consciousness; it refers to the process whereby separate pieces of information about a single entity are brought together and used for processing later (Chalmers, 1995).

Bringing together information about colour and shape to form an image of an object is one example of binding. When elements are bound together, Crick's theory argues, neural groups will oscillate in the same space and time. While Crick's theory has received much attention and credit for specifically tying consciousness to specific brain activity, it has been criticised for not being able to explain the importance of these oscillations. If these oscillations give rise to conscious experience, why? Again, this is exactly Chalmers's 'hard' problem, mentioned earlier.

Penrose's and Hameroff's quantum models

Another neurobiological approach to consciousness focuses on the importance of chaos or non-linear dynamics in explaining consciousness. Much of Penrose's work is rooted in some quite complex physics and mathematics and we need not dwell on the detail here. In essence, Penrose (1989, 1994) argues that consciousness is a form of non-algorithmic processing which is important to conscious mathematical insight (Penrose himself is a famous mathematician). That is, consciousness is not an all-or-nothing, straightforward, linear process; instead, it is an uneven, non-linear process.

Penrose's model relies on an understanding of quantum physics. Quantum physics suggests that although events are observable and seem to follow a logical order, these events themselves are altered by being observed (this is called the Heisenberg Uncertainty Principle). In a revision of the original model, Hameroff and Penrose (1996) and Hameroff (1998) have suggested that consciousness takes place in the skeletal structure of neurons (called **cytoskeleton**), specifically in parts of the neuron called **microtubules**, as seen in Figure 9.2.

Hameroff is an anaesthetist and his ideas have been based on the processes involved in anaesthesia which induce loss of consciousness. For example, under general anaes-

Figure 9.2 The black rods in the diagram represent microtubules. The green dots represent the neurotransmitter released by the presynaptic axon.

Source: From Hameroff, S.R., More neural than thou. In S.R. Hameroff, A.W. Kaszniak and A.C. Scott (eds) *Towards a Science of Consciousness II*. New York: Wiley, 1998.

thetic, individuals should not be able to move purposefully in response to a painful stimulus and should not be able to follow verbal commands (Franks and Lieb, 1998). The general process of anaesthesia is summarised in Table 9.1. There is some evidence that patients may be capable of remembering events/voices in the operating theatre during anaesthesia but this is quite controversial (Andrade, 1995).

Anaesthesia provides probably one of the most interesting challenges to researchers exploring the neural correlates of consciousness. One persuasive theory argues that anaesthesia is produced by blocking or disrupting sensory information that is processed via the thalamus. The activity of the thalamus, therefore, is a critical determinant of unconsciousness. Alkire *et al.* (2000) set up

Table 9.1 Stages of anaesthetic depth

Stage	Description
I	Analgesia. The patient is conscious but drowsy. The degree of analgesia (if any) depends on the anaesthetic
II	Excitement. The patient loses consciousness and does not respond to a non-painful stimulus. The patient may move, talk incoherently, be hypotensive or have other respiratory or cardiovascular irregularities
III	Surgical anaesthesia. Spontaneous movement ceases and ventilation becomes regular. As anaesthesia deepens, various reflexes are lost and the muscles relax
IV	Medullary depression. Respiration and vasomotor control cease, leading to death

PET study in which 11 participants received two types of anaesthesia. Brain activity during anaesthesia/unconsciousness was monitored. The group found that during unconsciousness, there was a significant reduction in output from the thalamus to other parts of the cortex.

In Hameroff's specific model of consciousness, microtubules in the neuron are essential to consciousness. The function of microtubules is to transport material inside the neuron and define the shape of the processes that they inhabit; they, therefore, serve an important neural function. The model suggests that quantum events occur in or around these microtubules and that these events give rise to our conscious experience. It suggests this for a number of reasons, not least the reason that microtubules are important for the functioning of the neuron. However, this model could be criticised on the same grounds as Crick's in the way that it does not explain why such neural events should be associated with consciousness. In fact, Churchland (1998) has suggested that these microtubules might just as well be called pixie dust in the synapses – essence which magically gives rise to consciousness – although Hameroff (1998) has argued that the mechanism by which microtubules give rise to consciousness is detailed and not as vague as pixie dust. The model, because it is derived from data from anaesthesia, is a highly specific neural model of consciousness and, because of this, holds some promise.

Cognitive theories

Cognitive theories of consciousness, although recognising that consciousness arises from the activity of the brain, describe the way in which it occurs in more mentalistic, cognitive terms.

Baars's global workspace theory

The global workspace theory (Baars, 1988; Baars *et al.*, 1998) states that the contents of consciousness are contained in a central processor called a global workspace. This is used to mediate the activity of non-conscious processes. When such processes need to inform the rest of the system, they send information to the workspace, which is a little like a blackboard used by the rest of the system (Baars *et al.*, 1998). The model can thus explain how different types of conscious information are available to us but it does not explain why this information in the global workspace is experienced; in other words it does not solve the 'hard' problem (Chalmers, 1995).

Dennett's multiple drafts

The philosopher and cognitive scientist Daniel Dennett had proposed a complex theory of consciousness that relies on

the idea that consciousness is not an all-or-nothing phenomenon that occurs in exactly the same way whenever it is evoked. Dennett (1991) begins the rationale for his theory by debunking the mind–body interactionism proposed by Descartes. The notion of the Cartesian theatre where mind and body are interacting protagonists is untenable according to Dennett. Instead, he argues that consciousness is not a theatre but the activation of revised collections of sensory information called 'drafts'. Because sensory information is received in various forms and at various times, conscious experience is an updating, constantly revising process a little like an author's manuscript which is in a constant state of redrafting and revision. Conscious experiences, therefore, result from multiple drafts of sensory information which are assembled at particular points in time. You can see why the theory is complex. One criticism of Dennett's theory is that, although it seems to abolish the notion of the Cartesian theatre, he is replacing it with a large number of theatres.

Shanon's theory

Shanon (1990, 1998) has argued, like Dennett and Baars, that consciousness is not unitary. Unlike Dennett and Baars, however, he invokes three components which he regards as making up consciousness: sensed being, mental awareness and reflection. Sensed being distinguishes between animate and living, and inanimate and dead; mental awareness refers to the idea that we are aware of thoughts that pass through our heads, that is, we are aware of the contents of consciousness; reflection refers to the idea that we are aware of our mental computations and that these 'mentations' can be the subject of future 'mentations'. According to Shanon, there are two types of reflection: meta-observation which reflects on the content of mental states, and monitoring or control which checks and evaluates thoughts; this control guides or governs our thinking process. According to Shanon, mental awareness is the core of consciousness whereas sensed being is a prerequisite and reflection is derived from it. How would one go about testing Shanon's theory, however? This would be difficult because the components are vaguely and generally described. It is also open to the criticism that it is too descriptive and actually explains very little.

Selective attention

We do not become conscious of all the stimuli detected by our sensory organs. For example, if you are writing an essay or laboratory practical report while the radio is on in the background and you have to meet an urgent deadline, you probably are unaware of what song is playing

on the radio, or of the noises outside your room, of the hum of the refrigerator. Attention is completely devoted to your work. The process that controls our awareness of particular categories of events in the environment is called **selective attention**.

As you saw in Chapter 8, sensory memory receives more information than it can transfer into short-term (working) memory. Sperling (1960) found that although people could remember only about four or five of the nine letters he flashed onto the screen if they tried to remember them all, they could direct their attention to any of the three lines of letters contained in sensory memory and identify them with perfect accuracy.

The process of selective attention determines which events we become conscious of. Attention may be controlled automatically, as when an intense stimulus (such as a loud sound) captures our attention; it may be controlled by instructions ('Pay attention to that one over there'); or it may be controlled by the demands of the particular task we are performing. For example, when we are driving a car, we pay special attention to other road users, pedestrians, road signs and so on. Our attentional mechanisms serve to enhance our responsiveness to certain stimuli and to tune out irrelevant information.

Attention plays an important role in memory. By exerting control over the information that reaches short-term memory, it determines what information ultimately becomes stored in explicit long-term memory – the portion of long-term memory that we can talk about and can become conscious of, as you saw in Chapter 8. But the storage of information in implicit memory does not require conscious attention. Not all the information we do not pay attention to is lost.

Why does selective attention exist? Why do we not simply process all the information that is being gathered by our sensory receptors? We sometimes miss something important because our attention is occupied elsewhere. According to Broadbent (1958), the answer is that the brain mechanisms responsible for conscious processing of this information have a limited capacity. There is only so much information that these mechanisms can handle at one particular moment. Thus, we need some system to serve as a gatekeeper, controlling the flow of information to this system. The nature of this gatekeeper – selective attention – is the subject of ongoing research.

Dichotic listening

The first experiments to investigate the nature of attention scientifically took advantage of the fact that we have two ears. Cherry (1953) devised a test of selective attention called **dichotic listening**, a task that requires a person to listen to one of two messages presented simultaneously, one to each ear (dichotic means 'divided into two parts'). He placed headphones on his participants and presented recordings of different spoken messages to each ear, illustrated in Figure 9.3.

He asked the participants to shadow the message presented to one ear – to repeat back as quickly but as accurately as possible what that voice was saying. **Shadowing** ensured that they would pay attention only to that message.

The information that entered the unattended ear appeared to be lost. When questioned about what that ear had heard, participants responded that they had heard something, but they could not say what it was.

Figure 9.3 Dichotic listening and shadowing. A person listens to two different spoken messages simultaneously and continuously repeats back what one voice is saying.

Even if the voice presented to the unshadowed ear began to talk in a foreign language or read English backwards, participants do not notice the change (Wood and Cowan, 1995). Shadowing, however, is easier if the messages are physically different, that is, they are spoken by different sexes or one is louder than the other or one is speech and the other non-speech based. See Figure 9.4.

Other evidence shows that selective attention is not achieved by simply closing a sensory channel. Some information, by its very nature, can break through into consciousness. For example, if a person's name is presented to the unattended ear, they will very likely hear it and remember it later (Moray, 1959). Or if the message presented to the unattended ear contains sexually explicit words, people tend to notice them immediately (Nielsen and Sarason, 1981). The fact that some types of information presented to the unattended ear can grab our attention indicates that even unattended information undergoes some verbal analysis. If the unattended information is 'filtered out' at some level, this filtration must not occur until after the sounds are identified as words.

Several studies have shown that information presented to the unattended ear can affect our behaviour even if we do not become conscious of the information. To put it another way, the information can produce implicit memories, memories of which we are unaware (Cleermans, 1993). Von Wright *et al.* (1975) showed that words previously presented along with an unpleasant electrical shock would produce an emotional reaction when the words were presented to the unattended ear. Even when the participant was not consciously attending to the voice, the information produced a non-verbal response – a classically conditioned emotional reaction. Thus, the unattended information could trigger the recall of an implicit memory.

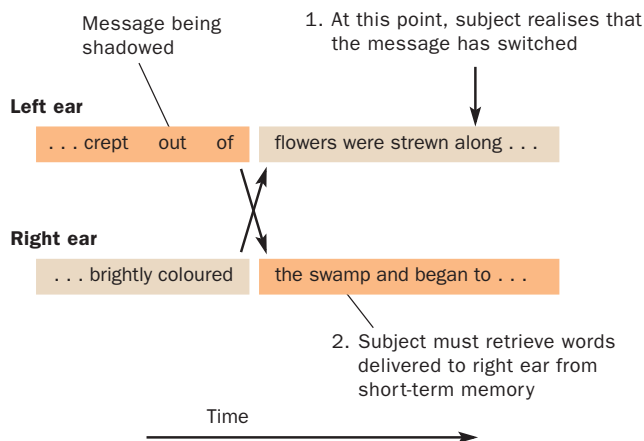

Figure 9.4 Shadowing a message that switches ears. When the message switches, the person must retrieve some words from memory that were heard by the unattended ear.

McKay (1973) showed that information presented to the unattended ear can influence verbal processing even when the listener is not conscious of this information. In the attended ear, participants heard sentences such as:

They threw stones towards the bank yesterday.

While this sentence was being presented, the participants heard the word 'river' or 'money' in the unattended ear. Later, they were asked which of the following sentences they had heard:

They threw stones towards the side of the river yesterday.

They threw stones towards the savings and loan association yesterday.

Of course, the participants had heard neither of these sentences. McKay found that the participants' choices were determined by whether the word 'river' or 'money' was presented to the unattended ear. They did not specifically recall hearing the words presented to the unattended ear, but obviously these words had affected their perception of the meaning of the word 'bank'.

Treisman (1960) showed that people can follow a message that is being shadowed even if it switches from one ear to the other. Suppose a person is shadowing a message presented to the left ear, while the message to the right ear is unshadowed. In the example given in Figure 9.4, the person will probably say 'crept out of the swamp' and not 'crept out of flowers'. Apparently, the switch occurs when the message begins to make no sense. However, by the time the person realises that 'crept out of flowers' makes no sense, the rest of the message, 'the swamp', has already been presented to the right ear. Because the person is able to continue the message without missing any words, he or she must be able to retrieve some words from memory. Thus, even though an unshadowed message cannot be remembered later, it produces some trace that can be retrieved if attention is directed to it soon after the words are presented.

The cocktail-party phenomenon

Selective attention to auditory messages has practical significance outside the laboratory. For example, sometimes we have to sort out one message from several others without the benefit of such a distinct cue; we seldom hear one voice in one ear and another voice

Controversies in Psychological Science – Does mobile phone use impair your driving?

The issue

The sale of mobile phones has been one of the marketing successes of the past few years: approximately 1 billion of them were in use worldwide in 2002 and it is estimated that 2.6 billion will be in use by the end of 2009. Mobile phones are portable, convenient and handy. So handy, that people often use them while doing other things. Surveys suggest that around 80 per cent of mobile phone users report having used the device while driving, despite the use of such devices being illegal in many countries (Goodman *et al.*, 1999). In 2003, for example, the UK passed an amendment to the Road Vehicles Act which made it an offence to drive a motor vehicle on a road while using a hand-held telephone (although not hands-free sets). The rationale for the ban is that factors such as holding the phone or dialling a number cause significant distraction and lack of control over the vehicle. Is there scientific evidence for this assumption?

The evidence

Strayer and Johnston (2001) have suggested that it is not the physical handling of mobile phones that leads to accidents but the conversations people have on them. They measured the errors made by drivers in a simulated driving task. These drivers either listened to a radio, listened to a book on tape, performed a word shadowing exercise on a mobile phone, held a conversation on a mobile phone or held a conversation using a hands-free set.

The authors cite previous studies that have shown a relationship between phone use and driving accidents. Redelmeier and Tibshirani's study (1997) of the phone records of those involved in driving accidents found that 24 per cent of people used their

phones within the 10 minutes before the accident. They argued that this rate suggested a danger that was as great as having excess alcohol in your bloodstream. Strayer and Johnston suggest that while the relationship appears causal, there may be other factors, such as the personality and disposition of the drivers, which caused the accident. Furthermore the study did not consider the conversational aspect of telephone use, although a study by Briem and Hedman (1995) suggested that holding a simple conversation did not significantly impair the ability to stay on the road.

Strayer and Johnston tested two hypotheses. The peripheral-interference hypothesis attributes driving accidents to non-conversational uses of the mobile phone such as holding and dialling. The attentional hypothesis attributes any driving impairment to the nature of the conversation taking place on the mobile phone.

In their simulated driving experiment, 48 undergraduates used a joystick to operate a cursor which they moved to follow a moving target on a computer screen. The target would move unpredictably, although not suddenly. Sporadically a green or red light would appear. If a green light appeared, the participant was asked to continue; if the red light appeared they were told to press a button which represented the brake on the joystick. The participants either conversed with a confederate on a mobile phone – they discussed President Bill Clinton's potential impeachment, and the Salt Lake City Olympic Committee bribery scandal – or conversed with a hands-free set or listened to a radio broadcast (which they could choose). The researchers found that the probability of missing a red light almost doubled when participants talked on the phone – whether hands-free or hand-held – compared with when they listened to the radio. There was no significant difference in the error rate between the two phone groups. Not only was the miss rate higher in these two groups, they were also slower to respond to the lights, as Figure 9.5 shows. People drove more poorly during the 'talking' portion of the conversation than the 'listening' portion.

To check that participants were listening to the material in the control condition – the authors did not assess this in their first experiment – and to ensure that the control condition was speech rather than music and speech-based, a second experiment required participants to complete the same simulated driving task but one group listened to a book on tape. This group did not perform significantly worse than the phone groups, suggesting that attending to verbal material is not enough to impair driving: active engagement in conversation is necessary for errors to be committed.

A hands-free set causes less distraction than a hand-held phone, when driving, but research suggests that it is the conversation you have that causes inattention'

Controversies in Psychological Science – Continued

Figure 9.5 The probability of missing a red traffic light **(a)** and the reaction time to changing signals **(b)** when participants either performed the tracking task or performed the tracking task while having a conversation on a mobile phone or listening to the radio.

Source: Strayer, D.L. and Johnston W.A., Driven to distraction: Dual-task studies of simulated driving and conversing on a cellular telephone. *Psychological Science*, 2001, 12(6), 462–6, reprinted by permission of Blackwell Publishers Ltd.

In a final experiment, participants performed easy or difficult versions of the simulated driving task as they either repeated a word said to them by the experimenter over a mobile phone or as they generated a word beginning with a letter given to them by the experimenter over a mobile phone. While errors increased from the easy to the difficult conditions in the control (no phone) and dual-task (phone conditions), generating words was associated with significantly poorer performance than was the word repetition condition. This poor performance was especially pronounced in the difficult condition.

Conclusion

Strayer and Johnston provide persuasive evidence that holding a conversation on a mobile phone can impair driving. They

suggest that the use of mobile phones while driving can impair attention when the context is an engaging one and not associated with the driving. Interestingly, they point to a study showing that as driving difficulty increases, conversation decreases (Parks, 1991). They also draw attention to the perhaps salient fact that, while eating a sandwich or holding a phone are activities under the sole control of the driver, a telephone conversation is not, and perhaps it is this lack of control which impairs driving performance.

This study is an intriguing one because it appears to contradict received and, indeed, legal wisdom: mobile phones do not cause accidents; conversations do.

in the other. We might be trying to converse with one person while we are in a room with several other people who are carrying on their own conversations. We can usually sort out one voice from another – an example of the **cocktail-party phenomenon**.

In this case, we are trying to listen to the person opposite us and to ignore the cross-conversation of the people to our left and right. Our ears receive a jumble of sounds, but we are able to pick out the ones we want, stringing them together into a meaningful message and ignoring the rest. This task takes some effort; following one person's conversation in such circumstances is more

difficult when what they are saying is not very interesting. If we overhear a few words of another conversation that seems more interesting, it is hard to strain out the cross-conversation.

The original cocktail party effect study was reported in 1959 by Moray. The laboratory finding seemed to mirror that of hearing one's name mentioned in someone else's conversation at a party even though you were not attending to that conversation. However, in Moray's study, only 33 per cent of participants responded in this way. Is there some fundamental, psychological difference, therefore, between those who attend and those who do not, and

would such a difference reflect different means of processing auditory or cognitive information?

According to a recent study, this difference could be working memory (Conway *et al.*, 2001). The researchers hypothesised that the least capable participants identified their names because they failed to demonstrate the working memory facility which would allow them to attend to the channel that they were meant to be attending to and ignore the channel they were not meant to.

Participants in the experiment were asked to complete a selective listening exercise similar to that of Moray. Participants listened to messages through headphones but were told only to attend to one channel; the participant's name would occur in the unattended channel. Participants also completed a working memory exercise that involved reading a simple mathematical equation followed by a word (e.g. 'Is $(6 + 4)/2 = 5$? DOG'), solving the equations and, at the end of all trials, writing down as many of the presented words as they could remember. The number of equation and word displays in each trial varied between two and six.

Those who excelled at this task were significantly better at ignoring their name than were those who performed less well.

The critical factor seems to be the ability to block information from the irrelevant message. High-span subjects are more capable of this and were, therefore, less likely to hear their names, and they were also less susceptible to a consequential disruption of relevant task performance. Conway *et al.* 2005.

One of the behaviours we have become increasingly engaged in and which involves selective attention is mobile phone use. The use of these handsets has exploded over the past decade but their widespread availability and convenience has prompted some concern that they may be dangerous to use when, for example, driving. The assumption behind the concern is that holding a phone while driving reduces the controllability of the vehicle, impairs attention and, therefore, poses a threat to driver, pedestrians and other road users. But is there any scientific merit in this assumption? The Controversies in Psychological Science box above tackles this question and describes some recent, counter-intuitive findings.

Background noise

implications. Background noise, for example, is common in office environments and is a source of interference in open-plan offices (Klitzman and Stellman, 1989). Although there are very few controlled scientific experiments, existing studies report that background office noise is associated with stress, lack of concentration, low levels of performance and reduced employee efficiency (Loewen and Suedfeld, 1992; Sundstrom *et al.*, 1994).

Of course, we would not expect background noise to interfere with every type of behaviour. Music played in the background, for example, may even improve our performance. Are there specific auditory stimuli, therefore, that selectively impair the performance of specific tasks? Salame and Baddeley (1982), for example, have suggested that performance on a cognitive task can only be disrupted if the auditory stimulus doing the disruption is speech; others have suggested that stimuli other than speech can affect performance, giving rise to what has been termed the irrelevant speech effect (LeCompte *et al.*, 1997). The irrelevant speech effect suggests that any disruptive sound (delivered at conversational level) can impair memory for verbal material during serial (that is, when the material has to be recalled in a specific order) and free recall (Salame and Baddeley, 1990; Jones, 1995). An alternative to the speech effect is that the noise which disrupts performance has to show some variation (rather than being speech-like) before recall is disrupted. This is called the changing state hypothesis (Jones *et al.*, 1992). This theory would suggest that, in an office environment, performance would be disrupted by speech plus office noise.

To test this hypothesis, Banbury and Berry (1998) exposed undergraduates to office noise with speech, office noise without speech, speech alone or no noise while they (1) memorised a prose passage describing martial arts instructions for the correct and incorrect way of stretching muscles, and (2) solved a variety of arithmetical problems (division and subtraction). Memory for the prose passage was measured shortly afterwards. The experimenters found that office noise with speech and speech alone had a detrimental effect on memory for the prose passage; individuals in the office noise without speech condition, however, did not perform significantly differently from the control group, suggesting that the speech component of the noise was important (as Salame and Baddeley suggested). All three noise conditions, however, were associated with deficits in arithmetic performance. The experimenters noted that individuals were exposed to a greater duration of noise during the arithmetic task. Before the irrelevant speech effect explanation could be ruled out, therefore, the experimenters

The opposite phenomenon to attention – where we try to exclude (become less conscious of) auditory information – has great practical

Noise – An international perspective

The consequences of auditory distraction are discussed in Dylan Jones's review, 'The cognitive psychology of auditory distraction' (Jones, 1999).

When a person's attention is directed elsewhere what degree of processing is undertaken on the material that the person is asked to ignore? Are all possible stimuli registered? Is their processing rudimentary, not going beyond, say, the representation of physical features, or is meaning also extracted? Jones, 1999.

A study of Dutch and Russian secretaries suggests that processing may be rudimentary. Zijlstra *et al.* (1999) looked at the work performance and psychological well-being of secretaries who were interrupted while undertaking a text-editing task. Contrary to expectations, interruptions made the participants work more quickly but no less efficiently, although these interruptions required more cognitive effort to deal with them. One strategy employed by participants was to ensure that their work had 'closure': that is, if they were interrupted mid-task, they would complete that task before dealing with the interruption. This would explain the increased speed in task performance.

These interruptions might be expected in a work environment and we may learn to adopt different strategies to avoid or ignore them. Noise over which we have little direct control may be more difficult to cope with. Aircraft noise or the noise of trains if you live under an airport flight path or near a railway track are examples of stimuli which can cause psychological impairment and annoyance. It has been estimated that 25 per cent of people in Europe have been exposed to noise level of 65dB or above (Berglund and Lindvall, 1995) and such people complain about the annoyance, the lack of sleep and the disruption to cognitive function that the noise causes (Smith and Jones, 1992).

Exposure to noise in children is correlated with deficits in reading, speech perception and long-term memory deficits (Evans and Lepore, 1993). Reading ability and long-term memory performance in children living next to a noisy, newly built airport in Munich was found to be severely impaired; those who had been exposed to airport noise and now lived near the old, closed airport, showed improvements in these tasks (Hygge *et al.*, 2002). Short-term memory also improved when the old airport closed.

suggested that length of exposure to noise needed to be extended in the prose recall condition. This they did by exposing individuals to office noise with speech, office noise without speech, meaningless speech or no noise during acquisition of the prose and during recall.

Extending the exposure period from five to nine minutes significantly and detrimentally affected memory performance when participants were exposed to office noise without speech and meaningless speech (duration did not affect performance in the office noise with speech condition). The greater impairment with greater exposure supported the results of other studies which showed that increasing the number of irrelevant background words presented during a primary task resulted in poorer memory performance (Bridges and Jones, 1996). This study, therefore, suggests that different categories of noise affect ongoing cognitive activity differently.

Models of selective attention

With all this evidence suggesting the robustness of selective attention, are we any closer to understanding how we selectively attend? In cognitive psychology, models of selective attention have been broadly divided into two: early selection models and late selection models. We consider the early selection models here.

Early selection models

The primary feature of early selection models (ESM) is that if items are not attended to they are not selected for perceptual analysis and so play no further part in information processing. Late selection models, on the other hand, argue that all information is attended to and is only selected later on in the information processing chain, that is, after perceptual analysis of the stimuli. Most of the influential ESM models were developed in the 1950s and 1960s when organisational psychology was making large inroads into workforce behaviour. Psychologists such as Donald Broadbent were interested in how psychological principles could be applied to understanding real-life problems, such as operating air traffic control systems or navigating a plane, both of which require extraordinary attention and selective attention.

Broadbent (1958) proposed a model of attention which was popular at the time because it was testable and falsifiable. However, evidence has shown that features of the model were incorrect. Broadbent proposed a filter theory of attention which suggested that processing information was a little like the operation of a filtering system: a channel of communication would process information and transmit this information to other cognitive systems for analysis. Specifically, Broadbent

suggested that this filter initially processes information from a 'sensory store' and transfers it to other cognitive systems. This was an all-or-nothing model: only selected material would pass through the filter system. This selected material would then make its way to a limited capacity P(erceptual) system which would identify the material.

The all-or-nothing feature of the model can certainly explain why material presented to the unattended ear in dichotic listening experiments is not processed. A series of experiments by Moray (1959), however, suggested that the basic feature of the model was wrong. Moray found that when participants were instructed to switch attention from one ear to another during the experiment, they were able to do this when the instruction was along the lines of, 'Robyn, switch ears.' According to the model, this channel should have been blocked and should have remained unattended to: the participant should have been attending exclusively to another channel. Another set of experiments also demonstrated that listeners could follow messages that were switched from one ear to the other. For example, a narrative would begin in one ear and be switched to the previously unattended ear (Treisman, 1960, 1964). Participants, contrary to the filter model, would switch attention to the unattended ear to follow the narrative.

Treisman proposed her own model of selective attention which was 'weaker' than that of Broadbent. She argued that selective attention is certainly an early information processing activity but that not only would attended messages get through to the system, but unattended material would also get through but in weakened, attenuated form. This is called the attenuation model (Treisman, 1960).

Visual information

Sperling's studies of sensory memory, discussed in Chapter 8, demonstrated the role of attention in selectively transferring visual information into verbal short-term memory (or, for our purposes, into consciousness). Other psychologists have studied this phenomenon in more detail. For example, Posner *et al.* (1980) had participants watch a computer-controlled video display screen as a small mark in the centre of the screen served as a fixation point for the participants' gaze. They were shown a warning stimulus near the fixation point followed by a target stimulus – a letter displayed to the left or the right of the fixation point. The warning stimulus consisted of either an arrow pointing right or left or simply a plus sign. The arrows served as cues to the par-

ticipants to expect the letter to occur either to the right or to the left. The plus sign served as a neutral stimulus, containing no spatial information. The participants' task was to press a button as soon as they detected the letter.

Eighty per cent of the time, the arrow accurately pointed towards the location in which the letter would be presented. However, 20 per cent of the time, the arrow pointed away from the location in which it would occur. The advance warning clearly had an effect on the participants' response times: when they were correctly informed of the location of the letter, they responded faster. This is illustrated in the graph in Figure 9.6.

This study shows that selective attention can influence the detection of visual stimuli: if a stimulus occurs where we expect it, we perceive it more quickly; if it occurs where we do not expect it, we perceive it more slowly. Thus, people can follow instructions to direct their attention to particular locations in the visual field. Because gaze remained fixed on the centre of the screen in this study, this movement of attention was independent of eye movement. How does this focusing of attention work neurologically? The most likely explanation seems to be that neural circuits that detect a particular kind of stimulus are somehow sensitised, so that they can more easily detect that stimulus. In this case, the mechanism of selective attention sensitised the neural circuits that detect visual stimuli in a particular region.

Figure 9.6 Location as a cue for selective attention. Mean reaction time in response to a letter displayed on a screen after subjects received a cue directing attention towards the location in which the letter appears was less than when no cue or an incorrect cue was received.

Inattention blindness

Sometimes we don't see a visual stimulus because our attention has been drawn to something else, even if this something else is near the stimulus we can't see or is above or behind it. For example, if we are asked to fixate on a particular task or a spot on a screen, we can often ignore objects that ordinarily we would have no trouble seeing in perception. This phenomenon is called **inattention blindness** (Mack and Rock, 1998). It is similar to another seen in perception – change blindness – where participants do not notice (even very large) changes in the stimuli they are viewing if their attention is directed elsewhere. Examples include a failure to notice that the heads in two photographs have been switched – the switch would need to occur during an eye movement, otherwise it would be detectable (Grimes, 1996); and a failure to notice that a person giving directions has changed to another as a door was being carried between them (Simons and Levin, 1998).

In Mack and Rock's experiments, participants were asked to indicate which of the two arms of a visually presented cross was longer. At the fourth trial, an unexpected object was presented at the same time as the cross and participants were asked whether they were aware of this object appearing. The next trials followed, with participants being told that an unexpected object might appear, and a final trial explicitly asked participants to look for an unexpected object. Around 75 per cent of participants did not recognise the appearance of an object when they were not directed to be aware of it, or had their attention directly drawn to it. Twenty-five per cent of participants failed to do this under the other (divided/full attention) conditions.

The inattention blindness effect can be seen in the most extraordinary contexts. A few years ago, a cinema advert (also available via youtube.com) was screened in which the viewers watched a basketball game between non-professional players. Cinema-goers were asked to pay attention to the number of passes made by the team in black or the team in white. After this, they were asked 'Did you see the gorilla?' This odd question was not as odd as the audience's reaction. Hardly any had seen the gorilla, even though a man in a gorilla suit walked along the screen during the game as the players participated.

The advert is based on an actual experiment designed and conducted by Daniel Simons and Christopher Chabris (Simons and Chabris, 1999). The audience behaved as the participants in their study behaved and the inattention blindness was seen for a man who walked across the screen carrying an umbrella and even for the gorilla when it walked along the screen, stopped in the middle, turned to face the front, thumped its chest, turned and walked to the other side of the screen. This segment took nine seconds. The whole film lasted 62 seconds. You can see shots of the film in Figure 9.7.

Divided attention

Although all people seem to attend selectively to stimuli in the environment, they also sometimes have to undertake tasks that are made up of multiple components. Imagine cooking a meal, for example. Monitoring your boiling pasta while chopping up peppers and warming up your bolognese sauce requires you to attend to several stimuli. When attention is split in this way it is called **divided attention**.

Figure 9.7 Shots from Simon's gorilla and umbrella films

Source: Simons, D. J. and Chabris, C. F. Gorillas in our midst: sustained inattention blindness for dynamic events. *Perception*, 1999, 28, 1059–74.

Various models have sought to explain divided attention and how we can (or, more often, cannot) undertake many tasks all at once. Single-capacity models, for example, suggest that there is one pool of resources available to deal with perceptual and cognitive challenges (Kahneman, 1973). You can probably gather from this that the more tasks an individual undertakes, the less capacity will be left to undertake these tasks effectively because each task is competing for the same pool of resources.

Resources are, then, normally allocated to the most important task. Single-capacity model theorists have found some support for this proposition in experiments where individuals have to undertake two tasks simultaneously (this is called **dual-task methodology**). When this occurs, performance on both tasks diminishes. Results like these suggest that when the resources necessary to complete tasks exceed the available single capacity, then performance will deteriorate. However, not all evidence supports this view. The anecdotal example of preparing a meal is one subjective example. Experiments in which typists were asked to transcribe text and complete a shadowing task at the same time found the participants were able to do this effectively (Shaffer, 1975). Sometimes, two tasks can be performed as well as one can.

An alternative to the single resource models are the multiple resource models. These argue that, in fact, we have several resource pools to deal with various cognitive and perceptual processes. It is because of these various pools that we can divide our attention between tasks successfully. These models suggest that when two tasks compete for the same resource, this will result in an impairment in task performance. When tasks compete for different resource pools, then they should be performed successfully. A problem with the resource model, however, is operationally defining a resource and the types of task that would use the different 'resources'. There is no general agreement on what the different types of resources are.

A final explanation for divided attention concerns the processes involved in various tasks. For example, Johnston and Heinz (1978) suggest that selective and divided attention clearly requires some form of selection. They divide the type of selection required into early (selecting perceptual/sensory information) and late (selecting meaning). Their process model does not agree that there is one structure or system which allows attention. It argues that early selection uses less capacity than late selection. To test this hypothesis, they asked participants to undertake a dichotic listening task where the stimuli differed in terms of their physical features (perceptual) or in terms of their meaning (semantic).

Concurrently, the participants undertook a reaction time task in which they had to press a button as soon as a light appeared. The experimenters found that although reaction time was slower when the participants listened to two messages, less capacity was required when the messages differed perceptually (such as the speaker's voice).

Brain mechanisms of selective attention

As we discussed earlier, one possible explanation for selective attention is that some components of the brain's sensory system are temporarily sensitised, which enhances their ability to detect particular categories of stimuli. For example, if a person were watching for changes in shapes, colours or movements (that is, if the person's attention were focused on one of these attributes), we might expect to see increased activity in the portions of the visual cortex devoted to the analysis of shapes, colours or movements.

This result is exactly what Corbetta *et al.* (1991) found. These investigators had participants look at a computerised display containing 30 coloured rectangles, which could change in shape, colour or speed of movement. The participants were asked to say whether they detected a change. On some trials, the participants were told to pay attention only to one attribute: shape, colour or speed of movement. The stimuli were counterbalanced so that the same set of displays was presented during each condition. Thus, the only difference between the conditions was the type of stimulus change that the participants were watching for.

In a PET study of brain activity during game watching, the experimenters found that paying attention to shape, colour or speed of movement caused activation of different regions of the visual association cortex. The locations corresponded almost precisely to the regions other studies have shown to be activated by shapes, colours or movements. Thus, selective attention towards different attributes of visual stimuli is accompanied by activation of the appropriate regions of the visual association cortex.

The left and right cerebral hemispheres seem to play different roles in attention. Focal attention (which involves attention to local cues) depends on the left hemisphere, whereas global attention (a holistic approach which takes in whole objects or scenes) is dependent on the right hemisphere (Fink *et al.*, 1996). This asymmetry of function may explain the symptoms seen in the perceptual disorder, spatial neglect, described in Chapter 6, in which brain-injured (usually right-hemisphere-damaged) patients are unable to report or respond to stimuli contralateral to the side of the brain injury.

Sustained attention has been associated with increased activation in the right prefrontal and parietal cortices,

based on PET and fMRI findings, but generally there is a network of regions traversing the right fronto-parietal regions that are involved in sustained attention (Coull *et al.*, 1996), as Figure 9.8 shows.

Selective attention has been associated with increases in activation in posterior regions, but the region of activation depends on the type of attention that is selectively applied. If one sensory modality is attended to, regions associated with other modalities show suppressed activation (Haxby *et al.*, 1994; Ghatan *et al.*, 1998). Attending to a stimulus's movement has been associated with activation in the occipito-temporal region (Beauchamp *et al.*, 1997), with the prefrontal cortex and the cerebellum possibly modulating attention (Rees *et al.*, 1997a). Divided attention also recruits the prefrontal cortex, especially the left (Benedict *et al.*, 1998; Vandenberghe *et al.*, 1997). Posner and Petersen (1990) have characterised the ability to shift attention in three ways: the first component of attention allows the disengagement of attention from its current location (a function of the posterior parietal cortex); the second guides attention from the current location to the new location (a function of the superior colliculus, frontal eye fields and related structures); the third component allows the re-engagement of attention to the new location (a function of the thalamus).

Control of consciousness

Every culture appears to have methods of altering consciousness, from the ingestion of coffee, tea, alcohol or

tobacco to taking marijuana or cocaine. Some of these you read about in Chapter 4. The urge to alter, expand, or even escape from one's consciousness does not require the use of drugs, however. There is some evidence that self-control may help to alter consciousness. The ancient Hebrews and early Christians often fasted for many days, undoubtedly because of the effects that their altered metabolism had on their consciousnesses. In earlier times, there was also much more emphasis on ritualised chants and movements, such as those of the early Jewish Hasidim and Cabbalists. In fact, the Christian Pentecostal sect and the Jewish Hasidic sects today practise dances and chanting that would not seem strange to thirteenth-century mystics, and these rituals encourage the 'taking over' of one's consciousness.

The one function that all methods of changing consciousness have in common is an alteration in attention. The various exercises can be divided into those that withdraw attention from the stimuli around us and those that increase attention to events that have become so commonplace that we no longer notice them, including our own behaviours that have become automatic and relatively non-conscious. We refer to exercises in both categories as meditation. Forms of meditation have developed in almost every culture. Zen Buddhism, Yoga, Sufism and Taoism are the best-known and most influential in Eastern societies, where they first developed, but there is also a tradition of meditation and contemplation in the Western world, still carried on in Christian monasteries. Even the ritualised recitation of the rosary and the clicking of the beads serve to focus a person's attention on the prayer they are chanting.

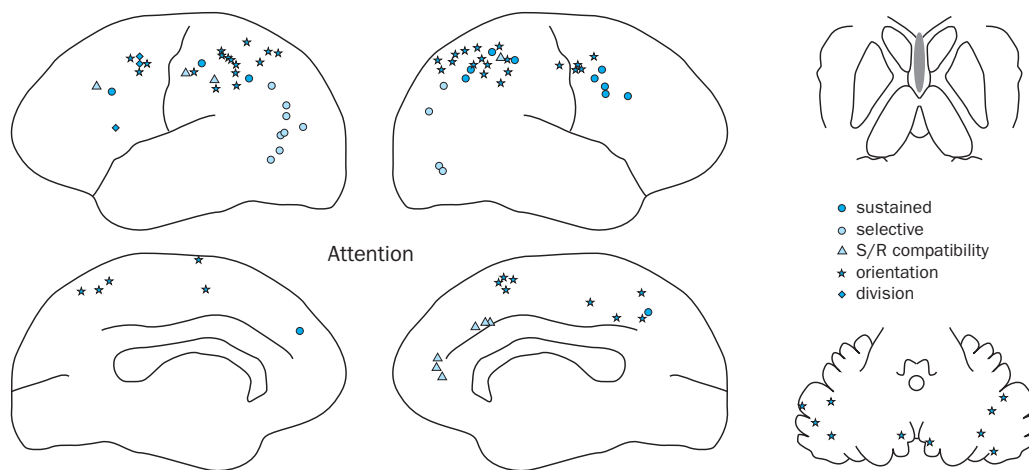

Figure 9.8 The areas of the brain involved in attention, according to recent neuroimaging data.

Source: Figure 4.6 from *Human Neuropsychology*, 2nd edn, Pearson/Prentice Hall (Martin, G.N., 2006).

Techniques for withdrawing attention

The goal of most meditation exercises is to remove attention from all sensory stimuli – to think of absolutely nothing. The various techniques require that the meditator directs their attention to a single object (such as a specially prepared symbol), to a spoken or imagined word or phrase (such as a prayer or mantra), to a monotonous sound (such as the rushing of a waterfall), or to a repetitive movement, such as breathing or touching the tips of each of the four fingers with the thumb (West, 1996).

By concentrating on an object, a sound or a repetitive movement we can learn to ignore other stimuli, a process called mental absorption. We achieve this kind of focus to some degree when we read a book intently or attempt to solve a problem. The difference is that the book or problem supplies a changing form of stimulation. Thoughts, words, images and ideas flow through our minds. In contrast, a person attempting to achieve a meditative trance selects an inherently static object of attention that leads to habituation. By concentrating on this unchanging source of information, continually bringing his or her attention back to it, the person achieves a state of utter concentration or nothing. Withdrawal of attention appears to have two primary goals: to reduce verbal control over non-verbal functions of the brain and to produce afterwards a ‘rebound phenomenon’ – a heightening of awareness and an increase

in attention. The second goal is identical to that of consciousness-increasing exercises. Techniques similar to those found in attention withdrawal are used to achieve a hypnotic trance and these are reviewed in the next section on hypnosis.

Hypnosis

Hypnosis is a process whereby verbal suggestions made by one individual can be acted on by another who would not normally and voluntarily perform those acts. Under hypnosis, a person can be induced to bark like a dog, act like a baby or tolerate being pierced with needles. Although these examples are interesting and amusing, hypnosis is important to psychology because it provides information about the nature of consciousness and has applications in the fields of medicine and psychotherapy.

Hypnosis, or **mesmerism**, was discovered by Franz Anton Mesmer (1734–1815), an Austrian physician. He found that when he passed magnets back and forth over people’s bodies (in an attempt to restore their ‘magnetic fluxes’ and cure them of disease), they would often have convulsions and enter a trance-like state during which almost miraculous cures

Psychology in action – Attention and pain

It was once thought that distraction was enough to help people take their mind off pain. Some studies, however, have shown that it is not necessarily distraction that is responsible for reducing pain but rather the emotional quality of the distractor. Positive stimuli, such as humour and laughter, are known to reduce pain perception (Cogan *et al.*, 1987; Rotton and Shats, 1996) but increasing the attention required to complete cognitive tasks (distraction without emotion) does not (McCaul and Malott, 1984).

Minet de Wied and Marinus Verbaten from Utrecht University, the Netherlands, investigated whether high- and low-arousing neutral, negative or positive emotional stimuli affected people’s experience of pain (de Wied and Verbaten, 2001). They presented pictures varying in emotional tone and arousal from the International Affective Picture System to 69 male students. The researchers hypothesised that if stimuli need to be emotionally distracting to reduce pain, then negative and positive pictures should reduce the experience of

pain in a similar way. If stimuli prime the participant or help them appraise their state (so that a pleasant stimulus may put them in a positive mood but an unpleasant stimulus may put them in a negative mood), then pleasant and unpleasant stimuli will have different effects on the experience of pain. The pain induction task used was the cold-pressor task in which the participant keeps their arm in freezing water for as long as possible.

Exposure to pleasant pictures was associated with a greater tolerance of pain. In a second experiment, in which unpleasant pictures which contained either pain-related or pain-unrelated stimuli were presented, participants who viewed the pictures without pain cues tolerated the pain for longer than did those who viewed the pictures with pain cues. The results suggest that distraction by emotional cue may not be successful in reducing the experience of pain unless the distractor enhances positive mood (or does not produce a negative one, as experiment two showed).

could be achieved. As Mesmer discovered later, the patients were not affected directly by the magnetism of the iron rods; they were responding to his undoubtedly persuasive and compelling personality. We now know that convulsions and trance-like states do not necessarily accompany hypnosis, and we also know that hypnosis does not cure physical illnesses. Mesmer's patients apparently had psychologically produced symptoms that were alleviated by suggestions made while they were hypnotised.

The induction of hypnosis

A person undergoing hypnosis can be alert, relaxed, tense, lying quietly or exercising vigorously. There is no need to move an object in front of someone's face or to say 'you are getting sleepy'; an enormous variety of techniques can be used to induce hypnosis in a susceptible person. The only essential feature seems to be the participant's understanding that they are to be hypnotised. Moss (1965) reported having sometimes simply said to a well-practised subject, in a normal tone of voice, 'Please sit in that chair and go into hypnosis', and the subject complied within a few seconds. Sometimes, this approach even worked on volunteers who had never been hypnotised before.

The induction process normally involves suggestions for sleep or relaxation, followed by a set of suggestions aimed to produce arm lowering or lifting, hand clasp (‘you cannot separate your hands’), hallucinations and amnesia.

Characteristics of hypnosis

Hypnotised people are very suggestible; their behaviour will conform with what the hypnotist says, even to the extent that they may appear to misperceive reality (Wagstaff, 1996). Under hypnosis, people can be instructed to do things that they would not be expected to do under normal conditions, such as acting out imaginary scenes or pretending to be an animal. Hypnotised people can be convinced that an arm cannot move or is insensitive to pain, and they then act as if that is the case. They can also be persuaded to have positive or negative hallucinations – to see things that are not there or not to see objects that are there.

One of the most dramatic phenomena of hypnosis is **posthypnotic suggestibility**, in which a person is given instructions under hypnosis and follows those instructions after returning to a non-hypnotised state. For example, a hypnotist might tell a man that he will become unbearably thirsty when he sees the hypnotist

Hypnos. The son of Nyx (night) and brother of Thanatos (death), the mythical Hypnos was thought to fan the weary to sleep.

Source: British Museum, London/The Bridgeman Art Library.

look at her watch. She might also admonish him not to remember anything upon leaving the hypnotic state, so that **posthypnotic amnesia** is also achieved. After leaving the hypnotic state, the man acts normally and professes ignorance of what he perceived and did during hypnosis, perhaps even apologising for not having succumbed to hypnosis. The hypnotist later looks at her watch, and the man suddenly leaves the room to get a drink of water.

Studies indicate that when changes in perception are induced in hypnotised people, the changes occur not in the people's actual perceptions but in their verbal reports about their perceptions. For example, Miller *et al.* (1973) used the Ponzo illusion to test the effects of hypnotically induced blindness. This effect is produced by the presence of the slanted lines to the left and right of two horizontal ones; if these lines are not present, the horizontal lines appear to be the same length. Through hypnotic suggestion, the experimenters made the slanted lines 'disappear'. But even though the participants reported that they could not see the slanted lines, they still perceived the upper line as being longer than the lower one. This result indicates that the visual system continues to process sensory information during hypnotically induced blindness; otherwise, the participants would have perceived the lines as being equal in length. The reported blindness appears to occur not because of altered activity in the visual system but because of altered activity in the verbal system (and in consciousness).

Theories of hypnosis

Most theories of hypnosis revolve around the question of whether hypnosis represents a different state of consciousness (Fellows, 1990; Lynn and Rhue, 1991). The state hypothesis of hypnosis suggests that this phenomenon is an example of an altered state of consciousness or a trance resulting from induction (Hilgard, 1986). Hilgard's neo-dissociation theory (Hilgard, 1978, 1991) suggests that we have multiple systems of control which are not all conscious at the same time. These systems are under the general, central control of an 'executive ego' which controls and motivates other systems. The theory suggests that when a person is under hypnosis, overall control is given up to the hypnotist who has access to various systems. Such a theory claims to find support from what is called the '**hidden observer**' phenomenon. This is where the experimenter places a hand on the shoulder of the hypnotised individual and appears to be able to talk to a hidden part of the person's body (Knox *et al.*, 1974).

The non-state hypothesis of hypnosis argues that the process does not reflect altered states of consciousness but more mundane psychological functions such as imagination, relaxation, role-enactment, compliance, conformity, attention, attitudes and expectations (Coe and Sarbin, 1991; Wagstaff, 1991, 1996). Wagstaff (1996), for example, has argued that hypnosis may well represent some altered state but the evidence suggests that hypnotic suggestion can be explained by what we already know about human behaviour and thought. Strategic role-enactment is common in psychological research, for example. The degree of role-taking depends on whether the participant is worried about giving up control or being manipulated. To experience a hand getting heavier, the individual can imagine a weight on their arm; to experience hypnotic 'amnesia', the individual can distract themselves. Of course, state theorists would argue that such compliance or acting out is part of hypnotic behaviour that occurs without subjective experience (Spanos, 1991, 1992).

Barber (1979) suggests that at least some aspects of hypnosis are related to events that can happen every day and argues that hypnosis should not be viewed as a special state of consciousness, in the way that sleep is a state of consciousness that differs from waking; rather, the hypnotised person should be seen as acting out a social role. The phenomena of hypnosis are social behaviours, not manifestations of a special state of consciousness. Hypnotised people willingly join with the hypnotist in enacting a role expected of them. Some of the rules governing this role are supplied by the direct instructions of the hypnotist, others are indirectly implied by what the hypnotist says and does, and still others consist of expect-

tations that the people already have about what hypnotised people do.

For example, Spanos (1992) induced negative hallucinations in participants who reported being unable to see the number eight (although it was visible before them). When these participants were told that 'real' hypnotisable individuals, unlike 'fakers', do see the number briefly at the beginning, almost all subjects confirmed that they had seen it. In a more amusing experiment, Barber *et al.* (1974) asked a group of 'hypnotised' participants whether they could hear the experimenter, to which they replied 'no'!

People's expectations about hypnosis do indeed play an important role in their behaviour while under hypnosis. In lectures to two sections of an introductory psychology class, Orne (1959) told one section (falsely) that one of the most prominent features of hypnosis was rigidity of the preferred (that is, dominant) hand. Later, he arranged a demonstration of hypnosis during a meeting of students from both sections. Several of the students who had heard that the dominant hand became rigid showed this phenomenon when hypnotised, but none of the students who had not heard this myth developed a rigid hand. Similarly, if people become willing to follow a hypnotist's suggestions, perhaps they do so because they believe that this suggested behaviour is what is supposed to happen. Perhaps people willingly follow a hypnotist's suggestion to do something silly (such as bark like a dog) because they know that hypnotised people are not responsible for their behaviour.

Compliance, role-enactment and other psychological process can also explain examples of antisocial or strange behaviour that individuals can apparently be hypnotised into doing. Hypnotists have induced individuals to expose themselves indecently, pick up dangerous snakes, steal, verbally attack others, put their hands in nitric acid, throw acid at the experimenter, deal heroin, mutilate the Bible and make homosexual approaches (Orne and Evans, 1965; Wagstaff, 1993). However, Orne and Evans (1965) reported that non-hypnotised individuals could also be instructed to perform these acts. What produces this apparent unusual behaviour is the need to want to help the hypnotist or thinking that the antics were safe or that someone else would take responsibility for them (Udolf, 1983).

The hypnotist, entertainer and erstwhile disc jockey Paul McKenna, for example, invokes such psychological mechanisms to explain the odd behaviour he can induce in members of the public during his stage show. There is no real, special trance-like state, only the ability of individuals to become more-or-less compliant, to be more-or-less willing to please the hypnotist. For this reason, among others, McKenna was found not guilty in 1998 of being responsi-

ble for turning an audience volunteer into a violent and aggressive schizophrenic during his show.

Neurobiological correlates of hypnosis

You can see in the Controversies in Psychological Science section on hypnosis and pain that some researchers have suggested a role for the prefrontal cortex in hypnotic suggestion because this area mediates aspects of attention. There is good evidence for the link between attention and frontal cortex activity but there is evidence that two aspects of the hypnotic trance or state – relaxation and mental absorption – may also activate other areas. Hypnotic relaxation is induced when a participant

listens to instructions to relax: these involve imagining feelings of warmth and heaviness, and drowsiness. Mental absorption is induced by having the participant listen carefully and continuously to the hypnotist's instructions and ignoring all other stimuli. A PET study of brain activity before and after hypnotic induction found that participants' self-ratings of relaxation and absorption was associated with activity in the anterior cingulate cortex, the thalamus and the brain stem, areas closely tied to states of consciousness (Rainville *et al.*, 2002). Mental absorption, in particular, was associated with activity in a network of cortical and subcortical regions, including the prefrontal cortex, as we would have predicted.

Controversies in Psychological Science – Can hypnosis reduce pain and stress?

The issue

Pain is the most unpleasant sensory experience humans can suffer. It can derive from many sources, although the commonest are illness and disease. Such pain is normally relieved by surgery or drugs (often the surgery itself causes pain and has to be relieved pharmacologically). There are instances, however, where surgical or pharmacological interventions in pain relief are not successful. Often, in such circumstances, patients turn to hypnotic analgesia as an alternative. **Hypnotic analgesia** refers to the ability to endure or eliminate surgical pain via hypnotic suggestion (Wagstaff, 1996). Does such analgesic intervention work?

The evidence

Hypnosis can play a useful role in medicine, dentistry and psychotherapy (Heap and Dryden, 1991). The analgesia – insensitivity to pain – produced by hypnosis has been reported to be more effective than that produced by morphine, tranquillisers such as Valium, or acupuncture (Stern *et al.*, 1977). Thus, it can be used to suppress the pain of childbirth or having one's teeth drilled or to prevent gagging when a dentist is working in a patient's mouth. It is also useful in reducing the nausea caused by the drugs used in chemotherapy for cancer. However, because not all people can be hypnotised, and because the induction of hypnosis takes some time, few physicians or dentists use hypnosis to reduce pain; drugs are easier to administer.

Barber (1996, 1998) has reviewed evidence which suggests that hypnotic treatment for acute pain resulting from

medical procedures (chemotherapy, surgery) or recurring pain is effective. Of course, different types of condition produce different types of pain: some pains are constant, some intermittent. Osteoarthritis and trigeminal neuralgia, for example, produce almost constant pain whereas migraine and sickle cell disease and lower back pain caused by spinal nerve compression produce recurring pain.

To investigate whether hypnosis would help mediate the effects of a temporarily stressful event and whether any buffering effect would be accompanied by immune system changes, Kiecolt-Glaser *et al.* (2001) took blood samples from medical and dental students who were hypnotically suggestible. They did this during periods of low stress and then three days before their first exams. Exams have been found to provoke considerable distress in examinees. Wounds tend to heal significantly more slowly before an important examination, for example, than during an exam-free period (Marucha *et al.*, 1998). Half of the group were assigned to a hypnosis-generated relaxation-training condition in this interval; the other half received no relaxation training. The authors examined various immune system variables including lymphocyte number and interleukin-1 (which assists wound healing).

They found that students in the hypnosis condition showed a significantly greater proliferation of lymphocytes and an increase in interleukin-1 production during the examination period, compared with the control group. These students were also able to maintain baseline levels of these antibodies. The authors suggest that the effects are similar to those seen in surgical patients – hypnotic relaxation training in some patients is associated with shorter hospital stays, decreased

Controversies in Psychological Science – *Continued*

pain and more rapid recovery following surgery (Blankfield, 1991; Lang *et al.*, 2000). The findings highlight the role of hypnotic relaxation in reducing stress and in altering immune system functioning.

While evidence suggests that pain can be reduced following hypnotic suggestion, the cognitive or physiological mechanisms underlying this reduction are not known. There are ‘non-hypnotic’ factors which could be involved in pain reduction. For example, non-specific coping strategies, pain relief through feeling numb or cold, the use of relaxation and pre-operative preparation to alleviate anxiety are all successful in reducing the degree of reported surgical pain (Barber *et al.*, 1974; Chaves, 1989).

These results have been explained in terms of the ironic processes theory (Wegner, 1994). According to this theory, the control of mental events is made possible by two processes working together. The operating process retrieves material that puts the organism in a desirable state; the maintaining process searches consciousness for any content that is inconsistent with the desired state. When cognitive tasks reduce the resources available, the effectiveness of the monitoring process increases in comparison with the operating process (Eastwood *et al.*, 1998). Eastwood tested this hypothesis by requiring participants low and high in hypnotisability to report the degree of pain they were experiencing in a pain-induction task at regular intervals. The experimenters found that the frequency of pain reporting was associated with an increase in the level of experienced pain but that highly hypnotisable participants reported less pain.

The fact that only highly hypnotisable participants showed this effect explains why the published research has focused

more on these individuals than on those who are not particularly susceptible to hypnotic suggestion (Crawford, 1994). Why are highly susceptible individuals more likely to report reductions in pain? Some psychologists have suggested that these individuals can partition their attentional resources more effectively (Hilgard and Hilgard, 1994). Crawford *et al.* (1993) have reported that highly susceptible individuals showed a bilateral increase in blood flow to the frontal cortex and somatosensory cortex during hypnotic analgesia and the experience of pain. According to Crawford *et al.* (1998), this evidence suggests that the frontal region deals with the active allocation of attention, whereas the posterior parts are concerned with the spatio-temporal aspects of pain perception (such as where and when the pain is experienced).

Conclusion

Wagstaff (1987) has suggested that many of the effects seen in hypnotic analgesia are the result of the same factors that result in other forms of hypnotism. These factors include social support, relaxation, covert modelling, placebo and social compliance. Belief in the efficacy of the hypnosis is also an important factor. Wagstaff and Royce (1994) found that although hypnotic suggestions for the alleviation of nail-biting was better than non-hypnotic suggestions, the best predictor of abstinence from nail-biting was belief in the efficacy of the procedure. There may, therefore, be a strong placebo effect seen in these studies.

What are the characteristics of a highly hypnotisable subject? How would you design an experiment to examine the effects of hypnotic analgesia on the pain induced by cancer and chemotherapy? How would you determine that any effect was attributable to hypnosis?

Sleep

Sleep is not a state of unconsciousness; it is a state of altered consciousness. During sleep, we have dreams that can be just as vivid as waking experiences, and yet we forget most of them as soon as they are over. Our amnesia leads us to think, incorrectly, that we were unconscious while we were asleep. In fact, there are two distinct kinds of sleep, and thus two states of altered consciousness. We spend approximately one-third of our lives sleeping, or trying to, although the reasons for why we sleep are not fully known.

The stages of sleep

Sleep is not uniform. We can sleep lightly or deeply; we can be restless or still; we can have vivid dreams, or our consciousness can be relatively blank. Researchers who have studied sleep have found that its stages usually follow an orderly, predictable sequence.

Most sleep research takes place in sleep laboratories. Because a person's sleep is affected by their surroundings, a sleep laboratory contains one or more small bedrooms, furnished and decorated to be as home-like and comfortable as possible. The most important apparatus of the sleep laboratory is the polygraph, a machine located in a

separate room that records on paper the output of various devices that can be attached to the sleeper. For example, the polygraph can record the electrical activity of the brain through small metal discs pasted to the scalp, producing an **electroencephalogram (EEG)**. It can record electrical signals from muscles, producing an **electromyogram (EMG)** or from the heart, producing an **electrocardiogram** (abbreviated as EKG or ECG). Or it can record eye movements through small metal discs attached to the skin around the eyes, producing an **electro-oculogram (EOG)**. Other special transducers can detect respiration, sweating, skin or body temperature, and a variety of other physiological states (Andreassi, 2001).

The EEG record distinguishes between alert and relaxed wakefulness. When a person is alert, the tracing looks rather irregular, and the pens do not move very far up or down. The EEG shows high-frequency (15–30 Hz), low-amplitude electrical activity called **beta activity**. When a person is relaxed and perhaps somewhat drowsy, the record shows **alpha activity**, a medium-frequency (8–12 Hz), medium-amplitude rhythm.

When the individual relaxes and becomes drowsy, the EEG changes from beta activity to alpha activity. Figure 9.9 illustrates this and the subsequent stages of sleep.

The first stage of sleep (stage 1) is marked by the presence of some **theta activity**, EEG activity of 3.5–7.5 Hz. This stage is actually a transition between sleep and wakefulness; the EMG shows that muscles are still active, and the EOG indicates slow, gentle, rolling eye movements. The eyes slowly open and close from time to time. Soon, the person is fully asleep. As sleep progresses, it gets deeper and deeper, moving through stages 2, 3 and 4. The EEG gets progressively lower in frequency and higher in amplitude. Stage 4 consists mainly of **delta activity**, characterised by relatively high-amplitude waves occurring at less than 3.5 Hz. Our sleeper becomes less responsive to the environment, and it becomes more difficult to awaken him. Environmental stimuli that caused him to stir during stage 1 produce little or no reaction during stage 4. The sleep of stages 3 and 4 is called **slow-wave sleep**.

Stage 4 sleep is reached in less than an hour and continues for as much as a half hour. Then, suddenly, the EEG begins to indicate lighter levels of sleep, back through stages 3 and 2 to the activity characteristic of stage 1. The sleeper's heartbeat becomes irregular and his respiration alternates between shallow breaths and sudden gasps. The EOG shows that the person's eyes are darting rapidly back and forth, up and down. The EEG record looks like that of a person who is awake and active. Yet the sleeper is fast asleep. Although EMG is generally quiet, indicating muscular relaxation, the hands and feet twitch occasionally.

At this point, the subject is dreaming and has entered another stage of sleep, called **rapid eye movement (REM)** sleep. The first episode of REM sleep lasts 20–30 minutes and is followed by approximately one hour of slow-wave sleep. As the night goes on, the episodes of REM sleep get longer and the episodes of slow-wave sleep get shorter, but the total cycle remains at approximately 90 minutes. A typical night's sleep consists of four or five of these cycles. Figure 9.10 shows a record of a person's stages of sleep; the coloured shading indicates REM sleep. The double-exposure images in Figure 9.11 simulate the movement of the eyes during REM.

Figure 9.11 Double exposure photographs showing the typical movement of eyes during REM sleep.

Source: Hobson, J.A., *Consciousness*. New York: W.H. Freeman, 1999.

Regions of the brain also become more or less active during REM sleep, as Figure 9.12 shows. We will return to the significance of brain activity changes in sleep, consciousness and alertness at the end of the chapter.

Although a person in REM sleep exhibits rapid eye movements and brief twitches of the hands and feet, the EMG shows that the facial muscles are still. In fact, physiological studies have shown that, aside from occasional twitching, a person actually becomes paralysed during REM sleep. Males are observed to have partial or full erections. In addition, women's vaginal secretions increase at this time. These genital changes are usually not associated with sexual arousal or dreams of a sexual nature. Table 9.2 lists the principal characteristics of REM sleep and slow-wave sleep.

Table 9.2 Principal characteristics of REM sleep and slow-wave sleep

REM sleep	Slow-wave sleep
Rapid EEG waves	Slow EEG waves
Muscular paralysis	Lack of muscular paralysis
Rapid eye movements	Slow or absent eye movements
Penile erection or vaginal secretion	Lack of genital activity
Dreams	

Cutting edge – Evening types are more creative, but also more maladaptive

Morning types or ‘larks’ are often viewed as conscientious, trustworthy and stable. Evening types or ‘owls’ are thought to be creative, unstable and have fractious social and family relationships (they also yawn more, Zilli *et al.*, 2007). Two studies have tried to determine whether there is empirical evidence for these characterisations.

In one study, evening and morning types completed a visual component of a well-known test of creativity, the Torrance Test of Creative Thinking (Giampietro and Cavallera, 2007). The test involved (i) drawing a picture using a shape provided by the experimenter and giving a name to it, and (ii) making complete shapes out of 10 incomplete straight and curved lines. Evening types out-scored morning types.

However, the increased creativity may be accompanied by maladaptive social behaviour. In a study which measured the IQ performance of adolescents classed as morning and evening types, in the morning and the evening, fluid intelligence was better if the time of testing matched the person’s circadian preference. There were no circadian preference effects for crystallised intelligence (Goldstein *et al.*, 2007). Morning types, however, reported fewer attention problems, less aggression, were more competent socially in school and were engaged in more activities. One reason for this might be that evening types have difficulty in adjusting to the demands of early morning rises for school (Andershed, 2005).

Functions of sleep

Sleep is one of the few universal behaviours. All mammals, all birds and some cold-blooded vertebrates spend part of each day sleeping. Sleep is seen even in species

that would seem to be better off without sleep. For example, the Indus dolphin (*Platanista indi*) which lives in the muddy waters of the Indus estuary in Pakistan (Pilleri, 1979). Over the ages, it has become blind, presumably because vision is not useful in the animal’s environment (it has an excellent sonar system, which it uses to navigate and find prey). However, despite the dangers caused by sleeping, sleep has not disappeared. The Indus dolphin never stops swimming; doing so would result in injury, because of the dangerous currents and the vast quantities of debris carried by the river during the monsoon season. Pilleri captured two Indus dolphins and studied their habits. He found that they slept a total of seven hours a day, in very brief naps of 4 to 60 seconds each. If sleep did not perform an important function, we might expect that it, like vision, would have been eliminated in this species through the process of natural selection.

Sleep deprivation

The universal nature of sleep suggests that it performs some important functions (Hobson, 1988). One approach to discovering the functions of sleep is the deprivation study. Consider, for example, the function of eating. The effects of starvation are easy to detect: the person loses weight, becomes fatigued and will eventually die if they

do not eat again. By analogy, it should be easy to discover why we sleep by seeing what happens to a person who goes without sleep.

Unfortunately, deprivation studies have not obtained persuasive evidence that sleep is needed to keep the body functioning normally. Horne (1978) reviewed over fifty experiments in which humans had been deprived of sleep. He reported that most of them found that sleep deprivation did not interfere with people’s ability to perform physical exercise. In addition, they found no evidence of a physiological stress response to sleep deprivation. If people encounter stressful situations that cause illness or damage to various organ systems, changes can be seen in such physiological measures as blood levels of cortisol and epinephrine. Generally, these changes did not occur.

Although sleep deprivation does not seem to damage the body, and sleep does not seem to be necessary for athletic exercise, sleep may be required for normal brain functioning. Several studies suggest that sleep-deprived people are able to perform normally on most intellectual tasks, as long as the tasks are short. They perform more poorly on tasks that require a high level of cortical functioning after two days of sleep deprivation (Horne and Minard, 1985). In particular, they perform poorly on tasks that require them to be watchful, alert and vigilant. Female flight attendants working on international trans-meridian flights, for example, perform attention tasks that require delayed responding more poorly than do their ground-bound colleagues (Cho *et al.*, 2000). People also show poor recency memory, but not recognition memory, after 36 hours’ lack of sleep (Harrison and

Horne, 2000) and free recall of verbal material tends to be impaired after the loss of one night's sleep (Drummond *et al.*, 2000). The effects of sleep deprivation on working memory depend on the length of deprivation. There is little difference in performance between 24 and 35 hours of deprivation (Chee *et al.*, 2006b). The sleep deprivation was associated with a reduction in activation in two regions of the brain: the superior parietal cortex and the left thalamus. Participants allowed to sleep normally following sleep deprivation show greater activation in the frontal-parietal area and this correlates with improved working memory performance.

One study has reported that when sleep is restricted by 50 per cent, feelings of sociability and optimism decline by approximately 15 per cent (Haack and Mullington, 2005), and the ability to identify odours declines after 52 hours' sleep deprivation (McBride *et al.*, 2006). Wells and Cruess (2006) examined the effect of sleep loss on food consumption in a group of 50 undergraduates who were instructed to sleep for only 4 hours on the second day of the study (on the first they recorded their sleep quality and food intake). Respondents kept diaries of what they ate and so the study relied on self-reporting, with all the caveats that implies. After sleep loss, participants ingested fewer calories two days after sleep deprivation. They also chose foods for reasons other than health, naturalness and price. The study highlights the unexpected nutritional consequences of sleep loss.

The way in which we cope with stress may affect how well we sleep, regardless of the source of stress. Sadeh *et al.* (2004) measured the sleeping patterns and sleeping quality of 36 students during periods of low stress – a normal academic week, and high stress – when their eligibility for acceptance on an important clinical psychology course was being assessed. They were classed as problem-focused copers (PFC; they manage or alter the stress-causing problem); emotion-focused copers (EFC; they regulate emotional responses to the stressor); and disengagers (DE; they try to disengage from the thoughts and feelings generated by the threat). Individuals with a predominantly EFC style slept less whereas those who used EFC less slept more during the period of high stress. The low EFC participants also improved their sleep quality during the stressful period whereas high EFC participants' sleep worsened. A general effect was found for PFC – people scoring high in this style slept more, regardless of whether the period was stressful or stress-free.

One of the most dangerous consequences of sleep deprivation is poor driving. The Psychology in Action box below reviews the evidence for the effects of sleep loss on driving and how these effects may be combated with appropriate intervention.

During stage 4 sleep, the metabolic activity of the brain decreases to about 75 per cent of the waking level

(Sakai *et al.*, 1979). Thus, stage 4 sleep appears to give the brain a chance to rest. In fact, people are unreactive to all but intense stimuli during slow-wave sleep and, if awakened, act groggy and confused, as if their cerebral cortex has been shut down and has not yet resumed its functioning. These observations suggest that during stage 4 sleep the brain is, indeed, resting.

Sleep deprivation studies of humans suggest that although the brain may need slow-wave sleep in order to recover from the day's activities, the rest of the body does not. Another way to determine whether sleep is needed for restoration of physiological functioning is to look at the effects of daytime activity on night-time sleep. If the function of sleep is to repair the effects of activity during waking hours, then we should expect that sleep and exercise are related. That is, we should sleep more after a day of vigorous exercise than after a day spent quietly at an office desk. In fact, the relation between sleep and exercise is not very compelling.

Although bodily exercise has little effect on sleep, mental exercise seems to increase the demand for slow-wave sleep. In an ingenious study, Horne and Minard (1985) found a way to increase mental activity without affecting physical activity and without causing stress. The investigators told volunteers to show up for an experiment in which they were supposed to take some tests designed to test reading skills. In fact, when the people turned up, they were told that the plans had been changed. They were invited for a day out, at the expense of the experimenters. They spent the day visiting an art exhibition, a shopping centre, a museum, an amusement park, a zoo and stately home. After a scenic drive through the countryside they watched a film in a local cinema. They were driven from place to place and certainly did not become overheated by exercise. After the film, they returned to the sleep laboratory. They said they were tired, and they readily fell asleep. Their sleep duration was normal and they awoke feeling refreshed. However, their slow-wave sleep, particularly stage 4 sleep, was increased.

Sleep-dependent memory consolidation

One of the functions of sleep is to allow us to consolidate what we have learned while we were awake. This phenomenon is called sleep-dependent memory consolidation (Marshall and Born, 2007). For example, there is considerable evidence now to show that our procedural, declarative, sensory and motor memory are better after sleeping (Walker *et al.*, 2003; Cohen *et al.*, 2005; Born *et al.*, 2006) and each appears to be dependent on the appearance of certain sleep stages. Motor skills, for

Psychology in action – How sleep loss affects behaviour

At around 6 a.m. on 28 February 2001, Gary Hart, a 37-year-old builder from Lincolnshire, drove his Land Rover and trailer off the M62 near Great Heck in North Yorkshire, and plummeted down the embankment onto the east coast mainline. Within minutes, the vehicle was hit by a southbound express passenger train travelling at 117 mph. At 6.14 a.m. the passenger train collided with another train carrying 1,600 tons of coal. The collision killed 10 men and injured 76 people. Hart was convicted of death by dangerous driving. He admitted that he had not slept the night before but denied falling asleep at the wheel. He admitted having had only a short nap in the last 24 hours.

Most road traffic accidents occur between four and six o'clock in the morning, with a second, slightly smaller peak occurring in the middle of the afternoon (Horne and Reyner, 1999). Most researchers attribute this finding to sleeplessness and/or fatigue. A lack of sleep seems to exacerbate driving performance as does a feeling of fatigue and the ingestion of carbohydrates (London *et al.*, 2004). Imagine the case of a person who has completed a night shift for the first time after having slept little in the past 24 hours, and who then drives the long, monotonous road journey home. All of these conditions present problems to the driver (Horne and Reyner, 1999), and driving performance is affected in those people who cut short their sleep to make an early morning journey. Even in the wakeful driver, prolonged driving induces subjective feelings of tiredness (Summala *et al.*, 1999) and lane drifting (Brookhuis and DeWaard, 1993). Long-haul lorry drivers, in particular, experience increased fatigue and tension as the driving progresses, although it seems as if difficult driving conditions result in fewer driving mistakes than do monotonous ones, such as a straight road (Matthews and Desmond, 2002). Fatigue appears to have the same detrimental effect on driving as does alcohol (DeWaard and Brookhuis, 1991).

Combined with long work hours, sleep loss can be fatal. Researchers at the Harvard Work Hours, Health and Safety Group studied a group of 2,737 US medical residents in their first postgraduate year (interns) (Barger *et al.*, 2005). The medical profession is notorious for having its physicians work long hours and shifts can frequently last longer than 24 hours. Forty per cent of the weeks in which interns worked involved them working for 80 hours; in 11 per cent, the physicians worked for over 100 hours. The researchers asked participants to note their work hours, extended work hours, documented motor vehicle crashes and near misses. Of the 320 crashes reported, 130 were severe enough to cause vehicle or person damage. The risk of a crash or near miss was significantly amplified if the physician was commuting after an extended rather than non-extended workshift. The majority of interns

reported spending as little as four hours asleep while working on extended shifts and they routinely worked 30 consecutive hours (see Table 9.3).

One way of preventing this erratic, lack-of-sleep-induced driving is to avoid it completely. But if this is not practical, one solution may be to ingest substances that are psychoactive and which might stimulate wakefulness. The most obvious example of such a substance is caffeine.

Reyner and Horne (2000) examined the effects of 200 mg of caffeine on the driving performance of individuals who had experienced significant sleep loss (no sleep during the night) or who had slept for only about five hours. The participants were collected at around 5.30 a.m. and were put in an immobile car which allowed them to make a simulated, computer-generated, dull, monotonous drive. The drivers were young and experienced and drove for two hours, from 6 to 8 a.m. Some participants received coffee with a 200 mg dose of caffeine, while others received no caffeine in their drink.

The caffeine significantly reduced the number of driving incidents (such as lane drifting) and subjective sleepiness in drivers who had experienced only five hours' sleep. For drivers deprived of all sleep, there were dramatic impairments on all measures and the experiment was abandoned after an hour. Even in these profoundly inattentive participants, caffeine reduced driving incidents in the first 30 minutes. The amount of caffeine they received was the equivalent of two to three cups (any more – five or more cups – would mean administering pharmacological amounts of caffeine). With most accidents occurring between 4 and 6 a.m. or mid-afternoon, a quick couple of coffees half an hour before setting off on a journey may help make drivers' behaviour safer. In separate experiments, Reyner and Horne (1998) found that two common interventions that drivers initiate when they feel sleepy – blowing cold air on the face or listening to the radio –

Table 9.3 The number of near misses and motor vehicle crashes in interns working extended (greater than 24 hours) and non-extended (less than 24 hours) shifts

	Extended work shift	Non-extended work shift
No. of crashes reported	58	73
No. of commutes	54,121	180,289
Rate (per 1,000 commutes)	1.07	0.40
Odds	2.3	1.0
No. of near misses reported	1,971	1,156
Rate (per 1,000 commutes)	36.42	6.41
Odds	5.9	1.0

Psychology in action – *Continued*

had only short-term effects on relieving sleepiness. However, combining caffeine intake with a nap improved driving performance and was associated with significantly less lane drifting (Horne and Reyner, 1996; Reyner and Horne, 1997).

A research group at the army and medical research centre in IMASSA in France found that healthy men who received 300 mg of slow-release caffeine at various points during 64 hours of uninterrupted wakefulness were more alert from the beginning of the experiment, compared with the placebo group. This vigilance was maintained to the end (Beaumont *et al.*, 2001). Alertness improved from the thirteenth hour, compared with the placebo group, and most tests of cognitive ability were better performed by the caffeine group in the early and middle stages of the experiment.

Gary Hart was convicted of death by dangerous driving after his car veered off a main road onto a railway line, and collided with a passenger train that subsequently collided with a coal train. The incident, which caused the deaths of 10 people, was found to be attributable to the fact that Hart had had only one brief nap in the previous 24 hours.

Source: © Corbis.

How long did these effects last and would they extend to the 'recovery' period after sleep deprivation? Would the person revert to normal fairly quickly regardless of whether they received caffeine or a placebo? The researchers measured EEG, sleepiness, sleep and cognitive function in the 42 hours of 'recovery' following the 64 hours of sleep deprivation in 16 healthy men who had received slow-release caffeine or a placebo (Beaumont *et al.*, 2005). In the two nights following deprivation, both groups showed a rebound of slow-wave sleep with the rebound of REM sleep seen during the second night. Cognitive function was similarly impaired in the placebo and caffeine groups on the first day of recovery and recovered – partially – to baseline levels on the second day.

Sleepiness does not 'just happen': it builds up and people try to fight it. People, however, may underestimate the point at which their sleepiness turns into actual sleep. Horne and Baulk (2004) examined the self-reported sleepiness, EEG and lane drifting of 38 sleep-restricted healthy adults who undertook a two-hour, monotonous simulated driving exercise in the afternoon. They found a strong, significant and positive correlation between subjective sleepiness and EEG changes indicative of sleepiness. Driving incidents followed reports/EEG indicators of sleepiness. When lane drifting occurred, the participants made a sharp corrective movement that momentarily increased arousal.

The results showed that the participants were aware of their sleepiness (and this correlated with predicted changes in EEG). Participants were asked to monitor their sleepiness, however, which may have drawn their attention more specifically to the way they felt. This suggests that drivers might be educated to reflect on the way they are feeling by prompting them to think about why they are opening windows, playing the radio loudly, etc.

The data reviewed here suggest that if a driver feels sleepy at the wheel, the first solution is to stop at a convenient place and take a nap. Coupling the nap with an intake of caffeine is an even better way of combating the potentially dangerous effects of sleepiness while driving. The practical consequences of this are clear: safer roads and, perhaps, a clearer head.

example, appear to be better consolidated after non-REM sleep or stage 2 sleep. Visual discrimination tasks are better remembered after slow-wave sleep and REM sleep (as evidenced by the findings that disrupting these sleep stages disrupts consolidation). The sleep after training appears to be resistant to the interference that you would expect to see during the delay between encoding and later retrieval. See Figures 9.13 and 9.14.

Slow-wave sleep (and lots of it) appears to be beneficial for remembering word pairs, remembering spatial locations and recognising words. REM sleep appears to be beneficial to non-declarative memory and emotional memory, i.e. those memory functions that rely less on encoding by the hippocampus. Studies of hippocampal function – navigation, for example – have found that after learning the navigation of a virtual town the hip-

pocampus becomes active during slow-wave sleep. This activation correlates with memory performance the following day: the greater the activation, the greater the performance (Peigneux *et al.*, 2004). There is no evidence

that sleep helps you forget certain memories (Marshall and Born, 2007).

Dreaming

A person who is awakened during REM sleep and asked whether anything was happening will almost always report a dream. The typical REM sleep dream resembles a play or film – it has a narrative form. Conversely, reports of narrative, story-like dreams are rare among people awakened from slow-wave sleep. In general, mental activity during slow-wave sleep is more nearly static; it involves situations rather than stories and generally unpleasant ones. For example, a person awakened from slow-wave sleep might report a sensation of being crushed or suffocated. Unless the sleep is heavily drugged, almost everyone has four or five bouts of REM sleep each night, with accompanying dreams. Yet if the dreamer does not happen to awaken while the dream is in progress, it is lost for ever. Some people who claimed not to have had a dream for many years slept in a sleep laboratory and found that, in fact, they did dream. They were able to remember their dreams because the investigator awakened them during REM sleep.

The reports of people awakened from REM and slow-wave sleep clearly show that people are conscious during sleep, even though they may not remember any of their experiences then. Lack of memory for an event does not mean that it never happened; it only means that there is no permanent record accessible to conscious thought during wakefulness. Thus, we can say that slow-wave sleep and REM sleep reflect two different states of consciousness.

Functions of dreams

There are two major approaches to the study of dreaming: a psychological analysis of the contents of dreams, and psychobiological research on the nature and functions of REM sleep.

Symbolism in dreams

Since ancient times, people have regarded dreams as important, using them to prophesy the future, decide whether to go to war, or to determine the guilt or innocence of a person accused of a crime. In the last century, Sigmund Freud proposed a very influential theory about dreaming. He said that dreams arise out of inner conflicts between unconscious desires (primarily sexual ones) and prohibitions against acting out these desires, which we learn from society. According to Freud, although all dreams represent unfulfilled wishes, their contents are disguised and expressed symbolically. The latent content

of the dream (from the Latin word for ‘hidden’) is transformed into the manifest content (the actual story-line or plot). Taken at face value, the manifest content is innocuous, but a knowledgeable psychoanalyst can supposedly recognise unconscious desires disguised as symbols in the dream. For example, climbing a set of stairs or shooting a gun might represent sexual intercourse. The problem with Freud’s theory is that it is not disprovable; even if it is wrong, a psychoanalyst can always provide a plausible interpretation of a dream that reveals hidden conflicts disguised in obscure symbols.

Hall (1966), who agrees that symbols can be found in dreams, does not believe that they are usually hidden. For example, a person may plainly engage in sexual intercourse in one dream and have another dream that involves shooting a gun. Surely the ‘real’ meaning of shooting the gun need not be hidden from a dreamer who has undisguised dreams of sexual intercourse at other times or who has an uninhibited sex life during waking. Why should this person disguise sexual desires while dreaming? As Hall says, people use their own symbols, not those of anyone else. They represent what the dreamer thinks, and therefore, their meaning is usually not hidden from the dreamer.

Hobson (1988) proposed an explanation for dreaming that does not involve unconscious conflicts or desires. As we will see later, research using laboratory animals has shown that REM sleep occurs when a circuit of acetylcholine-secreting neurons in the pons becomes active, stimulating rapid eye movements, activation of the cerebral cortex and muscular paralysis. The activation of the visual system produces both eye movements and images. In fact, several

experiments have found that the particular eye movements that a person makes during a dream correspond reasonably well with the content of a dream; that is, the eye movements are those that one would expect a person to make if the imaginary events were really occurring (Dement, 1974). The images evoked by the cortical activation often incorporate memories of episodes that have occurred recently or of things that a person has been thinking about lately. Presumably, the circuits responsible for these memories are more excitable because they have recently been active. Hobson suggests that although the activation of these brain mechanisms produces fragmentary images, our brains try to tie these images together and make sense of them by creating a more-or-less plausible story.

We still do not know whether the particular topics we dream about are somehow related to the functions that dreams serve or whether the purposes of REM sleep are fulfilled by the physiological changes in the brain regardless of the plots of our dreams. Given that we do not know for sure why we dream, this uncertainty is not surprising.

Effects of REM sleep deprivation

As we saw, total sleep deprivation impairs people’s ability to perform tasks that require them to be alert and vigilant, such as driving a car. What happens when only REM sleep is disrupted? People who are sleeping in a laboratory can be selectively deprived of REM sleep. An investigator awakens them whenever their polygraph records indicate that they have entered REM sleep. The investigator must also awaken control participants just as often at random intervals to eliminate any effects produced by being awakened several times.

When the person is no longer awakened during REM sleep, a rebound phenomenon is seen: the person engages in many more bouts of REM sleep than normal during the next night or two, as if catching up on something important that was missed.

Researchers have discovered that the effects of REM sleep deprivation are not very striking. In fact, medical journals contain reports of several patients who showed little or no REM sleep after sustaining damage to the brain stem (Lavie *et al.*, 1984; Gironell *et al.*, 1995). The lack of REM sleep did not appear to cause serious side effects. One of the patients, after receiving his injury, completed high school, attended law school and began practising law.

Several investigators have suggested that REM sleep may play a role in learning. For example, Greenberg and Pearlman (1974) suggest that REM sleep helps to integrate memories of events of the previous day – especially those dealing with emotionally related information – with existing memories. Crick and Mitchison (1983) suggest

The song, ‘Yesterday’, apparently came to Paul McCartney in a dream. Waking up, he immediately beat out the melody on a piano. Originally titled ‘Scrambled Eggs’, it is now the most commercially successful song in history.

Source: Debra L. Rothenberg/Rex Features.

that REM sleep helps flush irrelevant information from memory to prevent the storage of useless clutter. Many studies using laboratory animals have shown that deprivation of REM sleep does impair the ability to learn a complex task. However, although the animals learn the task more slowly, they still manage to learn it. Thus, REM sleep is not necessary for learning. If REM sleep does play a role in learning, it appears to be a subtle one, at least, in the adult. As we shall see next, REM sleep may be important for brain development.

Role of REM sleep in brain development

REM sleep begins early in development. Studies of human fetuses and infants born prematurely indicate that REM sleep begins to appear 30 weeks after conception and peaks at around 40 weeks (Roffwarg *et al.*, 1966; Petre-Quadens and De Lee, 1974; Inoue *et al.*, 1986). REM sleep of fetuses was recorded harmlessly by using ultrasound to watch eye movements. Approximately 70 per cent of a newborn infant's sleep is REM sleep. By six months of age, this proportion has declined to approximately 30 per cent. By eight years of age, it has fallen to around 22 per cent. By late adulthood, it is less than 15 per cent.

Researchers have long been struck by the fact that the highest proportion of REM sleep is seen during the most active phase of brain development. Perhaps, then, REM sleep plays a role in this process. Of course, no one has experimented on infants by depriving them of REM sleep to see whether their brain development was impaired. But such studies have been carried out on laboratory animals. For example, Mirmiran (1995) described a series of studies he and his colleagues performed with infant rats. They injected the rats with drugs that suppressed REM sleep during the second and third weeks of life and found that the animals showed behavioural abnormalities as adults. In addition, their cerebral cortices and brain stems were smaller than those of control participants.

Brain mechanisms of sleep

If sleep is a behaviour, then some parts of the brain must be responsible for its occurrence. In fact, researchers have discovered several brain regions that have special roles in sleep and biological rhythms.

All living organisms show rhythmic changes in their physiological processes and behaviour. Some of these rhythms are simply responses to environmental changes. For example, the growth rate of plants is controlled by daily rhythms of light and darkness. In animals, some rhythms are controlled by internal 'clocks', located in the brain. Mammals have two biological clocks that play a

role in sleep. One of these controls **circadian rhythms** – rhythms that oscillate once a day (*circa* 'about', *dies* 'day'). The second clock, which controls the cycles of slow-wave and REM sleep, oscillates several times a day.

The clock that controls circadian rhythms is located in a small pair of structures found at the bottom of the hypothalamus: the **suprachiasmatic nuclei (SCN)**. The activity of neurons in the SCN oscillates once each day; the neurons are active during the day and inactive at night. These changes in activity control daily cycles of sleep and wakefulness. If people are placed in a windowless room with constant lighting, they will continue to show circadian rhythms, controlled by the oscillations of their suprachiasmatic nuclei. However, because this biological clock is not very accurate, people's circadian rhythms will eventually get out of synchrony with the day/night cycles outside the building. But within a few days after leaving the building, their rhythms will become resynchronised with those of the sun. This resynchronisation is accomplished by a direct connection between the eyes and the SCN. Each morning, when we see the light of the sun (or turn on the room lights), our biological clock resets and begins ticking off the next day. A recent study suggests that there is a new class of light-detecting receptors in the retina – retinal ganglion cells – which contains a circadian photopigment molecule that responds to levels of illumination. This light-detecting system operates differently from the visual system (Berson *et al.*, 2002).

The second biological clock in the mammalian brain runs considerably faster, and it runs continuously, unaffected by periods of light and darkness. In humans, this clock cycles with a 90-minute period. The first suggestion that a 90-minute cycle occurs throughout the day came from the observation that infants who are fed on demand show regular feeding patterns (Kleitman, 1961). Later studies found 90-minute cycles of rest and activity, including such activities as eating, drinking, smoking, heart rate, oxygen consumption, stomach motility, urine production and performance on various tasks that make demands on a person's ability to pay attention. Kleitman (1982) termed this phenomenon the **basic rest–activity cycle (BRAC)**. During the night, the clock responsible for the BRAC controls the alternating periods of REM sleep and slow-wave sleep.

Studies using laboratory animals have found that the clock responsible for the BRAC is located somewhere in the pons. The pons also contains neural circuits that are responsible for REM sleep. The neurons that begin a period of REM sleep release acetylcholine. The release of this transmitter substance activates several other circuits of neurons. One of these circuits activates the cerebral cortex

and causes dreaming. Another activates neurons in the midbrain and causes rapid eye movements. Yet another activates a set of inhibitory neurons that paralyzes us and prevents us from acting out our dreams. The location of the two biological clocks is shown in Figure 9.15.

The first hint that REM sleep was turned on by acetylcholine-secreting neurons came from the observation that overdoses of insecticides that excite such neurons also cause visual hallucinations, like those of dreaming. Subsequent research using laboratory animals confirmed this suspicion. These acetylcholine-secreting neurons (referred to as REM-ON neurons) are normally inhibited by neurons that secrete another transmitter substance, serotonin. Thus, drugs that decrease the activity of serotonin-secreting neurons will permit the REM-ON neurons to become active. LSD is one of these drugs, and this fact explains why people who take LSD experience visual hallucinations similar to the ones that occur during dreams. On the other hand, drugs that increase the activity of serotonin-secreting neurons will suppress REM sleep. All antidepressant drugs have this effect, which suggests that excessive amounts of REM sleep may play a role in mood disorders.

What about the brain mechanisms responsible for slow-wave sleep? The most important brain region seems to be the **preoptic area**, located just in front of the hypothalamus, at the base of the brain (this region is named after the fact that it is located anterior to the point where some axons in the optic nerves cross to the other side of the brain). If the preoptic area is destroyed, an animal will sleep much less (McGinty and Serman, 1968;

Szymusiak and McGinty, 1986). If it is electrically stimulated, an animal will become drowsy and fall asleep (Serman and Clemente, 1962).

Neurobiological correlates of consciousness and awakening

The effects of waking up from sleep are similar to those of sleep deprivation. When we wake up, it normally takes between 20 and 30 minutes for consciousness to be re-established. During this time, people tend not to be very alert and experience psychological deficits called ‘sleep inertia effects’ (Lubin *et al.*, 1976). These include poor psychomotor performance, thinking and vigilance (Tassi and Muzet, 2000). These deficits are most pronounced at the beginning of awakening and become less pronounced as consciousness is restored. Our cortisol levels are higher following waking and these levels are associated with job or life stress (the greater the cortisol, the greater the stress we experience) (Chida and Steptoe, 2009).

Some studies have shown that the lack of alertness resulting from sleep deprivation is associated with reduced brain activation in the thalamus and prefrontal cortex (Thomas *et al.*, 2000), suggesting that these mechanisms may intrude on waking when people are emerging from sleep. To discover the changes that occur in the brain during sleep and awakening, a PET study measured cerebral blood flow during 3–5 hours of sleep and immediately after people were awakened from stage 2 sleep (Balkin *et al.*, 2002). When awoken, people were asked to remain awake and motionless while brain activity was recorded.

Blood flow recovered most rapidly in the brain stem and thalamus, perhaps reflecting the re-establishment of consciousness. Fifteen minutes following the wake-up call, activity began to increase in the frontal cortex, a finding the researchers suggest may reflect a return to alertness (rather than consciousness), given that a reduction in frontal cortex activity is seen in sleep-deprived people. However, the study does not suggest that these regions are solely responsible for consciousness and alertness. As the researchers themselves acknowledge, consciousness and alertness recruit a network of brain areas which interact with each other, with no one area having an exclusive input.

Sleep disorders

Sleep does not always go smoothly, and some of the brain mechanisms responsible for sleep can malfunction, causing medical problems that manifest themselves while a person is awake. Fortunately, some of the things that sleep researchers have learned can help people with sleep-associated disorders.

Figure 9.15 Two biological clocks in the human brain. The suprachiasmatic nucleus (SCN) of the hypothalamus is responsible for circadian rhythms. The clock in the pons is responsible for the basic rest–activity cycle (BRAC) and cycles of REM sleep and slow-wave sleep.

Insomnia

Insomnia appears to affect around 10 per cent of the population, with the figure rising to 20 per cent in older adults (Ancoli-Israel, 2000). There is no single definition of insomnia that can apply to all people but a general definition is an inability to initiate or maintain sleep over at least three nights. The lack of sleep can create daytime distress and an impairment in social, work and physical functioning (Drake *et al.*, 2003; Irwin *et al.*, 2006). The amount of sleep that individuals require is quite variable, however. A short sleeper may feel fine with five hours of sleep; a long sleeper may still feel unrefreshed after ten hours. Insomnia, therefore, must be defined in relation to a person's particular sleep needs.

One study found that occupational stress, defined as the inability to stop worrying about work when not at work, was the most common predictor of poor sleep (Akerstedt *et al.*, 2002). Workers who anticipated having a bad next day showed less slow-wave sleep, an increase in the amount of stage 2 sleep, anxiety prior to sleeping and poorer quality of sleep than did those who did not anticipate having a challenging day (Kecklund and Akerstedt, 2006). Next-day apprehension was highly correlated with feelings of tension, nervousness, uneasiness and stress. The study leaves open the question of why the stress produces these changes. Is the group which is apprehensive about the next day habitually stressful or prone to feelings of anxiety, for example? Are they more vulnerable to stressors than are the non-apprehensive individuals?

Ironically, the most important cause of insomnia seems to be sleeping medication. Insomnia is not a disease that can be corrected with a medicine, in the way that diabetes can be treated with insulin. Insomnia is a symptom. If it is caused by pain or discomfort, the physical ailment that leads to the sleeplessness should be treated. If it is secondary to personal problems or psychological disorders, these problems should be dealt with directly. Patients who receive sleeping medications develop a tolerance to them and suffer rebound symptoms if they are withdrawn (Weitzman, 1981). That is, the drugs lose their effectiveness, so the patient requests larger doses from the physician. If a patient attempts to sleep without their accustomed medication or even takes a smaller dose one night, they are likely to experience a withdrawal effect: a severe disturbance of sleep. The patient becomes convinced that the insomnia is worse than before and turns to more medication for relief. This common syndrome is called drug dependency insomnia. Kales *et al.* (1979) found that withdrawal of some sleeping medications produced a rebound insomnia after the drugs were used for as few as three nights.

An alternative to pharmacology is psychology and a number of behavioural interventions – including cognitive

behavioural therapy (CBT), described in more detail in Chapter 18 – have been found to be successful in improving sleep quality, lengthening the period of sleep and reducing the number of awakenings after sleep onset (Irwin *et al.*, 2006).

A common cause of insomnia, especially in older people, is **sleep apnoea** (apnoea means 'without breathing'): they cannot sleep and breathe at the same time. When they fall asleep, they stop breathing, the content of carbon dioxide in their blood builds up, and they awaken, gasping for air. After breathing deeply for a while, they go back to sleep and resume the cycle. Some people who suffer from sleep apnoea are blessed with a lack of memory for this periodic sleeping and awakening; others are aware of it and dread each night's sleep. Fortunately, some types of sleep apnoea in adults can be corrected by throat surgery.

Disorders associated with REM sleep

Two important characteristics of REM sleep are dreaming and paralysis. The paralysis results from a brain mechanism that prevents us from acting out our dreams. In fact, damage to specific regions of the pons of a cat's brain will produce just that result: the cat, obviously asleep, acts as if it were participating in a dream (Jouvet, 1972). It walks around stalking imaginary prey and responding defensively to imaginary predators.

This phenomenon can occur in humans, too. Several years ago, Schenck *et al.* (1986) reported the existence of an interesting syndrome: REM sleep behaviour disorder, the absence of the paralysis that normally occurs during REM sleep. Studies using laboratory animals have shown that the neural circuitry that controls the paralysis that accompanies REM sleep is located in the pons. In humans, **REM sleep behaviour disorder** seems to be produced by damage to this region (Culebras and Moore, 1989).

Dreams and muscular paralysis are fine when a person is lying in bed. But some people have periodic attacks of a sleep-related disorder called **cataplexy** (*kata-* 'down', *plessein* 'to strike'). They are struck down by paralysis while actively going about their business. They fall to the ground and lie there, paralysed but fully conscious. Attacks of cataplexy generally last less than a minute. The attacks are usually triggered by strong emotional states, such as anger, laughter or even lovemaking. People who have cataplectic attacks tend also to enter REM sleep as soon as they fall asleep, in contrast to the normal 90-minute interval.

Cataplexy is a biological disorder, probably involving inherited abnormalities in the brain. In fact, researchers have developed breeds of dogs that are subject to attacks of cataplexy so that they can study this disorder in the laboratory. As we saw, brain mechanisms responsible for

REM sleep are normally inhibited by serotonin-secreting neurons. Cataplexy can be treated by drugs that increase the activity of these neurons, thus increasing the inhibition.

Disorders associated with slow-wave sleep

Several phenomena occur during the deepest phase (stage 4) of slow-wave sleep. These events include sleepwalking, sleepwalking, night terrors and enuresis.

Sleepwalking can be as simple as getting out of bed and right back in again, or as complicated as walking out of a house and climbing into a car (sleepwalkers, apparently, do not try to drive). We know that sleepwalking is not the acting out of a dream because it occurs during stage 4 of slow-wave sleep, when the EEG shows high-amplitude slow waves and the person's mental state generally involves a static situation, not a narrative. Sleepwalkers are difficult to awaken; once awakened, they are often confused and disoriented. However, contrary to popular belief, it is perfectly safe to wake them up.

Sleepwalking seems to run in families; Dement (1974) reported a family whose grown members were reunited for a holiday celebration. In the middle of the night they awoke to find that they had all gathered in the living room – during their sleep.

Sleeptalking sometimes occurs as part of a REM sleep dream, but it more usually occurs during other stages of sleep. Often, one can carry on a conversation with the sleepwalker, indicating that the person is very near the boundary between sleep and waking. During this state, sleepwalkers are sometimes very suggestible. So-called truth serums are used in an attempt to duplicate this condition, so that the person being questioned is not on guard against giving away secrets and is not functioning well enough to tell elaborate lies. Unfortunately for the interrogators, there are no foolproof, reliable truth serums.

Night terrors, like sleepwalking, occur most often in children. In this disorder, the child awakes, screaming with terror. When questioned, the child does not report a dream and often seems confused. Usually, the child falls asleep quickly without showing any after-effects and seldom remembers the event the next day. Night terrors are not the same as nightmares, which are simply frightening dreams from which one happens to awaken. Apparently, night terrors are caused by sudden awakenings from the depths of stage 4 sleep. The sudden, dramatic change in consciousness is a frightening experience for the child. The treatment for night terrors, like that for sleepwalking, is no treatment at all.

The final disorder of slow-wave sleep, **enuresis**, or bed-wetting, is fairly common in young children. Most children outgrow it, just as they outgrow sleepwalking or night terrors. Emotional problems can trigger enuresis, but bed-wetting does not itself indicate that a child is psychologically unwell. The problem with enuresis is that, unlike the other stage 4 phenomena, there are after-effects that must be cleaned up. Parents dislike having their sleep disturbed and get tired of frequently changing and laundering sheets. The resulting tension in family relationships can make the child feel anxious and guilty and can thus unnecessarily prolong the disorder.

Fortunately, a simple training method often cures enuresis. A moisture-sensitive device is placed under the bed sheet; when it gets wet, it causes a bell to ring. Because a child releases only a few drops of urine before the bladder begins to empty in earnest, the bell wakes the child in time to run to the bathroom. In about a week, most children learn to prevent their bladders from emptying and manage to wait until morning. Perhaps what they really learn is not to enter such a deep level of stage 4 sleep in which the mechanism that keeps the bladder from emptying seems to break down.

Chapter review

The nature of consciousness

- Consciousness refers to our awareness of our own perceptions, thoughts and feelings and our experience of these.
- Some psychologists and philosophers regard consciousness as a by-product of cognitive processing and believe it is outside the scope of scientific study because of its subjective nature.
- Several theories seek to explain the nature of consciousness. These fall mainly into two camps: the neurobiological and the cognitive.
- The neurobiological explanations (such as those of Crick and Penrose) suggest that consciousness occurs when cell assemblies behave together or is generated by specific parts of a neuron.

- Perceptual disorders (such as blindsight and visual agnosia) and other deficits following brain injury (such as those seen after the split-brain operation) help demonstrate the importance of various brain regions to conscious awareness.

Attention

- The process of selective attention determines which stimuli will be noticed and which will be ignored. The factors that control our attention include novelty, verbal instructions and our own assessment of the significance of what we are perceiving.
- The cocktail-party phenomenon is an example of selective attention: we are able to detect relevant information in an environment that contains irrelevant and relevant information.

- Noise (such as office noise and speech) in the working environment can significantly impair memory for prose and arithmetic performance; the longer the duration of the noise, the greater the deficit.
- Dichotic listening experiments show that what is received by the unattended ear is lost within a few seconds unless something causes us to take heed of it; after those few seconds we cannot say what that ear heard. Even unattended information can produce implicit (as opposed to explicit) memories, however.
- Techniques of meditation have been used since the beginning of history and include methods for increasing or decreasing attention to the external world. In meditative techniques, a person pays strict attention to a simple stimulus such as a visual pattern, a word or a monotonous, repetitive movement.
- Studies of the effects of mobile phone use on attention have demonstrated that engagement in conversation impairs attention and driving performance, regardless of whether the phone is hand-held or hands-free. Listening to the radio does not produce these impairments.

Hypnosis

- Hypnosis is a form of verbal control over a person's consciousness in which the hypnotist's suggestions affect some of the person's perceptions and behaviours.
- State theorists argue that consciousness during hypnosis is a mysterious, trance-like state. Non-state theorists argue that it can be explained by psychological factors such as compliance, role-enactment, imagination and willingness to please. Evidence suggests invoking the concepts of trance or altered states of consciousness is unnecessary.
- Barber asserts that being hypnotised is similar to participating vicariously in a narrative, which is something we do whenever we become engrossed in a novel, a film, a drama or even the recounting of a friend's experience. When we are engrossed in this way, we experience genuine feelings of emotion, even though the situation is not 'real'.
- Although individuals under hypnosis appear to perform extraordinary, unusual or antisocial acts, non-hypnotic suggestion can result in the same behaviours being induced. People who would not normally perform antisocial or distasteful acts may do so because they (correctly) assume that the experimenter is responsible for what they do.
- Hypnosis has been shown to be useful in reducing pain, eliminating bad habits, reducing stress and helping people talk about painful thoughts and memories.
- The reasons for the efficacy of hypnotic analgesia have included highly hypnotisable participants' ability to partition attention and the role of the anterior brain regions in allocating attentional resources.

Sleep

- Sleep consists of several stages of slow-wave sleep, characterised by increasing amounts of delta activity in the EEG, and REM sleep. REM sleep is characterised by beta activity in the EEG, rapid eye movements, general paralysis (with twitching movements of the hands and feet), and dreaming.
- Sleep is a behaviour, not simply an altered state of consciousness.
- Although evidence suggests that sleep is not necessary for repairing the wear and tear caused by physical exercise, it may play an important role in providing an opportunity for the brain to rest.
- The consequences of sleep deprivation include fatigue, psychomotor and cognitive impairment and lack of vigilance.
- Although narrative dreams occur only during REM sleep, people often are conscious of static situations during slow-wave sleep. Freud suggested that dreams provided the opportunity for unconscious conflicts to express themselves through symbolism in dreams.
- Hobson suggested that dreams are the attempts of the brain to make sense of hallucinations produced by the activation of the cerebral cortex.
- The function of REM sleep in adults is uncertain, but it may be involved somehow in learning.
- Foetuses and infants engage in much more REM sleep than adults do, which suggests that REM sleep may play a role in brain development. Some experimental research supports this suggestion.
- The brain contains two biological clocks. One, located in the suprachiasmatic nucleus of the hypothalamus, controls circadian (daily) rhythms. This clock is reset when light strikes the retina in the morning. The second clock, located in the pons, controls the basic rest–activity cycle, which manifests itself in changes in activity during the day and alternating periods of slow-wave sleep and REM sleep during the night. A circuit of acetylcholine-secreting neurons in the pons, normally inhibited by serotonin-secreting neurons, turns on REM sleep. Slow-wave sleep is controlled by neurons in the preoptic area.
- Insomnia appears to be a symptom of a variety of physical and emotional disorders, not a disease. Although it is often treated by sleep medications, these drugs cause more sleep problems than they cure.
- Two neurological disorders involve mechanisms of REM sleep. REM sleep behaviour disorder occurs when brain damage prevents the paralysis that normally keeps us from acting out our dreams. Cataplectic attacks are just the opposite. They are caused by activation at inappropriate times of the mechanism that causes paralysis during REM sleep. Drugs that stimulate serotonin-secreting neurons are useful in treating cataplexy.
- The disorders of slow-wave sleep include sleepwalking, sleeptalking and night terrors.
- Sleepwalking and night terrors are primarily disorders of childhood. Sleepwalking is generally harmless so it probably should not even be considered a disorder.

Language

'Dyslex? You're making it up!'

A Labour MP has claimed dyslexia is a 'fictional malady' invented by the 'education establishment' to cover up bad teaching of reading and writing.

In an article for Manchester Confidential, Graham Stringer wrote: 'The education establishment, rather than admit that their eclectic and incomplete methods for instruction are at fault, have invented a brain disorder called dyslexia.'

The MP for Manchester Blackley said the dyslexia 'industry' should be 'killed off' through the 'magic bullet' of teaching children to read and write by using a phonetic system of sounding letters and words.

Mr Stringer said the disability had been eradicated in West Dunbartonshire where the council has eliminated illiteracy through a special programme.

'If dyslexia really existed then countries as diverse as Nicaragua and South Korea would not have been able to achieve literacy rates of nearly 100%. There can be no rational reason why this 'brain disorder' is of epidemic proportions in Britain but does not appear in South Korea or Nicaragua.'

But the British Dyslexia Association (BDA) says Mr Stringer 'misunderstands' the condition.

In a statement, they said: 'Mr Stringer assumes that literacy will solve the issue of dyslexia, however although many dyslexics have acquired the skills of reading, there is no doubt that they still remain dyslexic.'

'It is concerning that an MP does not recognise dyslexia, which affects 10% of his constituents, even though his Government has taken steps to make sure dyslexic children and young people with dyslexia are recognised and supported.'

WHAT YOU SHOULD BE ABLE TO DO AFTER READING CHAPTER 10

- Define psycholinguistics and describe the nature of spoken language.
- Describe and explain various models of reading.
- Describe various language disorders including the aphasias, the acquired dyslexias and developmental dyslexia and indicate what these tell us about normal language processing.
- Identify the neural mechanisms which might underlie different aspects of language such as speech perception, reading and speech comprehension.

QUESTIONS TO THINK ABOUT

- What is language?
- Why have humans evolved language?
- Can other primates learn language? Would this language approximate our own?
- What is the role of sound in understanding written and spoken language?
- What stages does language development go through?
- How do people learn to read? What is the best way of doing this?
- How do people learn to recognise words?
- What causes dyslexia?
- What are the effects of brain injury on reading, writing and speaking?
- Do all humans have the same central mechanism for producing language regardless of which language they speak?
- How are we able to comprehend language?

Explore the accompanying videos, simulations, and animations on MyPsychLab. This chapter includes activities on: Morphemes • Dyslexia detector • The Wernicke-Geschwind model of language • Handedness • Check your understanding and prepare for your exams using the multiple choice, short answer and essay practice tests also available.

The use of language

Communication is probably one of the most important of all human behaviours. Our use of language can be private – we can think to ourselves in words or write diaries that are meant to be seen by no one but ourselves – but language evolved through social contacts among our early ancestors. Speaking and writing are clearly social behaviours: we learn these skills from other people and use them to communicate with them. An effective language system also abides by certain rules.

Although an exact definition is difficult to pin down (Harley, 2008), language can be characterised as a system of visual and/or vocal symbols which have meaning to the user and to the recipient. There are thought to be around 6,000 distinct languages in the world. The world’s largest language is Chinese – it has more native speakers than any other – followed by English, Hindi/Urdu, Spanish and Arabic, as parts of Figure 10.1 and Table 10.1 show. The most popular foreign language is English (Montgomery, 2004) and Figure 10.2 shows the proportion of the population of selected European Union states which speak English (UK excluded).

We can use language to speak, write and read and we can also use it to remember and to think. Language also enables us to consider complex and abstract issues by encoding them in words and then manipulating the words according to specific rules. These rules are the subject of an area of study called linguistics.

Table 10.1 Estimates of native speakers of the most popular languages in the world (in 1995)

Language		No. of speakers (millions)
1	Chinese	1113
2	English	372
3	Hindi/Urdu	316
4	Spanish	304
5	Arabic	201
6	Portuguese	165
7	Russian	155
8	Bengali	125
9	Japanese	123
10	German	102

Psycholinguistics: the study of language acquisition and meaning

The study of **linguistics** involves determining the ‘rules’ of language and the nature and meaning of written and spoken language. In contrast, **psycholinguistics**, a branch of psychology devoted to the study of verbal behaviour, examines the role of human cognition in language acquisition and comprehension: it is the integration of psychology and linguistics.

Psycholinguists are interested in how we acquire language – how verbal behaviour develops – and how we learn to speak from our interactions with others. In short, they are interested in the interaction between the structure and processing of language.

Psycholinguistics is a relatively recent, distinct branch of psychology although psychologists have studied language since the discipline's early experimental days.

Wundt, for example, regarded as the father of psycholinguistics, argued that the sentence was the most basic element of speech production and comprehension. Speech production involved the transformation of thought process into sequences of speech segments; comprehension, on the other hand, was the reverse process. Wundt's view was not universally accepted. The linguist Hermann Paul, for example, argued that words, not sentences, were the building blocks of speech.

This essentially European debate became somewhat sterile during the 1920s and 1930s when the form of psychology championed by Wundt was usurped by behaviourism which, as you saw in Chapter 1, argued that psychology should concern itself only with observable behaviour. It was not until the 1950s that psychology began to take a renewed interest in the nature of language and, ironically, this interest was spurred by a linguist, Noam Chomsky. Chomsky's views of the nature of language are discussed later on in the chapter. This chapter reviews studies from psycholinguistics and cognitive psychology and introduces you to current understanding of the ways in which we produce and comprehend speech.

Perception of speech

Speech involves the production of a series of sounds in a continuous stream, punctuated by pauses and modulated by stress and changes in pitch. Sentences are written as sets of words, with spaces between them. Speech, however, is a more flexible means of communication than is writing. The sentences we utter are a string of sounds, some of which are emphasised (stressed), some are quickly glided over. We can raise the pitch of our voice when uttering some words and lower it when speaking others. We maintain a regular rhythmic pattern of stress. We pause at appropriate times, for example between phrases, but we do not pause after pronouncing each word. Thus, speech does not come to us as a series of individual words; we must extract the words from a stream of speech.

Recognition of speech sounds

The human auditory system is responsible for performing the complex task of enabling us to recognise speech sounds. The sound system of speech is called phonology.

These sounds vary according to the sounds that precede and follow them, the speaker's accent, and the stress placed on the syllables in which they occur. **Phonemes** are the elements of speech – the smallest units of sound that contribute to the meaning of a word. For example, the word 'pin' consists of three phonemes: /p/ + /i/ + /n/. It is important to note that phonemes are not the same as letters. The word 'ship', for example, has four letters but three phonemes: /sh/ + /i/ + /p/. Note that in linguistics phonemes are flanked by two forward-slanting lines to indicate that they are phonemes and not letters. The first step in recognising speech sounds, therefore, is the identification of phonemes.

Production of speech

The production of speech is the result of a coordinated set of muscles found in the face, mouth and throat. Those responsible for producing some common words are illustrated in Figure 10.3.

One detectable and distinctive phonetic feature is **voice onset time**, the delay between the initial sound of a voiced consonant and the onset of vibration of the vocal cords. Voicing refers to the vibration of the vocal cords. The distinction between voiced and unvoiced consonants allows us to distinguish between /p/ (unvoiced) and /b/ (voiced), between /k/ (unvoiced) and /g/ (voiced), and between /t/ (unvoiced) and /d/ (voiced).

For example, although the difference between uttering 'pa' and 'ba' are subtle, they are discernible. Uttering 'pa' involves building up pressure in the mouth. When the lips are opened, a puff of air comes out. The 'ah' sound does not occur immediately, because the air pressure in the mouth and throat keeps air from leaving the lungs for a brief time. The vocal cords do not vibrate until air from the lungs passes through them. Uttering 'ba', however, does not involve the initial build-up of pressure. The vocal cords begin vibrating as soon as the lips open. The delay in voicing that occurs when uttering 'pa' is slight, only 0.06 seconds.

An experiment by Lisker and Abramson (1970) illustrates this point. They presented participants with a series of computer-generated sounds consisting of a puff followed by an 'ah'. The sounds varied only in one way: the amount of time between the puff and the 'ah'. When we speak, we make a puff for 'pa' but not for 'ba'. However, even though the computer always produced a puff, participants reported that they heard 'ba' when the delay was short and 'pa' when it was long. Participants discriminated between the phonemes /p/ and /b/ strictly according to the delay in voicing. The experiment demonstrates that the auditory system is capable of detecting very subtle differences.

Figure 10.3 The areas in the vocal tract where production of consonants takes place.

Although the fundamental unit of speech, logically and descriptively, is the phoneme, research suggests that psychologically the fundamental unit is larger. For example, the two syllables 'doo' and 'dee' each consist of two phonemes. When spoken, the same phoneme, /d/, is heard at the beginning. However, when Liberman *et al.* (1967) analysed the sounds of the syllables, they found that the beginning phonemes were not the same. In fact, they could not cut out a section of a tape recording of the two syllables that would sound like /d/.

These results suggest that the fundamental unit of speech consists of groups of phonemes, such as syllables. The perception of a phoneme is affected by the sounds that follow it (Ganong, 1980). Using a computer to synthesise a novel sound that fell between those of the phonemes /g/ and /k/, Ganong reported that when the sound was followed by 'ift', the participants heard the word 'gift', but when it was followed by 'iss', they heard 'kiss'. These results suggest that we recognise speech sounds in pieces larger than individual phonemes.

Errors in speech production

As you will see later in this chapter, some individuals with damage to a specific part of the brain have an inability to produce speech or will produce meaningless speech. Speech errors or slips of the tongue, however, are not confined to the brain-damaged (Fromkin, 1988; Dell *et al.*, 1997) and some of these will be very familiar to you. Table 10.2 lists some of the common speech production errors made by normal individuals.

One obvious error is where the beginnings of words are transposed. So, for example, instead of saying 'dear old queen', you might say 'queer old dean'. This is an example of a Spoonerism, named after the Oxford don William A. Spooner who was noted for making such mistakes as saying 'noble tons of soil' instead of 'noble sons of toil'.

Speech errors are interesting because although they are errors they still follow the rules of grammar. For example, one might confuse nouns in a sentence ('would you pass me that cupboard from the pepper') but you would not confuse a noun with a verb ('would you cupboard the pass from the pepper'). Errors thus reflect what we had intended to say rather than what we want to say (Levelt, 1989). Somehow, an error occurs between conception and execution.

When President Kennedy addressed his German audience with the inclusive pronouncement, '*Ich bin ein Berliner*', what he actually said (to a Germanic ear) was – 'I am a cream pastry'. It is easy to see why we make such mistakes in languages which are unfamiliar, but why do you think that we make slips of the tongue in our native language?

Recognition of words: the importance of context

The perception of continuous speech involves different mechanisms from those used in the perception of isolated syllables. Because speech is full of hesitations, muffled sounds and sloppy pronunciations, many individual words can be hard to recognise out of context. For example, when Pollack and Pickett (1964) isolated individual words from a recording of normal con-

Table 10.2 Some common speech errors

1 Errors at phonemic segments
Consonant anticipation: a reading list/a leading list
Consonant deletion: speech error/peach error
Vowel exchange: fill the pool/fool the pill
2 Errors at phonetic features
Voicing reversal: big and fat/pig and vat
Nasality reversal: cedars of Lebanon/cedars of Lemadon
3 Errors at syllables
Syllable deletion: unanimity of opinion/unamity of opinion
Syllable reversal: Stockwell and Schacter/Schachwell and Stockter
4 Errors of stress (with the stressed syllable given in capital letters)
apples of the Origin/apples of the oRigin
eCONomists: ecoNOMists, I mean, eCONomists
5 Errors of word selection
Word exchange: tend to turn out/turn to tend out
Word movement: I really musy go/I must really go
6 Errors at morphemes
Inflection morpheme error: cow tracks/tracks cows
Derivational morpheme error: easily enough/easy enough
7 Errors at phrases
A hummingbird was attracted by the red colour of the feeder/the red colour was attracted by a hummingbird of the feeder
My sister went to the Grand Canyon/the Grand Canyon went to my sister
8 Semantic and phonological word errors
Semantic substitution: too many irons in the fire/too many irons in the smoke
Phonological substitution: white Anglo-Saxon Protestant/white Anglo-Saxon Prostitute
9 Errors at morphologically complex words
Lexical selection error: it spread like wild fire/it spread like wild flower
Exchange error: ministers in our church/churches in our minister

versations and played them back to other people, those people correctly identified the words only 47 per cent of the time. When they presented the same words in the context of the original conversation, the participants identified and understood almost 100 per cent of them.

Understanding the meaning of speech

The meaning of a sentence (or of a group of connected sentences that are telling a story) is conveyed by the words that are chosen, the order in which they are combined, the affixes that are attached to the beginnings or ends of the words, the pattern of rhythm and emphasis of

the speaker, and knowledge about the world shared by the speaker and the listener.

Syntax

The understanding of speech entails following the ‘rules’ of language. Words must be familiar and combined in specific ways. For example, the sentence, ‘The two boys looked at the heavy box’ is comprehensible; but the sentence, ‘Boys the two looking heavily the box at’ is not. Only the first sentence follows the rules of English grammar.

All languages have a **syntax**, or grammar, which is a set of rules governing the ways in which words are used to form sentences. They all follow certain principles, which linguists call syntactical rules, for combining words to form phrases, clauses, or sentences (syntax, like synthesis, comes from the Greek *syntassein*, ‘to put together’). Our understanding of syntax is automatic although learned. We are no more conscious of this process, for example, than a child is conscious of the laws of physics when he or she learns to ride a bicycle.

The automatic nature of syntactical analysis can be illustrated by experiments performed with artificial grammars. For example, Reber and Allen (1978) devised a set of (complex) rules for combining the letters M, V, R, T and X. For example, MRTXV and VXTTV were ‘grammatical’, but MXVTR and VMRTX were ‘ungrammatical’. They asked participants to look at 20 ‘grammatical’ strings of letters, printed on index cards. The participants were told to ‘pay the utmost attention to the letter strings’ but were not instructed to do anything else. Later, the participants were presented with 50 different strings of letters, half of which were ‘grammatical’ and half of which were not. Some of the ‘grammatical’ strings were ones they had already seen, and some were new to them. The participants were asked to indicate whether the strings were ‘grammatical’.

Although the participants did quite well – they correctly identified 81 per cent of the strings of letters – they could not express the rules verbally. The participants made statements like: ‘The shapes of the items began to make sense.’ ‘Almost all my decisions are based on things looking either very right or very wrong. Sometimes for some reason things came out and glared at me saying, ‘bad, bad, bad’, other times the letters just flowed together and I knew it was an OK item.’

This finding and others like it suggests that syntactic rules are learned implicitly (or not at all). Knowlton *et al.* (1991) found that patients with anterograde amnesia were able to learn an artificial grammar even though they had lost the ability to form explicit memories. In contrast, as Gabrieli *et al.* (1988) observed, such patients are unable to learn the meanings of new words. Thus, learning syntax and word meaning appears to involve different types of memory and, consequently, different brain mechanisms.

Word order

Word order is important in English. In the sentences ‘The boy hit the ball’ and ‘The ball hit the boy’, word order tells us who does what to whom. In English, the first noun of the sentence is the subject, the second noun is the object and the part in between is usually the verb. This structure is referred to as S–V–O word order (for subject–verb–object) and around 75 per cent of the world’s languages possess this sentence structure (Bernstein and Berko, 1993). Other languages, however, have different orders. Japanese, for example, uses the S–O–V order and both Welsh and Arabic use V–S–O. The assignation of words into meaningful categories (such as noun, verb, adjective and so on) is called parsing, and parsing involves being able to identify word classes.

Word class

Word class refers to the grammatical categories such as noun, pronoun, verb and adjective, and words can be classified as function words or content words. Function words include determiners, quantifiers, prepositions and words in similar categories: ‘a’, ‘the’, ‘to’, ‘some’, ‘and’, ‘but’, ‘when’, and so on. Content words include nouns, verbs and most adjectives and adverbs: ‘apple’, ‘rug’, ‘went’, ‘caught’, ‘heavy’, ‘mysterious’, ‘thoroughly’, ‘sadly’. Content words express meaning; function words express the relations between content words and thus are very important syntactical cues.

Affixes

Affixes are sounds that we add to the beginning (prefixes) or end (suffixes) of words to alter their grammatical function. For example, we add the suffix ‘-ed’ to the end of a regular verb to indicate the past tense (drop/dropped); we add ‘-ing’ to a verb to indicate its use as a noun (sing/singing as in ‘we heard the choir sing’ and ‘the choir’s singing was delightful’); and we add ‘-ly’ to an adjective to indicate its use as an adverb (bright/brightly). We are quick to recognise the syntactical function of words with affixes like these. For example, Epstein (1961) presented people with word strings such as the following:

a vap koob desak the citar molent um glox nerf
A vapy koob desaked the citar molently um glox nerfs

The people could more easily remember the second string than the first, even though letters had been added to some of the words. Apparently, the addition of the affixes ‘y’, ‘-ed’ and ‘-ly’ made the words seem more like a sentence and they thus became easier to categorise and recall.

Semantics

The meaning of a word – its **semantics** – provides important cues to the syntax of a sentence (semantics comes from the Greek *sema*, ‘sign’). For example, consider the following set of words: ‘Frank discovered a flea combing his beard’. The syntax of this sentence is ambiguous. It does not tell us whether Frank was combing Frank’s beard, the flea was combing the flea’s beard, or the flea was combing Frank’s beard. But our knowledge of the world and of the usual meanings of words tells us that Frank was doing the combing, because people, not fleas, have beards and combs.

Function words and content words

Function words (such as ‘the’, ‘and’, ‘some’) help us determine the syntax of a sentence; **content words** help us determine its meaning. For example, even with its function words removed the following set of words still makes pretty good sense: ‘man placed wooden ladder tree climbed picked apples’. You can probably fill in the function words yourself and get ‘The man placed the wooden ladder against the tree, climbed it, and picked some apples.’

Prosody

Prosody is a syntactic cue which refers to the use of stress, rhythm and changes in pitch that accompany speech. Prosody can emphasise the syntax of a word or group of words or even serve as the primary source of syntactic information. For example, in several languages (including English), a declarative sentence can be turned into a question by means of prosody. Read the following sentences aloud to see how you would indicate to a listener which is a statement and which is a question.

You said that.
You said that?

We do this by intonation. In written communication, prosody is emphasised by punctuation marks. For example, a comma indicates a short pause, a full stop indicates a longer one along with a fall in the pitch of voice, and a question mark indicates an upturn in the pitch of voice near the end of the sentence. These devices serve as only partial substitutes for the real thing. Because writers cannot rely on the cues provided by prosody, they must be especially careful to see that the syntax of their sentences is conveyed by other cues: word order, word class, function words, affixes and word meaning.

The relationship between semantics and syntax

Sentences can be read or heard semantically in more than one way. Noam Chomsky (1957, 1965), the noted linguist, suggested that language can partly be explained by reference to sentence grammar. Although Chomsky's ideas underwent several revisions, the 1965 version of his theory suggests that there are three grammars. The first – generative grammar – represents the rules by which a speaker's ideas can be transformed into a final grammatical form. These transformed ideas or thoughts are called deep structures (the second grammar). The final output is the surface grammar or structure which is the end spoken product.

The deep structure represents the kernel of what the person intended to say. In order to utter a sentence, the brain must transform the deep structure into the appropriate surface structure: the particular form the sentence takes.

Most psychologists agree that the distinction between surface structure and deep structure is important (Tanenhaus, 1988; Bohannon, 1993; Hulit and Howard, 1993). Individuals with a language disorder known as conduction aphasia have difficulty repeating words and phrases, but they can understand them. The deep structure of other people's speech appears to be retained, but not its surface structure.

Knowledge of the world

Comprehension of speech also involves knowledge about the world and the particular situations encountered in it (Carpenter *et al.*, 1995). Schank and Abelson (1977) suggested that this knowledge is organised into scripts, which specify various kinds of events and interactions that people have witnessed or have learned about from others. Once a speaker has established which script is being referred to, the listener can fill in the details. For example, in order to understand what the speaker means in the following sentences:

I learned a lot about the clubs in town yesterday. Do you have an aspirin?

we must be able to do more than simply understand the words and analyse the sentence structure (Hunt, 1985). We must know something about clubs; for example, that they serve alcohol and that 'learning about them' probably involves some drinking. We must also realise that imbibing these drinks can lead to a headache and that aspirin is a remedy for headaches. Hunt notes that when we describe an event to someone else, not all the details are spelled out. For example:

Alison was hungry and so she went to a restaurant and ordered a pizza. When she had finished, she discovered that she had forgotten to take her purse with her. She was embarrassed.

In this story we need to understand that after eating in a restaurant, you are expected to pay.

What is meaning?

Words refer to objects, actions, or relations in the world. Thus, the meaning of a word (its semantics) is defined by particular memories associated with it. For example, knowing the meaning of the word 'tree' means being able to imagine the physical characteristics of trees: what they look like, what the wind sounds like blowing through their leaves, what the bark feels like, and so on. It also means knowing facts about trees: about their roots, buds, flowers, nuts, wood and the chlorophyll in their leaves. These memories are not stored in the primary speech areas but in other parts of the brain, especially regions of the association cortex. Different categories of memories may be stored in particular regions of the brain, but they are linked, so that hearing the word 'tree' activates all of them.

To hear a familiar word and understand its meaning involves first recognising the sequence of sounds that constitute the word. We must, therefore, have some form of memory store which contains the auditory representations of words. This store forms part of our auditory word recognition system. When we find the auditory entry for the word in our **mental lexicon** (lexicon means 'dictionary'), we must be able to access semantic information about this word. The region of the brain responsible for the auditory comprehension of words must somehow communicate with another region (or regions) which allows us to ascribe meaning to what we have just heard.

Is there a universal language?

Or, put less controversially, are there some features of language that are shared by most, if not all, languages? The answer seems to be yes. For example, all languages have nouns and words to represent states of action or states of being because we all need a way of referring to objects, people and events. Hockett (1960a, b) has suggested that all languages share similar features. These are listed in Table 10.3. Are there others that you think could be added to the list?

Table 10.3 The features that Hockett regards as common to all languages

Universal	Description
Arbitrariness	There is no inherent connection between symbols and the objects they refer to
Broadcast transmission	Messages are transmitted in all directions and can be received by any hearer
Cultural transmission	Language is acquired through exposure to culture
Discreteness	A distinct range of possible speech sounds exists in language
Duality of structure	A small set of phenomes can be combined and recombined into an infinitely large set of meanings
Interchangeability	Humans are both message perceivers and message producers
Productivity	Novel messages can be produced according to the rules of the language
Semanticity	Meaning is conveyed by the symbols of the language
Specialisation	Sounds of a language are specialised to convey meaning (as compared with non-language sounds)
Total feedback	The speaker of a language has auditory feedback that occurs at the same time as the listener receives the message
Transitoriness	Linguistic messages fade quickly
Vocal–auditory channel	Means of transmission of the language is vocal–auditory

Gesture and communication

When we communicate orally, we often gesture and gesture was probably the evolutionary forerunner of vocal language. Some have argued that our language is gestural in nature, rather than acoustic (Gentilucci and Corballis, 2006). Ploog (2002) has hypothesised that we have two neural systems which mediate vocal behaviour. The first is in the cingulate cortex (and is found in non-humans) and the second is neocortical (seen in humans), which controls contralateral voluntary motor movement. The function of gesture appears manifold: it is used to express feeling, tone and meaning. Many of the gestures we make are intended to communicate an idea or thought or request. We point in order to direct people where to go; we beckon with our hands if we want someone to come near us; we have a number of gestures signifying disapproval of others.

But can combining speech and gesture improve comprehension of another's intention? Kelly *et al.* (1999) set up a

series of experiments in which they asked participants to watch video footage of a specially created scenario. For example, two characters, Adam and Bill, are going home when they meet each other in the street just outside their flat. Adam is on a bike and Bill is walking. Adam asks Bill if he had brought the burgers. Bill had not. Adam says to Bill that he had better get them. Bill protests that the burger bar is in another part of town. In one condition, Bill makes eye contact with Adam and gestures towards his friend's bike; in another, he maintains eye contact and just says the dialogue. In the experiment, participants are asked to indicate how they think the last person addressed in the scenario would react to what had been communicated. All scenarios featured indirect requests; in none was a target mentioned (in the example here, a bike) or an intended action explicitly suggested.

The authors found that those in the gesture and speech condition were almost twice as likely to understand the nature of the indirect request than were those in the speech-only condition. The authors found a similar result in another experiment in which participants had to remember information spoken by a woman who made or did not make meaningful gestures (e.g. shooting a basketball) when describing her brother, a basketball player.

To investigate whether speakers gesture to help listeners better understand what they are saying, Alibali *et al.* (2001) observed the gestures made by individuals who were asked to narrate to a colleague the contents of an animated cartoon. In one part of the experiment, the listener was face-to-face with the gesturer and could see the speaker's gestures; in the other, a screen blocked the view of the speaker. The gestures were filmed by a hidden camera and were classified into two categories: representational gestures, those used to gesture meaning in speech, and beat gestures, those which conveyed no semantic content and were simple and rhythmic.

The rate of beat gestures was comparable in the visible and the blocked condition but the rate of representational gesture varied according to condition. Specifically, speakers used more representational gestures when the listeners could see them than when they could not.

The researchers suggest that these results support the semantic information hypothesis of gesture. This states that a speaker's visibility to the listener influences the production of meaningful gestures. We seem to gesture to convey meaning when we speak, even when our listeners cannot see these gestures.

Gestures, like language, are very culture-specific bits of behaviour. A gesture in one language may mean something entirely different – or nothing at all – in another. To determine how well people could distinguish between real gestures and fake ones, Molinsky *et al.* (2005) asked native-born and non-native American students to view videotaped gestures which were genuinely used in America or ones which had been invented by the experimenter. Examples can be seen in Table 10.4.

Table 10.4 Examples of the types of fake and real gestures used in Molinsky *et al.*'s study (2005)

Real	Fake
Shoulder shrug	Twirl right finger in front of
Cup left hand around ear (so signify not being able to hear)	body from chest to above the head
Wave hand back and forth	Push front of nose inward
Slice throat with second finger of hand	with second finger
Thumbs up	Right hand in front of face, palm facing in; make
Using first two fingers of hand to mine quotation marks	downward motion like guillotine
Tap second finger of hand to head several times	Cup fist and twist towards the ground
Making circle with thumb and second finger (OK)	

There was a significant and positive relationship between accurate gesture recognition and length of stay in America – the longer participants had been there, the better the recognition. Specifically, however, the more competent they felt in communicating in their adopted culture, and the more motivated they were to learn about their new culture, the better they were at distinguishing fake from real gestures.

Reading

Speech first developed as a means of communication between two or more people facing each other, or at least within earshot of each other, and probably occurred around 200,000 to 300,000 years ago. Indo-European languages

Psychology in action – Sex differences in communication

The prolific American linguist, Deborah Tannen, has reported some curious differences between men and women in the way they hold conversations and communicate with each other. Take the following example, from Tannen's book, *You Just Don't Understand* (1992):

'A married couple was in a car when the wife turned to her husband and asked, 'Would you like to stop for a coffee?'

'No, thanks,' he answered truthfully. So they didn't stop.

The result? The wife, who had indeed wanted to stop, became annoyed because she felt her preference had not been considered. The husband, seeing his wife was angry, became frustrated. Why didn't she just say what she wanted?

This, according to Tannen's research, sums up one important difference between men's and women's language use: women often make a suggestion to start a negotiation. Men see it as a direct question to be answered directly. Another of Tannen's findings is that men's conversation can be a little like witnessing a verbal contest: it is a way of establishing dominance, not being pushed around, getting the upper hand. Women use conversation to encourage intimacy, closeness and support. Men are more independent, exemplified by a man's ability to make a unilateral decision which directly affects his partner without consulting her. Women try to win an argument by agreement – requests are formulated as proposals, not demands. Another difference is that men and women behave differently when dis-

puting advice and understanding – when a woman expresses a problem or difficulty, a man will suggest a solution, when what is usually desired is understanding and reassurance.

A recent meta-analysis of men's and women's talkativeness and the type of speech they engage in has found some surprising differences (Leaper and Ayres, 2007). The researchers examined degrees of affiliative speech – that used to affirm or positively engage with another person – and assertive speech – that used to advance a point of view, be direct and give information.

Women, as predicted, engaged in more affiliative speech (but did not act unassertively during exchanges) but there was no general difference between the sexes in terms of assertive speech. The authors found the following specific results:

- Men were more talkative and used assertive speech more.
- Men used assertive speech less during interactions with strangers than close relations.
- Men were more likely to give suggestions in speech and approached conversations in a task-oriented way.
- Women made more critical statements.
- Female undergraduates used more affiliative and less assertive speech, but there was no difference in non-students.
- When mothers and fathers were with their child, the mother would talk more.
- Men were more talkative than women in mixed-sex interactions but there was no sex difference when interactions were with the same sex.
- Women were more likely to use affiliative speech in same-sex than mixed sex interactions.

Psychology in action – *Continued*

- Women disclosed more information than men but not in mixed-sex interactions.
- Women smiled more (and for longer in same-sex interactions).
- Men used assertive speech more in same-sex interactions (perhaps seeing the exchange as a form of competition).
- If a researcher was present, men used more assertive speech; when one was absent, the women did (although this finding was based on limited data).
- Greater affiliative speech in women and greater talkativeness in men was more likely when research was done in a university laboratory.
- Women were more likely to discuss socio-emotional-oriented topics; men discussed instrumental-oriented topics.

- Women were more assertive when interacting with children.
- Women used more affiliative speech when observed for brief periods (4–8 minutes), but not for 10–15 minutes or 20–300 minute periods.
- Talkativeness favouring men was greater in research published in top-tier journals.

The analysis suggests that sex differences in speech and the amount of speech can depend on a number of social and environmental factors, including the sex of the person the participant is interacting with, how long they interact, where they interact, how they interpret the situations they find themselves in, and whether they are students or non-students.

(144 tongues), for example, seem to have a common root, as Figure 10.4 shows.

The invention of writing, which made it possible for people to communicate across both space and time, was an important turning point in civilisation. The first system of writing appears to have been developed around 4000 BC in Sumeria (the location of present-day Iran and Iraq), apparently in response to the need to keep records of ownership and of business transactions. The earliest forms of writing were stylised drawings of real objects (pictographs), but most cultures soon developed symbols based on sounds. For example, Egyptian hieroglyphic writing used some symbols as pictographs but used others phonetically, to spell out people's names or words that denoted concepts not easily pictured (Ellis, 1992).

With the notable exception of Chinese (and other Asian writing systems based on Chinese), most modern languages use alphabetic writing systems in which a small number of symbols represent (more or less) the sounds used to pronounce words. For example, most European languages are represented by the Roman alphabet, originally developed to represent the sounds of Latin and subsequently adopted by tribes of people ruled or influenced by the Roman Empire. The Roman alphabet was adapted from the Greek alphabet, which in turn was adapted from the Phoenician alphabet. For example, the letter D has its origin in the Phoenician symbol 'daleth', which meant 'door'. At first, the symbol literally indicated a door, but it later came to represent the phoneme /d/. The Greeks adopted the symbol and its pronunciation but changed its name to delta. Finally, the Romans took it, altering its shape into the one we recognise in English today.

Scanning text

When we scan a scene, our eyes make rapid jumps called saccades. These same rapid movements occur during reading (a French ophthalmologist in the nineteenth century discovered saccadic eye movements while watching people read).

The study of eye movements is made possible by a device called an eye tracker. This device consists of an apparatus that holds a person's head in a fixed position and a special video camera that keeps track of the person's gaze by focusing on an eye and monitoring the position of the pupil. The person reads material presented by a computer on a video monitor.

Perception does not occur while the eyes are actually moving but during the brief **fixations** that occur between saccades. The average fixation has a duration of about 250 milliseconds, but their duration can vary considerably. Figure 10.5 shows the pattern of fixations made by both good and poor readers.

The ovals above the text indicate the location of the fixations (which occur just below the ovals, on the text itself), and the numbers indicate their duration (in milliseconds). The fixations of good readers were made in the forward direction; the poor readers looked back and examined previously read words several times (indicated by the arrows). In addition, the good reader took, on average, considerably less time to examine each word.

Familiar words tend to be skipped over more frequently than are visually similar non-words (Drieghe *et al.*, 2005). University students fixate on most words when they are asked to read text carefully enough to under-

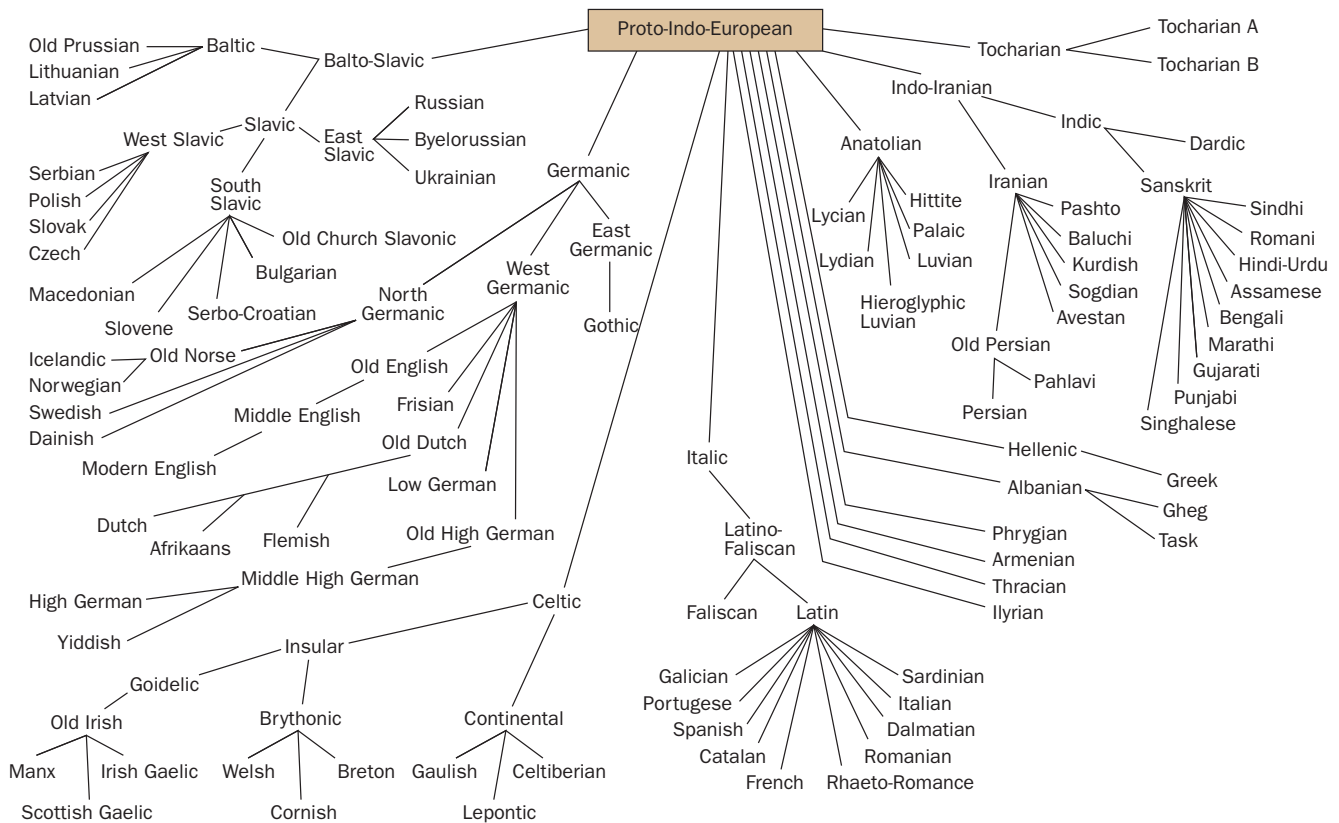

Figure 10.4 A language tree showing the suggested derivation of the most well-developed languages.

Source: 'Evolution of language', *Science*, 303, 27 February 2004, p. 1325, unnumbered figure.

stand its meaning. They fixate on 80 per cent of the content words but on only 40 per cent of the function words such as 'the' and 'and' (Just and Carpenter, 1980). Function words are generally shorter than content words, but the difference is not only a matter of size. Readers are more likely to skip over short function words such as 'and' or 'the' than over short content words such as 'ant' or 'run' (Carpenter and Just, 1983). For example, read the following sentence:

I love Paris in the
the springtime

You may not have noticed that second 'the' at the beginning of the second line and would have read the sentence as normal; we seem to be able to glide over function words such as 'the' without it detrimentally affecting the way in which we perceive and understand meaning.

As sentences are read, they are usually analysed word by word (Rayner and Pollatsek, 1989). Some words contribute more to our understanding than do others, and some sentences cannot make sense until we reach the end (compare and contrast: 'The capital of Kenya is Nairobi'; 'Nairobi is the capital of Kenya'). The more unusual a

word is, the longer a reader fixates on it. The word 'sable', for example, receives a longer fixation than the word 'table'. The word that follows an unusual word does not receive a longer-than-usual fixation, which indicates that the reader finishes processing the word before initiating the next saccade (Thibadeau *et al.*, 1982). Readers also spend more time fixating on longer words. In fact, if word familiarity is held constant, the amount of time a word receives is proportional to its length (Carpenter and Just, 1983). In addition, Just *et al.* (1983) found that the amount of time that Chinese readers spent fixating on a Chinese character was proportional to the number of brush strokes used to make it. Because all Chinese characters are of approximately the same size, the increased fixation time appears to reflect the complexity of a word rather than the amount of space it occupies.

Phonetic and whole-word recognition

Most psychologists who study the reading process believe that readers have two basic ways of recognising words: phonetic and whole-word recognition. **Phonetic reading** involves the decoding of the sounds that letters or groups of

letters make (in a similar way to which the units of speech are called phonemes, the units of written language are called **graphemes**). For example, the ability to pronounce nonsense words depends on our knowledge of the relation between letters and sounds in the English language. Such knowledge is used to ‘sound the word out’. When we do this we apply **grapheme–phoneme correspondence (GPC)** rules: the rules which govern the ways in which we are able to translate written letters into the appropriate sounds. This is called **whole-word reading**: reading by recognising a word as a whole. But do we have to ‘sound out’ familiar, reasonably short words such as ‘table’ or ‘grass’? Probably not. Familiar words are perceived as whole words. However, consider this list of words: ‘knave’, ‘shave’, ‘slave’, ‘have’. How did you pronounce the last word? You probably pronounced it to rhyme with ‘slave’. This example illustrates that although whole-word reading would seem to be intuitively correct, our pronunciation of words can depend on the context in which words are used.

The process of reading

A relatively inexperienced reader will have to sound out most words and, consequently, will read rather slowly. Experienced, practised readers will quickly recognise most of them as individual units. In other words, during reading,

phonetic and whole-word reading are engaged in a race. If the word is familiar, the whole-word method will win. If the word is unfamiliar, the whole-word method will lose and the phonetic method will have enough time to compete.

When we read a word, we must have some store of knowledge which allows us to identify words as words. In the same way that the auditory store was considered part of the auditory word recognition system, the visual store can be considered part of the visual word recognition system. But is our recognition of written words purely visual? Or can we read by ‘ear’?

To answer this question, Rubenstein *et al.* (1971) presented individuals with three types of non-word (strings of letters which make invalid English words): **pseudo-words**, which conformed to the rules of English but had no meaning (for example GANK), non-words which were pronounceable but illegally spelled (for example MIRQ), and non-words which were unpronounceable and illegally spelled (for example HTRR). The participants had to decide whether these words, presented on a computer screen, were real English words or not (this is called a lexical decision task). The experimenters found that participants took longest to reject the pseudowords, followed by illegally spelled pronounceable words, followed by illegally spelled unpronounceable words. In a second experiment, Rubenstein *et al.*, included a set of words called **pseudohomophones**; these are words which are

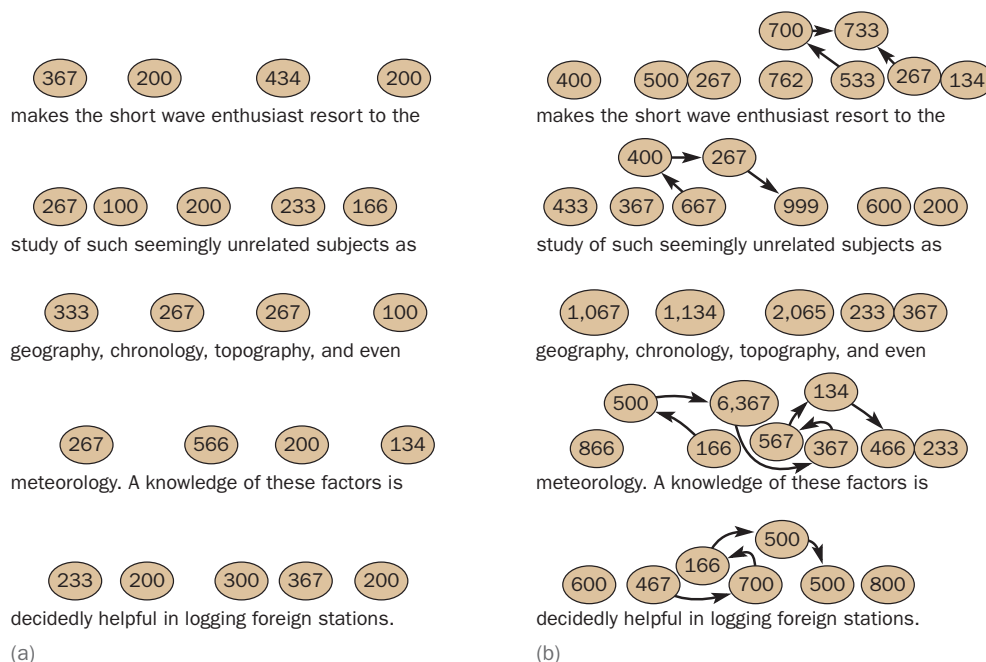

Figure 10.5 The pattern of fixations made by two readers. The ovals are placed above the locations of the fixations; the numbers within them indicate the durations of the fixations (in milliseconds). Arrows indicate backtracking to words already examined.

(a) A good reader. (b) A poor reader.

legally spelled, are pronounceable, sound like real words but have no meaning (for example PHICKS, which sounds like 'fix'). They would, therefore, pass an auditory word recognition system, but not the visual word recognition system. As predicted, pseudohomophones took longest to reject, followed by pseudowords.

Rubenstein *et al.* suggested that visual information is translated into a phonological code, a sound-based representation of the word, using grapheme to phoneme conversion. This representation is then checked by the auditory word recognition system which decides whether the word sounds like a real word or not. Pseudowords would fail this test – they do not sound like real words. Pseudohomophones, however, would pass because they do sound like real words. They, therefore, need to be checked by the visual word recognition system in order to determine whether the word is real. The visual word recognition system checks the orthography of a word (the way in which it is spelled). The recognition of words, therefore, involves phonic mediation: the conversion of written language into a sound-based representation.

Phonic mediation, however, appears to be necessary only for the recognition of unfamiliar words (Ellis, 1992). When we see a familiar word, we normally recognise it as a whole and say it aloud. If we see an unfamiliar word or a pronounceable non-word, we must try to read it phonetically. We recognise each letter and then sound it out, based on our knowledge of how letters are sounded out (phonetics).

Whole-word recognition is not only faster than phonetic decoding, but also essential in a language (such as English) in which spelling is not completely phonetic. In the following pairs of words:

cow/blow bone/one post/cost limb/climb

no single set of phonological rules can account for the pronunciation of both members of each pair (phonology refers to the relation between letters and the sounds they represent in a particular language). Yet all these words are familiar and easy to read. The ability to recognise words as wholes, therefore, may be necessary in order to read irregularly spelled words (although our 'have' example earlier on suggests how whole-word reading can fail).

Phonology, however, appears to be crucial for the development of language ability, as we will see later. Having good phonological skills appears to place children at an advantage linguistically. Gathercole and Baddeley (1990) found that 5-year-old children with good phonological skills were better at remembering nonsense words than were those with poor phonological skills. This ability to repeat nonsense words appears to be a good predictor of later, successful vocabulary acquisition (Gathercole *et al.*, 1992). The role of phonology (and other processes) in

learning to read is the topic of the Psychology in Action section below. There is much debate over the best way to teach children how to learn to read, and psychologists have discovered much that teachers can use in their instruction.

The dual-route model of reading

The **dual-route model of reading** proposes that there are two routes that take the reader from spelling to sound (Coltheart, 1978; Morton and Patterson, 1980). The lexical route retrieves pronounced words from a lexicon, i.e. it 'looks up' words in an internal word pool which contains items learned through experience, a little like a personalised dictionary. This route is also known as the 'direct', 'lexical', 'lexico-semantic' or 'addressed' route: all refer to the same path. The sublexical route is the system which converts letters into sounds – a process called grapheme–phoneme correspondence. It 'translates' letters into sounds based on sound–letter associations that have been learned. Other terms for this route include indirect, assembled, sublexical and graphological. The lexical route would be able to identify all known words, regardless of whether they follow grapheme–phoneme correspondence rules; the sublexical route would be able to identify non-words using these rules (it would be able to recognise 'flound' as a non-word, for example, because the word follows normal grapheme–phoneme correspondence rules).

The model derived from studies of brain-injured patients who appear to rely more on one route than the other. People with a type of dyslexia called phonological dyslexia (see below), for example, appear to have access only to whole word forms (the direct, lexical route) and have difficulty in reading regularly spelled words (suggesting an impairment in the indirect, sublexical route). The reading of non-words is significantly worse than the reading of (familiar) words. An alternative to the dual-route model has argued that the same mechanisms underlie the reading aloud of words and non-words (such as 'nep' and 'cabe').

In a test of these competing models, Caccappoulo-van Vliet *et al.* (2004) described two patients with dementia who showed pure phonological dyslexia. These patients were unable to read non-words but they were able to read familiar, irregularly spelled words accurately. However, their phonological skills were intact, thus lending support to the dual-route model explanation of phonological dyslexia rather than the alternative (because phonological ability was generally unimpaired).

A meta-analysis of 35 neuroimaging studies of the dual-route model suggests that the two routes of reading can also be mapped in the healthy brain (Jobard *et al.*, 2003). Access to the visual representation of words was found to rely on two routes, but there was no consistent brain region devoted to storing the shapes of word forms. Instead, a general region located at the occipitotemporal junction

appeared to be involved in the initial segmentation or classification of word-like stimuli. The phonological route was subserved by parts of the temporal lobe and also regions involved in working memory (because of the process involved in matching letters and sounds). The so-called direct route, according to this review, recruited a pathway linking the occipitotemporal cortex with those involved in semantic processing (these regions are found in or around the temporal cortex).

Connectionism and the dual-route model

Are both routes in the dual-route model activated simultaneously during reading? One view holds that both systems operate in parallel and are in some form of race, the winner being the system which produces the best pronunciation. A second view holds that the two processes are pooled until a match is made that would prompt articulation. No clear

agreement on this process has been reached, although a great deal of excitement in cognitive psychology and psycholinguistics has been roused by the possibilities of connectionism, a form of computer modelling of human cognitive function, in solving this problem. This approach argues that there are no qualitatively different processes involved in recognising words and that there is no localised lexicon.

Connectionism takes as its starting point the view that the brain, or our information processing system, operates in a similar way to a computer and can, therefore, be modelled. Such a model should be capable of learning (as our brain is). This idea, of course, is not new. Rosenblatt (1962) had developed a parallel processing machine which was capable of simple learning. Modern, computer-based models of human computation, however, were pioneered by Seidenberg and McClelland (1989). Their **parallel distributed processing (PDP) model** did away with the notion of dual routes and instead posited one route only which

Figure 10.6 An example of the macrostructure (a) and microstructure (b) of McClelland and Rumelhart's activation model. The macrostructure illustrates the general organisation of the model. The microstructure shows how nodes within the model are connected. In these diagrams the arrows ending in points are excitatory connections, and the arrows ending in dots are inhibitory connections. The nodes at the bottom of (b) represent the physical features of words; the nodes at the next level represent the letters of words. Finally, the nodes at the top represent the actual words. You can see that there is an excitatory connection between the letter 'T' and the word 'TRIP' because the word contains this letter. However, there is an inhibitory connection between the letter 'N' and the word 'TRIP' because the word does not contain this letter.

Source: McClelland, J.L. and Rumelhart, D.E., An interactive activation model of context effects in letter perception. Part 1: An account of basic findings. *Psychological Review*, 1981, 88, 375–407. © 1981 The American Psychological Association, reprinted with permission.

was non-lexical. Their model is an example of a computational model of behaviour because it translates units of behavioural phenomena into computations. Seidenberg and McClelland's model was a three-layer neural network which sought to read regular, exception and non-words from spelling to sound. The three layers were: features, letters and words. Perception within each of these layers was argued to occur in parallel so that the system could analyse features while it identified letters and attempt to name the word a stimulus might represent (Zorzi *et al.*, 1998). An example of the type of network proposed by PDP can be seen in Figure 10.6.

However, the model has run into some difficulty. It cannot read non-words, for example, and it cannot simu-

late a form of dyslexia called surface dyslexia, which is described later in the chapter (Besner *et al.*, 1990; Coltheart *et al.*, 1993). The PDP model has been replaced by that of Plaut and colleagues (Plaut and McClelland, 1993; Plaut *et al.*, 1996) which seems to have met with some success in that it is at least capable of reading monosyllabic non-words but does not appear to account for the flexibility of human language (see Zorzi *et al.*, 1998, for a review). We will not say too much more about PDP and connectionism here. Although the PDP model and connectionism are difficult concepts to grasp it is important to take note of them because there is great debate in psychology over the relevance and validity of connectionism in trying to explain the process of visual word recognition.

Psychology in action – How children learn to read

Reading is an artificial activity and it must be taught to us (usually at an early age). A beginning reader has much of their work cut out because they have no vocabulary and no set of rules. Are there any cognitive skills (such as an awareness of rhyme or having an effective short-term memory) that can help develop the child's vocabulary and skills? Does reading develop naturally or in stages? And how can we best teach children to read?

To begin with, reading requires adequate sight, so a child would need to be visually competent. Of course, blind children can be taught Braille, but our concern here is with the development of visual word recognition and visual reading. The next important step is for the child to relate written letters or groups of letters to sounds. In some languages this is easier to do than it is in others. The rules needed to undertake this task are more complex in English, say, than in Finnish or Italian. Some of these rules will be simple – 'b' corresponds to /b/. Others are not – the 'c' in 'car' and 'mince' is sounded differently, for example. These general rules are called spelling-to-pronunciation correspondence rules or, more accurately, grapheme-phoneme correspondence rules. The essential feature of these rules is that the child must break up words into segments and put them back together again to form a pronounceable whole. This breaking and putting together again are called **segmentation** and **blending**, respectively, and are two tasks the beginning reader has great difficulty in undertaking.

According to Oakhill and Garnham (1988), the child's reading process is dependent on the development of a number of skills. Whether these skills give rise to reading, are associated with reading or develop from reading is an interesting psychological question that many developmental psychologists and psycholinguists have attempted to answer. However, this debate need not concern us here. What will concern us are the skills associated with reading development. Oakhill and Garnham's list includes the following features/skills: word con-

sciousness, awareness of lower-level features, orthographic awareness, phonemic awareness and use of analogy.

- **Word consciousness.** Word consciousness or **lexical awareness** refers to the ability to understand that speech and writing are composed of different, distinct elements called words. Of course, to us, as skilled readers, this is quite obvious. It is not, however, to a child who is learning to read and has not encountered such stimuli at any great length. Although it appears that young children have difficulties in indicating word boundaries (where one ends and another begins), children with strong lexical awareness tend to develop better reading ability (Ryan *et al.*, 1977).
- **Awareness of lower-level features.** A young child has a limited sight vocabulary and what it does have will have been learned through breaking down the elements of words into manageable, processable pieces. As suggested above, this is difficult for a young child to do. English, for example, although having an alphabet of 26 letters, has 45 phonemes. When Rozin *et al.* (1974) presented children with two words such as 'mow' and 'motorcycle' and asked them – auditorily – which one was 'mow', the maximum correct response varied from 50 per cent for suburban nursery children to 10 per cent for inner-city children.
- **Orthographic awareness.** The ability to recognise that writing systems have sets of rules that must be followed is called **orthographic awareness**. For example, in English, we know that some sequences of letters are acceptable (for example 'able') but know that others are not ('kqyg').
- **Phonological awareness.** Perhaps the most important skill a child needs in order to develop adequate reading ability is the capacity to appreciate sound and be able to identify letters with sounds (this is sometimes called **phonological awareness**). To explore the contribution of phonological processing to reading, Bradley and Bryant 1983; Bryant and

Psychology in action – *Continued*

Bradley, 1985) have administered a series of phonological tasks to children at various stages of learning to read. Such tasks include finding the odd one out from the following two sets of spoken words: sun, sea, sock, rag; weed, need, peel, deed. (Notice how these two examples rely on the respondent noting both the beginning and ending sounds of words.) Good performance at tasks such as these is a good predictor of later reading ability.

- *Use of analogy.* Sometimes, children will not use grapheme–phoneme correspondence rules to read a word because it looks like another word. For example, Marsh *et al.* (1977) asked children and adults to pronounce nonsense words such as ‘tepherd’. This word, if pronounced according to grapheme–phoneme correspondence (GPC) rules (with ‘ph’ pronounced as /f/) would be pronounced ‘tefferd’. Children, however, pronounce it to rhyme with ‘shepherd’. Adults do not. This is called children’s use of analogy in reading.

The major ways in which children are taught to develop and use some or all of these skills are based on two systems: whole-word reading and phonics. Whole-word reading, as its name suggests, involves teaching the child to read whole words rather than analyse components of words and put them together to form whole words. This is sometimes called the look-and-say method because there is no room for segmentation of words. It is also called the meaning-based system because it encourages the child to think about the object the word represents. Words are usually displayed singly on cards and classrooms might have objects and pictures with word-labels attached to them. This means that the child begins to generate a pool of words which they will then be able to read in books after a sufficient number of words has been learned. Whole-word reading is easier for the child because it does not rely on segmentation. It also, as we have already mentioned, encourages the child to think about word meaning. One disadvantage of the system, however, is its inability to teach children how to decode new or unfamiliar words because no rule-based system is learned. If one considers that the average adult has a reading vocabulary of 50,000 words, the number of words a child would have to learn would be impracticable.

The alternative approach is called phonics. This rule-based system teaches the child correspondences between letters and sounds (that is, GPC rules, segmentation and blending). There are many forms of this teaching system and most teach the children letter-to-sound correspondences first before exposing them to actual words. Recently, a year-long comparison of phonics versus standard teaching methods in a group of English children found that phonics was associated with a reduction in reading difficulties (Shapiro and Solity, 2008). The disadvantages of the system are that it cannot cope well

with teaching the child irregular words and that 4–5-year-old children find the segmentation of phonemes difficult.

Many other teaching-of-reading systems exist. For example, one approach, the Initial Teaching Alphabet, reforms the orthography of irregular words by transforming them into regular words. Other approaches teach the child the letters of the alphabet first (success in which is a good predictor of reading ability). Another approach colour-codes letters in words. For example, a letter written in a certain colour can only be pronounced in one way. Yet another approach places marks underneath certain letters to indicate how they should be pronounced (the technical name for this is the ‘diacritical marking system’).

There is a close link between phonological skill and the ability to read. Some authors argue that is the key skill in the development of a child’s reading ability. If this is so, one might hypothesise that if children are trained well in phonological awareness (an awareness of the sounds of words), they might develop better reading skills than those without the benefit of this training. Hatcher *et al.* (2004) tested this hypothesis by randomly assigning 410 British children of kindergarten age (4–5 years) to one of three teaching conditions or a control group. The conditions were Reading with Rhyme (a learning-to-read package with additional emphasis on rhyme), Reading with Phoneme (a learning-to-read package with additional emphasis on phoneme training such as syllable and word identification), and Reading with Rhyme and Phoneme (a combination of the first two). The control group was taught the standard reading programme. Measures of cognitive ability – including reading, arithmetic and literacy – were taken.

While children whose reading was progressing normally did not benefit significantly from the additional phonological training, children who had been identified as poor readers improved their reading skill and awareness of phonemes. The decline in reading ability was halted by the second school year in children who received phoneme training and by the third year in children who received the rhyme training.

Evidence suggests that children who learn transparent orthographies (where the letters are sounded out exactly as they are written) learn to read these languages more quickly than do those who learn to read opaque ones (where the relationship between what is written and how what is written is spoken is inconsistent). This is what Patel *et al.* (2004) found when they investigated the learning skills of 6–11-year-old Dutch and English children. Children learning to read Dutch (a transparent language) were more accurate and faster in reading words and non-words in their native language than the English (an opaque language) children were in theirs.

A study of 382 children from 21 primary schools in England found that phonological awareness was a significant predictor

Psychology in action – *Continued*

of later school success, including maths, reading and science performance, and teachers' positive assessments of the pupils (Savage *et al.*, 2007). 'Practically,' the authors conclude, 'screening of phonological awareness and basic reading skills by school staff in year 1 significantly enhances the capacity of schools to predict curricular outcomes in year 6' (p. 732).

Is there a 'best' approach amid these myriad of approaches? As you have seen, although some of the well-developed approaches have distinct advantages, all have certain disadvantages.

However, one consistent predictor of later reading ability is successful phonological awareness. Pronunciation is also better if the phonetic aspects of speech are emphasised during the early stages of teaching. This may explain why developmental dyslexics often have good cognitive ability but have poor phonological processing skills, a topic we discuss in the section on language disorders below. If you were teaching a child to read, how would you start? What aspect of reading would you consider the most important to teach at the initial stages?

Understanding the meanings of words and sentences

The meanings of words are learned through experience. The meanings of content words involve memories of objects, actions and their characteristics; thus, the meanings of content words involve visual, auditory, somatosensory, olfactory and gustatory memories. These memories of the meanings of words are distributed throughout the brain. Our understanding of the meaning of the word 'apple', for example, involves memories of the sight of an apple, the way it feels in our hands, the crunching sound we hear when we bite into it, and the taste and odour we experience when we chew it. The understanding of the meanings of adjectives, such as the word 'heavy', involves memories of objects that are difficult or impossible to lift.

A phenomenon known as semantic priming gives us some hints about the nature of activation of memories triggered by the perception of words and phrases. **Semantic priming** is a facilitating effect on the recognition of words having meanings related to a word encountered earlier. A particular word can be more easily read if the word preceding it is related in meaning. If an individual sees the word 'bread', they will be more likely to recognise a fuzzy image of the word 'butter' or an image that is presented very briefly by means of a tachistoscope (Johnston and Dark, 1986). Presumably, the brain contains circuits of neurons that serve as 'word detectors' involved in visual recognition of particular words (Morton, 1979; McClelland and Rumelhart, 1981). Reading the word 'bread' activates word detectors and other neural circuits involved in memories of the word's meaning. Apparently, this activation spreads to circuits denoting related concepts, such as butter. Thus, our memories must be linked according to our experience regarding the relations between specific concepts.

Context effects, an example of top-down processing, have been demonstrated through semantic priming. Zola (1984), for example, asked people to read sentences such as the following:

1 Cinemas must have adequate popcorn to serve their patrons.

2 Cinemas must have buttered popcorn to serve their patrons.

while he recorded their eye movements with an eye tracker.

Zola found that individuals fixated for a significantly shorter time on the word popcorn in the second sentence. Because the word 'adequate' is not normally associated with the word 'popcorn', individuals reading the first sentence were unprepared for this word. However, 'buttered' is commonly associated with popcorn, especially in the context of a cinema. The context of the sentence, therefore, activated the word detector for 'popcorn', making the recognition of the word easier.

Semantic priming studies have also shed some light on another aspect of the reading process, the development of a mental model. It has been suggested that when a person reads some text, he or she generates a mental model of what the text is describing (Johnson-Laird, 1983). If the text contains a narrative, for example, the reader will imagine the scenes and actions that are being recounted. These issues of semantic priming and semantic networks are taken up in Chapter 11.

On the relative importance of consonants and vowels

Do vowels provide more information to readers than consonants during visual word recognition, or vice versa? Or is there no difference between them? Some psychologists argue that consonants are the more useful of the two because they are of more help in decoding the sound of a word from its orthography – the way in which it is spelled – during the early stages of visual word recognition (Brown and Besner, 1987).

To examine which is the more important to word identification, Lee *et al.* (2001) designed a sophisticated eye

tracking experiment which carefully noted the time participants spent fixated on words. On a computer monitor, participants read the following sentence:

I went to the hardware store to buy a tgfx for the lamp in my bedroom.

An eye-tracking device followed the course of the participant’s eye across the sentence. When it reached the word ‘buy’ the nonsense string ‘tgfx’ was replaced with either ‘b-lb’ or ‘bu-b’. Participants were told to pay attention to the sentences as they would be asked questions about them later (in fact they were asked questions only about a quarter of the sentences). The change from nonsense string to word occurred while participants blinked. The amount of time the participant spent fixated on the actual word was measured. If vowels were processed more quickly than consonants then participants should fixate longer on the word with the missing vowel (‘b-lb’) than the one with the missing consonant (‘bu-b’). The opposite would occur if consonants were processed more quickly.

The study found that gazes were longer when the consonant was missing and there was a 30 ms delay before the nonsense string was replaced by a word. However, this time difference disappeared when the delay was increased to 60 ms. The results suggest that in the early stages of visual word recognition, consonants are more important than vowels to readers when they try to identify words.

angry voice from a pleasant one; an angry voice produces crying, whereas a pleasant one causes smiling and cooing.

One device used to determine what sounds a very young infant can perceive is the pacifier nipple, placed in the baby’s mouth. The nipple is connected by a plastic tube to a pressure-sensitive switch that converts the infant’s sucking movements into electrical signals. These signals can be used to turn on auditory stimuli. Each time the baby sucks, a particular sound is presented. If the auditory stimulus is novel, the baby usually begins to suck at a high rate. If the stimulus remains the same, its novelty wears off (habituation occurs) and the rate of sucking decreases. With another new stimulus, the rate of sucking again suddenly increases, unless the baby cannot discriminate the difference. If the stimuli sound the same to the infant, the rate of sucking remains low after the change.

Using this technique, Eimas *et al.* (1971) found that 1-month-old infants could tell the difference between the sounds of the consonants ‘b’ and ‘p’. Like Lisker and Abramson (1970) in the study discussed earlier, they presented the sounds ‘ba’ and ‘pa’, synthesised by a computer. The infants, like the adult participants in the earlier study, discriminated between speech sounds having voice-onset times that differed by only 0.02 of a second. Even very early during post-natal development, the human auditory system is ready to make very fine discriminations. Table 10.5 lists some of the responses infants make to various types of speech sound.

Language acquisition by children

Perception of speech sounds by infants

Language development begins even before birth. Although the sounds that reach a foetus are somewhat muffled, speech sounds can still be heard. And some learning appears to take place prenatally (foetal learning is considered in more detail in Chapter 12). The voice that a foetus hears best and most often is obviously that of its mother. Consequently, a newborn infant prefers its mother’s voice to that of others (DeCasper and Fifer, 1980). DeCasper and Spence (1986) even found that newborn infants preferred hearing their mothers reading a passage they had read aloud several times before their babies were born to hearing them read a passage they had never read before.

An infant’s auditory system is well developed. Wertheimer (1961) found that newborns still in the delivery room can turn their heads towards the source of a sound. Babies 2 or 3 weeks of age can discriminate between the sound of a voice and other sounds. By the age of 2 months, babies can tell an

Table 10.5 Examples of responses infants make to various speech sounds

Age of first occurrence	Response
Newborn	Is startled by a loud noise Turns head to look in the direction of sound Is calmed by the sound of a voice Prefers mother’s voice to a stranger’s Discriminates among many speech sounds
1–2 months	Smiles when spoken to
3–7 months	Responds differently to different intonations (e.g. friendly, angry)
8–12 months	Responds to name Responds to ‘no’ Recognises phrases from games (e.g. ‘Peekaboo’, ‘How big is baby?’) Recognises words from routines (e.g. waves to ‘bye bye’) Recognises some words

The pre-speech period and the first words – An international perspective

The first sound that a baby makes is crying, a useful noise for attracting the attention of its carers. At about 1 month of age, infants start making other sounds, including ‘cooing’ (because of the prevalence of the ‘ooing’ sound). Often during this period, babies also make a series of sounds that resemble a half-hearted attempt to mimic the sound of crying (Kaplan and Kaplan, 1970).

At around 6 months, a baby’s sounds begin to resemble those that occur in speech. Even though their babbling does not contain words – and does not appear to involve attempts to communicate verbally – the sounds that infants make, and the rhythm in which they are articulated, reflect the adult speech that babies hear. Mehler *et al.* (1988) found that 4-day-old infants preferred to hear a voice speaking French, their parents’ native language. This ability to discriminate the sounds and rhythms of the language spoken around them manifested itself in the infants’ own vocalisations very early on. Boysson-Bardies *et al.* (1984) had adult French speakers listen to recordings of the babbling of children from various cultures. The adults could easily distinguish the babbling of 8-month-old French infants from that of babies with different linguistic backgrounds.

A study by Kuhl *et al.* (1992) provides further evidence of the effect of children’s linguistic environment on their language development. Native speakers learn not to distinguish between slight variations of sounds present in their language. In fact, they do not even hear the differences between them. For example, Japanese contains a sound that comes midway between /l/ and /r/. Different native speakers pronounce the sound differently, but all pronunciations are recognised as examples of the same phoneme. When native speakers of Japanese learn English, they have great difficulty distinguishing the sounds /l/ and /r/; for example, ‘right’ and ‘light’ sound to them like the same word. Presumably, the speech sounds that a child hears alter the brain mechanisms responsible for analysing them so that minor variations are not even perceived. The question is, when does this alteration occur? Most researchers have supposed that it happens only after children begin to learn the meanings of words, which occurs at around 10–12 months of age.

Kuhl and her colleagues found, however, that this learning takes place much earlier. They studied 6-month-old infants in the USA and Sweden. The infants were seated in their mothers’ laps, where they watched an experimenter sitting nearby, playing with a silent toy. Every two seconds, a loudspeaker on the infant’s left presented the sound of a vowel. From time to time, the sound was altered. If the infant noticed the change and looked at the loudspeaker, the experimenter reinforced

the response by activating a toy bear which pounded on a miniature drum.

The experimenters presented two different vowel sounds, one found in English but not in Swedish and the other found in Swedish but not in English. From time to time, they varied the sound slightly. The reactions of the Swedish infants and the American infants were strikingly different. Swedish infants noticed when the English vowel changed but not when the Swedish vowel changed; and American infants did the opposite. In other words, by the age of 6 months, the infants had learned not to pay attention to slight differences in speech sounds of their own language, but they were still able to distinguish slight differences in speech sounds they had never heard. Even though they were too young to understand the meaning of what they heard, the speech of people around them had affected the development of their perceptual mechanisms.

These results seem to support the **native language recognition hypothesis** – that infants have the ability to recognise words which belong to their native language (Moon *et al.*, 1993). Another hypothesis, the **general language discrimination hypothesis**, suggests that infants are capable of discriminating sentences from any two languages because they can extract sets of properties that these languages possess. The evidence above suggests that there is little support for this hypothesis. An alternative to these two hypotheses states that newborns are sensitive to prosody and can discriminate between languages on the basis of intonation and rhythm. This is called the **rhythm-based language discrimination hypothesis** (Nazzi *et al.*, 1998).

To test this hypothesis, Nazzi *et al.* compared the ability of 5-day-old infants to discriminate between rhythmic and non-rhythmic sentences in various languages. They found that infants were able to discriminate between English and Japanese but not English and Dutch, thereby supporting the rhythm hypothesis. This suggests that infants may be more attuned to the rhythmic as opposed to the phonetic quality of speech.

Interestingly, there is evidence to suggest that the ability to discriminate between phonetic sounds successfully may change with age. Stager and Werker (1997) have reported that 8-month-old infants are capable of discriminating phonetic detail in a task in which 14-month-old infants cannot. The researchers suggest that this represents a reorganisation in the infant’s language processing capacity: it shifts from the processes needed to learn syllables to the process needed to learn words. This is advantageous to the infant as it grows and has to put names to objects, events and situations. Because these activities are computationally complex and involve a huge increase in input, the amount of detail that needs to be processed is, therefore, limited.

Infant communication

Even before infants learn to talk, they display clear intent to communicate. Most attempts at pre-verbal infant communication fall into three categories: rejection, request (for social interaction, for an object or for an action), and comment (Sachs, 1993). Rejection usually involves pushing the unwanted object away and using facial expression and characteristic vocalisations to indicate displeasure. A request for social interaction usually involves the use of gestures and vocalisations to attract the caregiver's attention. A request for an object usually involves reaching and pointing and particular vocalisations. A request for an action (such as the one described above) similarly involves particular sounds and movements. Finally, a comment usually involves pointing out an object or handing it to the carer, accompanied by some vocalisation.

Infants babble before they talk. They often engage in serious 'conversations' with their carers, taking turns 'talking' with them. Infants' voices are modulated, and the stream of sounds they make sound as though they are using a secret language (Menn and Stoel-Gammon, 1993). At about 1 year of age, a child begins to produce words. The first sounds children use to produce speech appear to be similar across all languages and cultures: the first vowel is usually the soft 'a' sound of 'father', and the first consonant is a stop consonant produced with the lips – 'p' or 'b'.

Thus, the first word is often 'papa' or 'baba'. The next feature to be added is nasality, which converts the consonants 'p' or 'b' into 'm'. Thus, the next word is 'mama'. Mothers and fathers all over the world recognise these sounds as their children's attempts to address them. The first sounds of a child's true speech contain the same phonemes that are found in the babbling sounds that the child is already making; thus, speech emerges from pre-speech sounds. During the course of learning words from their carers and from older children, infants often invent their own **protowords**, unique strings of phonemes that serve word-like functions. The infants use these protowords consistently in particular situations (Menn and Stoel-Gammon, 1993).

The development of speech sounds continues for many years. Some sequences are added very late. For example, the 'str' of string and the 'bl' of blink are difficult for young children to produce; they usually say 'tring' and 'link', omitting the first consonant. Most children recognise sounds in adult speech before they can produce them.

The two-word stage

At around 18–20 months of age, children start learning language by putting two words together, and their linguistic development takes a leap forward. It is at this stage that linguistic creativity begins.

As for first sounds, children's two-word utterances are remarkably consistent across all cultures. Children use words in the same way, regardless of the language their parents speak. Even deaf children who learn sign language from their parents put two words together in the same way as children who can hear (Bellugi and Klima, 1972). And deaf children whose parents do not know sign language invent their own signs and use them in orderly, 'rule-governed' ways (Goldin-Meadow and Feldman, 1977). Thus, the grammar of children's language at the two-word stage appears to be universal (Owens, 1992).

For many years, investigators described the speech of young children in terms of adult grammar, but researchers now recognise that children's speech simply follows different rules. Young children are incapable of forming complex sentences – partly because their vocabulary is small, partly because their short-term 'working' memory is limited (they cannot yet encode a long string of words), and partly because their cognitive development has not yet reached a stage at which they can learn complex rules of syntax (Locke, 1993).

How adults talk to children

When parents talk to children they use only short, simple, well-formed, repetitive sentences and phrases (Brown and Bellugi, 1964) called **child-directed speech** (Snow, 1986). Adults' speech to children is characterised by clear pronunciation, exaggerated intonations, careful distinctions between similar-sounding phonemes, relatively few abstract words and function words, and a tendency to isolate constituents that undoubtedly enables young children to recognise them as units of speech (deVilliers and deVilliers, 1978).

Another important characteristic of child-directed speech is that it tends to refer to tangible objects the child can see, to what the child is doing and to what is happening around the child (Snow *et al.*, 1976). Words are paired with objects the child is familiar with, which is the easiest way to learn them.

Adults, particularly carers who have a continuing relationship with a child, tend to act as tutors when talking to children. For example, Snow and Goldfield (1982) found that as a mother and child repeatedly read a book over a period of 13 months, the mother's speech became more and more complex, especially when they were discussing a picture that they looked at again and again.

Adults often expand children's speech by imitating it but putting it into more complex forms, which undoubtedly helps the child learn about syntactical structure (Brown and Bellugi, 1964):

Child: Baby highchair.

Adult: Baby is in the highchair.

Child: Eve lunch.

Adult: Eve is having lunch.

Child: Throw daddy.

Adult: Throw it to daddy.

People make allowances for the age of the child with whom they are talking. Mothers talk differently to 2-year-olds compared with 10-year-olds (Snow, 1972a). Even 4-year-old children talk differently to 2-year-olds compared with how they talk to adults or other 4-year-olds (Shatz and Gelman, 1973). It seems unlikely that these differentiated speech patterns are innately determined. Snow (1972a) compared the speech patterns of a mother talking to a child with her speech patterns when she only pretended to be talking to a child. The woman's speech when the child was absent was simpler than it would have been if addressed to an adult, but when the child was present, it was simpler still. Clearly, then, feedback from children is important.

The most important factor controlling adults' speech to children is the child's attentiveness. When a child looks interested, an adult continues with what they are doing. Signs of inattention in the child prompt an adult to advance or simplify the level of speech until the child's attention is regained. Stine and Bohannon (1983) found that when children give signs that they do not understand what an adult is saying the adult adjusts their speech by simplifying it.

Infants also exert control over what their carers talk about. The topic of conversation usually involves what the infant is playing with or is guided by what the infant is gazing at (Bohannon, 1993). This practice means that infants hear speech that concerns what they are already paying attention to, which undoubtedly facilitates learning. In fact, Tomasello and Farrar (1986) found that infants of mothers who talked mostly about the objects of their infants' gazes uttered their first words earlier than other infants and also developed larger vocabularies early in life.

One of the intriguing findings in the literature on the development of language is that twins tend to develop language later than do singletons. On average, the delay is about three months by the time infants have reached 3 years of age. Several reasons have been mooted for this discrepancy. Among these are obstetric complications, family background and the interaction between the mother and infant.

Rutter *et al.* (2005) measured the communication and language abilities of 96 pairs of twins and 98 pairs of singletons who were no more than 30 months apart in terms of chronological age. Measures were taken when the chil-

dren were 20 months and 3 years old. The language ability of twins was 1.7 months below singletons when the infants were 20 months; this difference increased to 3.1 months at 3 years. There was no significant relationship between language development and obstetric/neonatal complications, birthweight or congenital abnormalities, thus ruling out these factors as probable causes of the language delay in twins.

In a second study, Thorpe *et al.* (2005) used the same sample but this time measured the degree of mother–infant communication. Having a mother who encouraged the child to speak, who elaborated the children's comments, who read with her child and who talked about the story she was reading was associated with significantly better language development. This interaction was significantly less apparent in the twin group. The mothers did not differ significantly in terms of their education or social background, which suggests that these factors had negligible effects on the results.

Acquisition of adult rules of grammar

The first words that children use tend to be content words: these words are emphasised in adult speech and refer to objects and actions that children can directly observe (Brown and Bellugi, 1964). As children develop past the two-word stage, they begin to learn and use more and more of the grammatical rules that adults use. The first form of sentence lengthening appears to be the expansion of object nouns into noun phrases (Bloom, 1970). For example, 'that ball' becomes 'that a big ball'. Next, verbs are used more frequently, articles are added, prepositional phrases are mastered and sentences become more complex. These results involve the use of **inflections** and function words. Table 10.6 shows the approximate order in which children acquire some of these inflections and function words.

It is more difficult for children to add an inflection or function word to their vocabulary than to add a new content word because the rules that govern the use of inflections or function words are more complex than those that govern the use of most content words. In addition, content words usually refer to concrete objects or activities. The rules that govern the use of inflections or function words are rarely made explicit. A parent seldom says, 'When you want to use the past tense, add '-ed' to the verb', nor would a young child understand such a pronouncement. Instead, children must listen to speech and figure out how to express such concepts as the past tense.

The most frequently used verbs in most languages are irregular. Forming the past tense of such verbs in English does not involve adding '-ed' (for example, go/went, throw/threw, buy/bought, see/saw). The past tense of such verbs must be learned individually. Because irregular verbs get more use than do regular ones, children learn

Table 10.6 The approximate order in which children acquire inflections and function words

Item	Example
1 Present progressive: <i>ing</i>	He is <i>sitting</i> down.
2 Preposition: <i>in</i>	The mouse is <i>in</i> the box.
3 Preposition: <i>on</i>	The book is <i>on</i> the table.
4 Plurals;– <i>s</i>	The <i>dogs</i> ran away.
5 Past irregular: e.g. <i>went</i>	The boy <i>went</i> home.
6 Possessive:– ‘ <i>s</i>	The <i>girl’s</i> dog is big.
7 Uncontractable copula <i>be</i> : e.g. <i>are, was</i>	<i>Are</i> they boys or girls? <i>Was</i> that a dog?
8 Articles: <i>the, a, an</i>	He has <i>a</i> book.
9 Past regular: <i>-ed</i>	He <i>jumped</i> the stream
10 Third person regulars:– <i>s</i>	She <i>ran</i> fast.
11 Third person irregular: e.g. <i>has, does</i>	<i>Does</i> the dog bark?
12 Uncontractable auxiliary <i>be</i> : e.g. <i>is, were</i>	<i>Is</i> he running? <i>Were</i> they at home?
13 Contractible copula <i>be</i> : e.g. ‘ <i>s, -re</i>	That’s a spaniel. <i>They’re</i> pretty.
14 Contractible auxiliary <i>be</i> : e.g. ‘ <i>s, -’re</i>	<i>He’s</i> doing it. <i>They’re</i> running slowly.

them first, producing the past tense easily in sentences such as ‘I came’, ‘I fell down’, and ‘she hit me’. Shortly after this period, they discover the regular past tense inflection and expand their vocabulary, producing sentences such as ‘he dropped the ball’. But they also begin to say ‘I comed’, ‘I falled down’, and ‘she hitted me’. Having learned a rule, they apply it to all verbs, including the irregular ones that they were previously using correctly. It takes children several years to learn to use the irregular past tense correctly again.

Children’s rudimentary understanding, or at least recognition, of language and parts of speech seems to begin in the first few months of life. Children learn to assign meaning to words – decide whether they are nouns, verbs and so on – and use these words to form semi-structured sentences. That is, the child begins to follow the rules of grammar. Grammatical words tend to be phonetically and structurally smaller than lexical words – nouns, verbs and so on – and the commonest of them (‘in’, ‘a’, ‘and’) are used more frequently in conversation than are the most common lexical words. Does the child, therefore, show a preference for spoken grammatical or lexical words?

One study exposed 6-month-old infants to spoken lexical and grammatical words and measured their preference for each type of stimulus (Shi and Werker, 2001). The researchers found that the infants showed a preference for

the lexical words. The authors suggest that although grammatical words are the most commonly used, lexical words may be more striking and acoustically interesting. Lexical words tend to be longer and have a more complex structure; mothers also tend to use lexical words in isolation (i.e. without the accompanying grammar). The preference for lexical words may help the child to give meaning to its world and act as a first essential step to developing more complex communication. It may be that children prefer and use lexical words first and then clamp them on to grammatical structures later.

Acquisition of meaning

The simplest explanation of why children use and understand language is that they hear a word spoken at the same time that they see (or hear, or touch) the object to which the word refers. After several such pairings, they add a word to their vocabulary. In fact, children first learn the names of things with which they interact, or things that change (and thus attract their attention). For example, they are quick to learn words like ‘biscuit’ or ‘blanket’, but are slow to learn words like ‘wall’ or ‘window’ (Ross *et al.*, 1986; Pease *et al.*, 1993).

Fast mapping

This quick learning of new, content words has been called **fast mapping** (Carey and Bartlett, 1978; Markman, 1989). There is some debate over whether fast mapping is specific to language or whether it is generated by other, cognitive processes. For example, if fast mapping is seen only for words then this would suggest that the process is language based; if fast mapping can extend to other domains, this suggests that the process is underpinned by general cognitive abilities (such as the ability to memorise).

In two experiments, Markson and Bloom (1997) taught 3–4-year-old children and a group of university undergraduates to learn a word referring to an object (‘kobi’) and a fact about this object. In one experiment, participants were told that this was an object given to the experimenter by her uncle. The participants’ ability to remember and identify the object was tested immediately after learning, one week after or one month after. Although the adults were better at remembering the object and object name than were the children, all children performed comparably well when asked to retrieve the word, identify the object about which facts were presented, and to identify the object given to the experimenter by her uncle. The study suggests that fast mapping may not necessarily be specific to language processing but is made possible by learning and memory mechanisms that are not specific to the language domain.

Waxman and Booth (2000) replicated Markson and Bloom's original finding but suggested that there is a crucial difference between the principles underpinning noun learning and fact learning. They introduced pre-school children to an unfamiliar object, such as those seen in Figure 10.7, and required them to associate it with a noun ('This is a koba') or a fact ('My uncle gave this to me'). The researchers then investigated whether (1) the children were able to map the word or fact correctly by choosing the 'koba' or 'the object the uncle gave to the experimenter', from a series of 10 familiar objects and (2) the children were able to extend their knowledge of the object by identifying the object from unfamiliar ones. In the second condition, the children were asked, 'Is this one a koba?' (word condition), or 'Is this the one my uncle gave me?' (fact condition). The children were able to map successfully using the word or the fact. However, there was a difference between the two conditions when children had to extend their knowledge – the children extended the noun to other, similar objects but did not extend the fact.

In another study, 2–4-year-old children were taught a novel name for an object ('My cat stepped on this agnew') and given an arbitrary fact for a second, unfamiliar object (such as metal shelving brackets and Allen keys) (Behrend *et al.*, 2001). The children extended the novel name to more exemplars than they did facts, suggesting that some of the principles underpinning the learning of words and facts are different.

Overextension and underextension

Often a child may commit what are called errors of overextension or underextension. If a child has learned to identify a ball but says 'ball' when they see an apple or an orange, or even the moon, we must conclude that they do not know the meaning of 'ball'. This type of error is called **overextension** – the use of a word to denote a larger class of items than is appropriate. If the child uses the word to refer only to the small red plastic ball, the error is called

Figure 10.7 Some of the unfamiliar objects referred to in Waxman and Booth's (2000) study.

an **underextension** – the use of a word to denote a smaller class of items than is appropriate. Table 10.7 lists some examples of children's overextensions while learning the meanings of new words.

Both overextensions and underextensions are normal; a single pairing of a word with the object does not provide enough information for accurate generalisation.

Carers often correct children's overextensions. The most effective type of instruction occurs when an adult provides the correct label and points out the features that distinguish the object from the one with which the child has confused it (Chapman *et al.*, 1986). For example, if a child calls a yo-yo a ball, the carer might say, 'That's a yo-yo. See? It goes up and down' (Pease *et al.*, 1993).

Many words, including function words, do not have physical referents. For example, prepositions such as 'on', 'in' and 'towards' express relations or directions, and a child needs many examples to learn how to use them appropriately. Pronouns are also difficult; for example, it takes a child some time to grasp the notion that 'I' means the speaker: 'I' means me when I say it, but 'I' means you when you say it. In fact, parents usually avoid personal pronouns in speaking with their children. Instead, they use sentences such as 'Does [baby's name] want another one?'

(meaning ‘Do you want another one?’), and ‘Daddy will help you’ (meaning ‘I will help you’). Abstract words such as ‘apparently’, ‘necessity’, ‘thorough’ and ‘method’ have no direct referents and must be defined in terms of other words. Therefore, children cannot learn their meanings until after they have learned many other words.

Bilingualism

The defining feature of bilingualism is the ability of the individual to meet the communication demands of the self or the individual’s culture in two or more languages (Mohanty and Perregaux, 1997). **Bilingualism** is described as ‘simultaneous’ when two or more languages develop in childhood more or less simultaneously, spontaneously and naturally, and ‘successive’ when a second (and third) language is learned after the first, such as learning a second language during puberty (Romaine, 1989).

Until relatively recently, it was thought that bilingualism was detrimental to cognitive performance. The early studies, which compared Spanish–English bilinguals in America and English–Welsh bilinguals in Wales with monolinguals, showed that being able to speak two languages from childhood had negative consequences for intellectual development. It now appears that such conclusions are incorrect and that these early studies did not take into account socio-economic status, the degree of bilingualism or the skill in the second language (Lambert, 1977; Cummins, 1984). Rather than impairing cognitive ability, bilingualism seems beneficial to it (Perregaux, 1994). Mohanty (1982a, b, 1990) compared the cognitive performance of monolinguals with bilinguals in the Kond people of India; the bilinguals spoke Kui at home and Oriya outside the home environment. The bilinguals performed significantly better than the monolinguals on a series of cognitive and linguistic tasks. This superior performance in bilinguals was seen even in unschooled bilinguals (Mohanty and Das, 1987).

The learning of a second language can have two effects: additive and subtractive. A second language has an additive effect when it adds to cognitive ability allowed by the first language, that is, it enriches the use of the second language; a second language has a subtractive effect when it replaces the first language. For example, a second language might interfere with the production of words in the first language (you are speaking in one language but you can only remember some words in the other).

Is there a language acquisition device?

According to Pinker (1984), ‘In general, language acquisition is a stubbornly robust process; from what we can tell there is virtually no way

to prevent it from happening, short of raising a child in a barrel.’ The absence of barrels permitting, what shapes this linguistic learning process, and what motivates it?

There is vigorous controversy about why children learn to speak and, especially, why they learn to speak grammatically. Chomsky (1965) observed that the recorded speech of adults is not as correct as the dialogue we read in a novel or hear in a play; often it is ungrammatical, hesitating and full of unfinished sentences. In fact, he characterised everyday adult speech as ‘defective’ and ‘degenerate’. If this speech is really what children hear when they learn to speak, it is amazing that they manage to acquire the rules of grammar.

The view that children learn regular rules from apparently haphazard samples of speech has led many linguists to conclude that the ability to learn language is innate. All a child has to do is to be in the company of speakers of a language. Linguists have proposed that a child’s brain contains a **language acquisition device** which embodies rules of ‘universal grammar’; because each language expresses these rules in slightly different ways, the child must learn the details, but the basics are already there in the brain (Chomsky, 1965; Lenneberg, 1967; McNeill, 1970).

The assertion that an innate language acquisition device guides children’s acquisition of a language is part of a general theory about the cognitive structures responsible for language and its acquisitions (Pinker, 1990). The most important components are as follows:

- Children who are learning a language make hypotheses about the grammatical rules they need to follow. These hypotheses are confirmed or disconfirmed by the speech that they hear.
- An innate language acquisition device guides children’s hypothesis formation. Because they have this device, there are certain types of hypothetical rule that they will never entertain and certain types of sentence that they will never utter.
- The language acquisition device makes reinforcement unnecessary; the device provides the motivation for the child to learn a language.
- There is a critical period for learning a language. The language acquisition device works best during childhood; after childhood, languages are difficult to learn and almost impossible to master.

Evaluation of the evidence for a language acquisition device

No investigator regards the first assertion – that children make and test hypotheses about grammatical rules – as tenable. Thus, we cannot simply ask children why they say what they do. Children’s hypothesis-testing is a convenient metaphor for the fact that their speech sometimes follows one rule or another.

A more important – and testable – assertion is that the hypothesis testing is guided by the language acquisition device. The most important piece of evidence in favour of this assertion is the discovery of language universals: characteristics that can be found in all languages that linguists have studied. Some of the more important language universals include the existence of noun phrases ('the quick brown fox . . .'); verb phrases ('. . . ate the chicken'); grammatical categories of words such as nouns and adjectives; and syntactical rules that permit the expression of subject–verb–object relations ('John hit Andy'), plurality ('two birds'), and possession ('Rachel's pen').

However, the fact that all languages share certain characteristics does not mean that they are the products of innate brain mechanisms. For example, Hebb *et al.* (1973) observed that language universals may simply reflect realities of the world. When people deal with each other and with nature, their interactions often take the form of an agent acting on an object. Thus, the fact that all languages have ways of expressing these interactions is not surprising. Similarly, objects come in slightly different shapes, sizes and colours, so we can expect the need for ways (such as adjectives) to distinguish among them. It is not unreasonable to suppose that the same kinds of linguistic device have been independently invented at different times and in different places by different cultures. After all, archaeologists tell us that similar tools have been invented by different cultures all around the world. People need to cut, hammer, chisel, scrape and wedge things apart, and different cultures have invented similar devices to perform these tasks. We need not conclude that these inventions are products of a 'tool-making device' located in the brain. But even if some language universals are dictated by reality, others could indeed be the result of a language acquisition device. For example, consider the following sentences, adapted from Pinker (1990):

- A1. Bill drove the car into the garage.
- A2. Bill drove the car.
- B1. Bill put the car into the garage.
- B2. Bill put the car.

Someone (such as a child learning a language) who heard sentences A1 and A2 could reasonably infer that sentence B1 could be transformed into sentence B2. But the inference obviously is false; sentence B2 is ungrammatical. The linguistic rules that say that sentence A2 is acceptable but that sentence B2 is not very complex; and their complexity is taken as evidence that they must be innate, not learned. Pinker (1990, p. 206) concludes: 'The solution to the problem [that children do not utter sentence B2] must be that children's learning mechanisms ultimately do not allow them to make the generalisation.'

This conclusion rests on the assumption that children use rules similar to the ones that linguists use. How, the reasoning goes, could a child master such complicated rules at such an early stage of cognitive development unless the rules were already wired into the brain? But perhaps the children are not following such complex rules. Perhaps they learn that when you say 'put' (something) you must always go on to say where you put something. Linguists do not like rules that deal with particular words, such as put (something) (somewhere); they prefer abstract and general rules that deal with categories: clauses, prepositions, noun phrases and the like. But children learn particular words and their meanings – why should they not also learn that certain words must be followed (or must never be followed) by certain others? Doing so is certainly simpler than learning the complex and subtle rules that linguists have devised. It would seem that both complex and simple rules (or innate or learned ones) could explain the fact that children do not utter sentence B2.

The third assertion is that language acquisition occurs without the need of reinforcement, or even of correction. Brown and Hanlon (1970) recorded dialogue between children and parents and found that adults generally did not show disapproval when the children's utterances were ungrammatical and approval when they were grammatical. Instead, approval appeared to be contingent on the truth or accuracy of the children's statements. If there is no differential reinforcement, how can we explain the fact that children eventually learn to speak grammatically? It is undoubtedly true that adults rarely say, 'Good, you said that correctly', or, 'No, you said that wrongly'. However, adults do distinguish between grammatical and ungrammatical speech of children. A study by Bohannon and Stanowicz (1988) found that adults are likely to repeat children's grammatically correct sentences verbatim but to correct ungrammatical sentences. For example, if a child says, 'That be monkey', an adult would say, 'That is a monkey'. Adults were also more likely to ask for clarifications of ungrammatical sentences. Thus, adults do tend to provide the information children need to correct their faulty speech.

Chomsky's assertion about the defectiveness and degeneracy of adult speech is not strictly true, at least as far as it applies to what children hear. In fact, according to Newport *et al.* (1977), almost all the speech that a young child hears (at least, in industrialised English-speaking societies) is grammatically correct. If that is so, why should we hypothesise that a language acquisition device exists? Because, say some researchers, not all children are exposed to child-directed speech. 'In some societies people tacitly assume that children aren't worth speaking to and don't have anything to say that is worth listening to. Such children learn to speak by overhearing streams of adult-to-adult speech' (Pinker, 1990, p. 218).

Pinker's statement is very strong; it says that children in some cultures have no speech directed towards them until

they have mastered the language. It implies that the children's mothers do not talk to them and ignores the fact that older children may not be quite so choosy about their conversational partners. To conclude that such an extreme statement is true would require extensive observation and documentation of child-rearing practices in other cultures. One of the strongest biological tendencies of our species is for a mother to cherish, play with and communicate with her offspring. If there really is a culture in which mothers do not do so, we need better documentation.

In fact, children do not learn a language that they simply overhear. Bonvillian *et al.* (1976) studied children of deaf parents whose only exposure to spoken language was through television or radio. This exposure was not enough; although the children could hear and did watch television and listen to the radio, they did not learn to speak English. It takes more than 'overhearing streams of adult-to-adult speech' to learn a language. The way that parents talk to their children is closely related to the children's language acquisition (Furrow *et al.*, 1979; Furrow and Nelson, 1986). Thus, the question is, just how much instruction (in the form of child-directed speech) do children need?

The fact that parents do not often reward their children's speech behaviours with praise or tangible reinforcers (such as sweets) does not prove that reinforcement plays no role in learning a language. We humans are social animals; our behaviour is strongly affected by the behaviour of others. It is readily apparent to anyone who has observed the behaviour of children that the attention of other people is extremely important to them. Children will perform a variety of behaviours that get other people to pay attention to them. They will make faces, play games and even misbehave in order to attract attention. And above all, they will talk.

The final assertion – that the language acquisition device works best during childhood – has received the most experimental support. For example, Newport and Supalla (1987) studied the ability of people who were deaf from birth to use sign language. They found that the earlier the training began, the better the person was able to communicate. Johnson and Newport (1989) also found that native Korean and Chinese speakers who moved to the USA learned English grammar better if they arrived during childhood. The advantage did not appear to be a result of differences in motivation to learn a second lan-

guage. Such results are consistent with the hypothesis that something occurs within the brain after childhood that makes it more difficult to learn a language.

Conclusion

Observational studies such as these do not prove that a cause-and-effect relation exists between the variables in question. Johnson and Newport (1989) suggest that people's age (in particular, the age of their brain) affects their language-learning ability. But other variables are also correlated with age. For example, the Korean and Chinese speakers who moved to the USA as children spent several years in school; and perhaps the school environment is a particularly good place to learn a second language. In addition, adults are generally more willing to correct the grammatical errors made by children than those made by adolescents or other adults; thus, children may get more tutoring. It is certainly possible that the investigators are correct, but their results cannot be taken as proof that the brain contains an innate language acquisition device.

In one sense, a language acquisition device does exist. The human brain is a language acquisition device; without it, languages are not acquired. The real controversy is over the characteristics of this language acquisition device. Is it so specialised that it contains universal rules of grammar and provides innate motivation that makes reinforcement unnecessary?

The issue is made more interesting, if controversial, if we consider the ability of other higher primates to learn language. Other higher primates such as gorillas or chimpanzees do not naturally produce language although they have their own system of communication. Their vocal apparatus is different from that of humans so it would be unrealistic to assume that they would be able to articulate human language. However, these animals are the ones that are genetically closest to us; similar brain asymmetries, especially in those parts of the brain which are thought to mediate language, are seen in humans and apes. Would it be possible to teach primates human language? Do higher primates also possess an innate language acquisition device but need an environmental prompt for such a device to start working? These questions form the basis of the following Controversies in Psychological Science section.

Controversies in Psychological Science – Can other primates acquire language?

The issue

The members of most species can communicate with one another. Even insects communicate: a female moth that is ready to mate can release a chemical that will bring male

moths from miles away; a dog can tell its owner that it wants to go for a walk by bringing its lead in its mouth and whining at the door. But, until recently, humans were the only species that had languages – flexible systems that use symbols to express many

Controversies in Psychological Science – *Continued*

meanings. But are other primates able to learn and use symbols in the same linguistic way that humans do?

The evidence

In the 1960s, Beatrice and Roger Gardner of the University of Nevada began Project Washoe (Gardner and Gardner, 1969, 1978), a remarkably successful attempt to teach sign language to a female chimpanzee named Washoe. Previous attempts to teach chimps to learn and use human language focused on speech (Hayes, 1952). These attempts failed because, as we noted above, chimps lack the control of tongue, lips, palate and vocal cords that humans have and thus cannot produce the variety of complex sounds that characterise human speech.

Gardner and Gardner realised this limitation and decided to attempt to teach Washoe a manual language – one that makes use of hand movements. Chimps' hand and finger dexterity is excellent, so the only limitations in their ability would be cognitive ones. The manual language the Gardners chose was based on ASL, the American sign language used by deaf people. This is a true language, containing function words and content words and having regular grammatical rules.

Washoe was 1 year old when she began learning sign language; by the time she was 4, she had a vocabulary of over 130 signs. Like children, she used single signs at first; then, she began to produce two-word sentences such as 'Washoe sorry', 'gimme flower', 'more fruit', and 'Roger tickle'. Sometimes, she strung three or more words together, using the concept of agent and object: 'You tickle me'. She asked and answered questions, apologised, made assertions – in short, did the kinds of things that children would do while learning to talk. She showed overextensions and underextensions, just as human children do. Occasionally, she even made correct generalisations by herself. After learning the sign for the verb 'open' (as in open box, open cupboard), she used it to say open faucet, when requesting a drink. She made signs to herself when she was alone and used them to 'talk' to cats and dogs, just as children will do. Although it is difficult to compare her progress with that of human children (the fairest comparison would be with that of deaf children learning to sign), humans clearly learn language much more readily than Washoe did.

Inspired by Project Washoe's success (Washoe died in 2007), several other investigators have taught primate species to use sign language. For example, Patterson began to teach a gorilla (Patterson and Linden, 1981), and Miles (1983) began to teach an orangutan. Washoe's training started relatively late in her life, and her trainers were not, at the beginning of the project, fluent in sign language. Other chimpanzees, raised from birth by humans who are native speakers of ASL, have begun to use signs when they are 3 months old (Gardner and Gardner, 1975).

Many psychologists and linguists have questioned whether the behaviour of these animals can really be classified as verbal behaviour. For example, Terrace *et al.* (1979) argue that the apes simply learned to imitate the gestures made by their trainers and that sequences of signs such as, 'please milk please me like drink apple bottle' (produced by a young gorilla) are nothing like the sequences that human children produce. Others have challenged these criticisms (Fouts, 1983; Miles, 1983; Stokoe, 1983), blaming much of the controversy on the method that Terrace and his colleagues used to train their chimpanzee.

Certainly, the verbal behaviour of apes cannot be the same as that of humans. If apes could learn to communicate linguistically as well as children can, then humans would not have been the only species to have developed language. The usefulness of these studies rests in what they can teach us about our own language and cognitive abilities. Through them, we may discover what abilities animals need to communicate as we do. They may also help us to understand the evolution of these capacities.

These studies have already provided some useful information. For example, Premack (1976) taught chimpanzees to 'read' and 'write' by arranging plastic tokens into 'sentences'. Each token represents an object, action or attribute such as colour or shape, in much the same way as words do. His first trainee, Sarah, whom he acquired when she was 1 year old, learned to understand complex sentences such as 'Sarah insert banana in pail, apple in dish'. When she saw the discs arranged in this order, she obeyed the instructions.

Chimpanzees can, apparently, use symbols to represent real objects and can manipulate these symbols logically. These abilities are two of the most powerful features of language. For Premack's chimpanzees, a blue plastic triangle means 'apple'. If the chimpanzees are given a blue plastic triangle and asked to choose the appropriate symbols denoting its colour and shape, they choose the ones that signify 'red' and 'round', not 'blue' and 'triangular'. Thus, the blue triangle is not simply a token the animals can use to obtain apples; it represents an apple for them, just as the word apple represents it for us.

Even though humans are the only primates who can pronounce words, several other species can recognise them. Savage-Rumbaugh (1990; Savage-Rumbaugh *et al.*, 1998) taught Kanzi, a pygmy chimpanzee, to communicate with humans by pressing buttons that contained symbols for words, as seen in Figure 10.8.

Kanzi's human companions talked with him, and he learned to understand them. Although the structure of his vocal apparatus prevented him from responding vocally, he often tried to do so. During a three-month period, Savage-Rumbaugh and her colleagues tested Kanzi with 310 sentences, such as 'Put a

Controversies in Psychological Science – Continued

toothbrush in the lemonade’. Three hundred and two of these had never been heard by the chimpanzee before. Only situations in which Kanzi could not have been guided by non-verbal cues from the human companions were counted; often, Kanzi’s back was to the speaker. He responded correctly 298 times. Table 10.8 presents specific examples of these sentences and the actions that Kanzi took.

Conclusion

The most successful attempts at teaching a language to other primates are those in which the animal and the trainer have established a close relationship in which they can successfully communicate non-verbally by means of facial expressions, movements and gestures. Such interactions naturally lead to attempts at communication; and if signs (or spoken words) serve to make communication easier and more effective, they will most readily be learned.

Figure 10.8 Researcher Sue Savage-Rumbaugh taught her chimp, Kanzi, to communicate using a special keyboard.

Table 10.8 Semantic relations comprehended by Kanzi, a pygmy chimpanzee

Semantic relations	N	Examples (spoken)
Action–object	107	<i>‘Would you please carry the straw?’</i> Kanzi looks over a number of objects on the table, select the straw, and takes it to the next room.
Object–action	13	<i>‘Would you like to ball chase?’</i> Kanzi looks around for a ball, finds one in his swimming pool, takes it out, comes over to the keyboard, and answer ‘Chase’
Object–location	8	<i>‘Would you put out the grapes in the swimming pool?’</i> Kanzi selects some grapes from among several foods and tosses them into the swimming pool
Action–location	23	<i>‘Let’s chase to the A–frame,’</i> Kanzi is climbing in trees, has been ignoring things that are said to him. When he hears this he comes down rapidly and runs to the A-frame
Action–object–location	36	<i>‘I hid the surprise by my foot,’</i> Kanzi has been told that a surprise is around somewhere, and he is looking for it. When he is given this clue, he immediately approaches the speaker and lifts up her foot
Object–action	9	<i>‘Kanzi, the pine cone goes in your shirt,’</i> picks up a pine cone
Action–location–object	8	<i>‘Go to the refridgerator and get out a tomato,’</i> Kanzi is playing in the water in the sink. When he hears this he stops, goes to the refrigerator, and gets a tomato
Agent–action–object	7	<i>‘Jeannine hid the pine needles in her shirt,’</i> Kanzi is busy making a nest of blankets, branches and pine needles. When he hears this, he immediately walks over to Jeannine, lifts up her shirt, takes out the pine needles, and puts them in his nest
Action–object–recipient	19	<i>‘Kanzi, please carry the cooler to Penny,’</i> Kanzi grabs the cooler and carries it over to Penny
Other–object–action –recipient; action–recipient –location; etc.	69

Brain development and language

In his book *The Biological Foundations of Language*, Lenneberg (1967) argued that the functional lateralisation of language – one cerebral hemisphere's superiority for processing language – begins at the same time as the child begins to acquire language and is complete at puberty. This conclusion was based on studies showing that in half a sample of children with lesions to the right or left sides of the brain, language was delayed if the lesion occurred in the first two years of life. The other half developed language normally (Basser, 1962). In adults and adolescents, language difficulties were associated with left-hemisphere lesions whereas mild language difficulties were associated with right-hemisphere lesions. Lenneberg thus argued that there was a sensitive period during which language should be acquired and lateralisation would develop.

Others (e.g. Krashen, 1973) argued that the hemispheres of the brain are equipotential at birth – each hemisphere is capable of undertaking the function for which the other becomes specialised. The critical period for lateralisation was complete by the age of 5 or 6 years. If lesions to the right hemisphere occurred before the age of 5 years, the child would show symptoms of aphasia, a disorder involving the inability to produce or comprehend speech. If damage occurred after the age of 5, no deficits in speech would arise suggesting that the normal left-for-language functional asymmetry had developed and was relatively complete. Krashen was involved in the study of an unusual case in which a young girl had been deprived of auditory stimulation and failed to develop normal language.

The case of Genie

Genie was a 13-year-old girl who had been chronically abused since infancy. The girl's father had harnessed her to a potty in a room in the back of the family house since she was at least 20 months old and deprived her of any linguistic stimulation. She slept in a crib covered with wire mesh. Her father was intolerant of noise and would beat her whenever she made any sound. Her mother fed her a diet of baby food, cereals and, occasionally, boiled eggs. When eventually spotted by social workers, the girl was 4 feet 6 inches tall and weighed 4 stone. She could not eat solid food and had nearly two complete sets of teeth. She was 13 years and 9 months old.

Her most remarkable psychological feature was her almost complete lack of language. She could not talk and had a vocabulary of about twenty words (she could understand concepts such as 'red', 'blue', 'green'). Her speech production was limited to 'nomore', 'stopit' and other negatives. Following her discovery, she was admit-

ted to the Children's Hospital in Los Angeles for treatment. Researchers were interested in how handicapped Genie's language had become and what possible recovery could be made from such gross linguistic impairment (Fromkin *et al.*, 1972/73; Curtiss, 1977). There had been isolated instances of 'accidental' cases of language deprivation before, such as Victor, the 'wild boy of Aveyron', who had been found in 1800, lurking naked in front of a cottage in the Languedoc region of France. He had spent his 12 years from infancy living in the woods, surviving on a diet of acorns and potatoes. He had had his throat cut as a toddler and been left to die. Victor had no language, and while he never learned to speak, he achieved a rudimentary ability to spell.

A year after she was discovered, Genie's language ability underwent marked improvement. Her ability to structure according to rules was the equivalent of a 20-year-old's, and her spatial ability placed her in the adult ability category. She could tell the difference between singular and plural words and positive and negative sentences and could understand some prepositions. Her speech was limited to one or two word sentences, however, eventually becoming very descriptive and concrete ('big rectangular pillow', 'very, very, very dark-green box'). The 'explosion' of language, normally expected after such dramatic improvements, never materialised.

It became clear that Genie could develop new but basic language skills. She made a dramatic recovery from the time of her discovery to the time when the scientists had to abandon their studies. Yet, her language never fully recovered, remaining steadfastly descriptive, almost at the level one would expect primates to achieve with intensive language training. Her study showed, however, the remarkable, devastating effects of language and auditory deprivation on the development of language ability.

Plasticity and language development

In a series of famous experiments, Dennis and Whitaker (1976) and Woods (1980) found that the incidence of aphasia, an inability to produce or comprehend speech, following right-hemisphere damage was greater during infancy than if the lesions had occurred later in life. Other authors suggest that left-hemisphere lesions would produce the greatest deficits in language and speech if they occurred after the age of 5 or 6 years (Vargha-Khadem *et al.*, 1985). The evidence from the human literature was consistent with earlier experimental lesioning work in primates. This work found that if the brain of a monkey was lesioned during infancy, its recovery was significantly superior to that seen after the brain of an adult monkey was lesioned. This became known as the Kennard principle: the notion that recovery from brain damage during infancy is better than from damage during adulthood.

Another source of data suggesting a critical period for the development of asymmetry comes from studies of hemispherectomy, where one hemisphere is removed for medical reasons, usually because of the growth of a large tumour or because of intractable epilepsy. In adults, left hemispherectomies result in fairly severe aphasia, but left hemispherectomies in children are associated with almost complete recovery of language function (Searleman, 1977).

What these data suggest is that the brain has a degree of plasticity when it is developing. That is, specialised functions have not developed in any sophisticated way in one or other hemisphere during early growth. After a specific age, however, this specialisation has begun, but one or other hemisphere can undertake the functions of the other if the other is damaged.

For example, studies have shown that early brain lesions in children between 13 and 36 months old are associated with a delay in the development of expressive vocabulary, especially if damage is to the left side. However, there seems to be little effect on the next stage of language development, sentence production (Vicari *et al.*, 2000). If the damage occurs later, in adulthood, then it is hypothesised that the right hemisphere undertakes the language functions of the left (Hertz-Pannier *et al.*, 1999). One study has found that injury to the left temporal lobe is associated with subsequent increased activation of the right frontal lobe during verbal fluency (Voets *et al.*, 2006). MEG studies also suggest that lateralisation increases as a function of age (Ressel *et al.*, 2008).

Is half a brain enough?

In a novel experiment to explore the nature of plasticity, Hertz-Pannier *et al.* (2002) studied six children who underwent left hemispherectomy for intractable epilepsy (epilepsy that cannot be controlled by drugs) and monitored their brain activity during language tasks before and after the surgery. They hypothesised that if the brain shows evidence of plasticity, then we might expect the right hemisphere to take over the language function of the left. They used fMRI to study the children at age 6 years and 10 months and found the typical left lateralisation for language tasks such as word generation; there was little right hemisphere activity.

Following surgery, receptive language recovered quickly but expressive language and reading was slower to recover. When fMRI scanning was undertaken again at 10 years 6 months, there was a shift in activity to the right hemisphere during expressive and receptive language tasks. The regions that were activated – the inferior frontal temporal and parietal cortices – were analogous to those in the left hemisphere prior to the surgery.

This activation in the right hemisphere is also seen in adults recovering from aphasia. For example, Cappa *et al.* (1997) found that activation in the right temporoparietal

region during the acute phase of recovery predicted improvement in auditory comprehension later on. More recently, a group of researchers has found that a period of intensive training in a group of patients who had suffered a stroke destroying parts of the left frontal cortex and who had difficulty in comprehending speech, led to increased activation in the bilateral network of regions associated with language. There were also increases in right hemisphere regions.

Another case study highlights how successful language development could be following such radical surgery (Battro, 2000). Nico is an Italian boy who was born with left hemiplegia. He managed to walk by age 18 months but developed intractable epilepsy at 22 months. Drugs and selective lesioning of the brain failed to halt the epilepsy and so, as a last resort and with the permission of Nico's parents, surgeons performed a right hemidecortication when the boy was 3 years and 7 months.

Nico recovered well and he did not lose his speech. His IQ was 107 and he learned to develop the basics of spelling and grammar at the same age as normal children through the use of a computer. He is still behind other children in his ability to draw and has difficulty forming letters of the alphabet and numbers with the right hand. The outcome of Nico's surgery suggests that the right hemisphere may be what Popper and Eccles (1977) described as a 'minor brain'. Without it, Nico has learned to develop the important function of language although his 'right hemisphere' functions, such as drawing, are impaired.

The neuropsychology of language and language disorders

You saw in Chapters 1 and 4 that neuropsychology aims to localise not only basic perceptual and sensory functions, such as touching, seeing, recognising objects and so on, but also quite sophisticated cognitive functions. The most extensively studied cognitive function is language, and our knowledge of the neuropsychology of language has come from three sources: studies of individuals with brain injury who show language impairment, individuals who do not develop language adequately, and neuroimaging studies in which activation of the brain in healthy individuals is monitored while they complete language tasks. These sources indicate that the mechanisms involved in perception, comprehension and production of speech are located in different areas of the cerebral cortex.

Language disorders

Brain damage can result from a large number of factors and can cause a wide variety of impairments in cognitive function. Some of the most pronounced impairments are

those related to language. Some language impairments result directly from brain injury, others do not but are likely to be the result of disorganised or abnormal brain activity or structure. The most common language disorders are called the aphasias. The key feature of the aphasias is the loss of language function; the patient is unable to produce or comprehend speech. Other important disorders of language are reading impairment (dyslexia) and stuttering and all three of these disorders are considered in the next sections.

Aphasia

Aphasia literally means ‘total loss of language function’, although patients with the disorder do not lose all language: they are able to perform some language tasks, for example, depending on the site of the brain injury. Because of this, the term ‘dysphasia’ is sometimes used (dys- means ‘partial loss of’). There are different types of aphasia, and the most common are summarised in Table 10.9. Two of the most common types are non-fluent (Broca’s) aphasia and receptive (Wernicke’s) aphasia. The areas of the brain which, when damaged, cause these aphasias can be seen in Figure 10.9.

Speech production: evidence from non-fluent (Broca’s) aphasia

In order to produce meaningful communication, we need to convert perceptions, memories and thoughts into speech. The neural mechanisms that control speech production appear to be located in the frontal lobes. Damage to a region of the motor association cortex in the left frontal lobe (Broca’s area) disrupts the ability to speak: it causes **non-fluent (Broca’s) aphasia**, a language disorder characterised by slow, laborious, non-fluent speech (it is also called expressive, production or motor aphasia). When trying to talk with patients who have non-fluent aphasia, most people find it hard to resist supplying the words the patients are groping for. But although these patients often mispronounce words, the ones they manage to produce are meaningful. They have something to say, but the damage to the frontal lobe makes it difficult for them to express these thoughts.

Here is a sample of speech from a man with Broca’s aphasia, who is telling the examiner why he has come to the hospital. His words are meaningful but what he says is not grammatical. The dots indicate long pauses.

Table 10.9 (a) Types of aphasia, their primary symptoms and the site of the associated brain lesion

Type of aphasia	Primary symptoms	Brain lesion to
Sensory (Wernicke’s) aphasia	General comprehension deficits, neologisms, word retrieval deficits, semantic paraphasias	Post-perisylvian region: postero-superior temporal opercular supramarginal angular and posterior insular gyri; planum temporale
Production (Broca’s) aphasia	Speech production deficit, abnormal prosody; impaired syntactic comprehension	Posterior part of the inferior frontal and precentral convolutions of the left hemisphere
Conduction aphasia	Naming deficits and impaired ability to repeat non-meaningful single words and word strings	Arcuate fasciculus, posterior parietal and temporal regions; left auditory complex, insula supramarginal gyrus
Deep dysphasia	Word repetition deficits; verbal (semantic) paraphasia	Temporal lobe, especially regions which mediate phonological processing
Transcortical sensory aphasia	Impaired comprehension, naming reading and writing, semantic irrelevancies in speech	Temporoparieto-occipital junction of the left hemisphere
Transcortical motor aphasia	Transient mutism and telegraphic dysprosodic speech	Connection between Broca’s area and the supplementary motor area; medial frontal lobe regions anterolateral to the left hemispheres frontal horn
Global aphasia	Generalised deficits in comprehension, repetition, naming and speech production	Left perisylvian region, white matter, basal ganglia and thalamus

Lesions that produce non-fluent aphasia must be centred in the vicinity of Broca's area. However, damage restricted to the cortex of Broca's area does not appear to produce Broca's aphasia; the damage must extend to surrounding regions of the frontal lobe and to the underlying subcortical white matter (Damasio, 1989; Damasio *et al.*, 1996). Dronkers *et al.* (2007) used MRI to measure, in detail, the extent of the damage to the preserved brains of two of Broca's patients, including the famous Leborgne ('Tan').

They found that damage was much deeper than Broca reported (MRI was not available in his day) and other areas were also damaged including a large tract of fibre that connects the posterior and anterior language areas. Although damage to Broca's area can lead to transient impairment in speech production, it seems likely that damage to this fibre is necessary to produce severe speech difficulty.

Confusion about where – or what – Broca's area is exists even in the psychology literature today. A recent survey found that although 27 per cent of neuroimaging studies referred to Areas 44 and 45 as Broca's area, 52 per cent of the journal articles surveyed either did not define Broca's area or gave misleading or broad definitions of the region (Lindenberg *et al.*, 2007).

Wernicke (1874) suggested that Broca's area contains motor memories – in particular, memories of the sequences of muscular movements that are needed to articulate words. Talking involves rapid movements of the tongue, lips and jaw, and these movements must be coordinated with each other and with those of the vocal cords; thus, talking requires some very sophisticated motor control mechanisms. Because damage to the lower left frontal lobe (including Broca's area) disrupts the ability to articulate words, this region is the most likely candidate for the location of these 'programmes'. The fact that this region is

Figure 10.9 Words into thoughts and thoughts into words. The dictionary in the brain relates the sounds of words to their meanings and permits us to comprehend the meanings of words and translate our own thoughts into words. Black arrows represent comprehension of words; red arrows represent translation of thoughts or perceptions into words.

located just in front of the part of the primary motor cortex that controls the muscles used for speech certainly supports this conclusion.

In addition to their role in the production of words, neural circuits located in the lower left frontal lobe appear to perform some more complex functions. Damage to Broca's area often produces **agrammatism**: loss of the ability to produce or comprehend speech that employs complex syntactical rules. For example, people with non-fluent aphasia rarely use function words. In addition, they rarely use grammatical markers such as '-ed' or auxiliaries such as 'have' (as in 'I have gone'). A study by Saffran *et al.* (1980) illustrates this difficulty. The following quotations are from agrammatic patients attempting to describe pictures:

Picture of a boy being hit in the head by a baseball: 'The boy is catch . . . the boy is hitch . . . the boy is hit the ball.' (p. 229)

Picture of a girl giving flowers to her teacher: 'Girl . . . wants to . . . flowers . . . flowers and wants to . . . The woman . . . wants to . . . The girl wants to . . . the flowers and the woman.' (p. 234)

In an ordinary conversation, non-fluent aphasics seem to understand everything that is said to them. They appear to be irritated and annoyed by their inability to express their thoughts well, and they often make gestures to supplement their scanty speech. The striking disparity between their speech and their comprehension often leads people to assume that their comprehension is normal. Their comprehension, however, is not normal. To test agrammatic people for speech comprehension, Schwartz *et al.* (1980) showed them a pair of drawings, read a sentence aloud and then asked them to point to the appropriate picture. The patients heard 48 sentences such as, 'The clown applauds the dancer' and 'The robber is shot by the cop'. For the first sample sentence, one picture showed a clown applauding a dancer, and the other showed a dancer applauding a clown. On average, the brain-damaged people responded correctly to only 62 per cent of the pictures (responses at chance levels would be 50 per cent). In contrast, the performance of normal people is around 100 per cent.

The agrammatism that accompanies non-fluent aphasia appears to disrupt patients' ability to use grammatical information, including word order, to decode the meaning of a sentence. Thus, their deficit in comprehension parallels their deficit in production. If they heard a sentence such as, 'The mosquito was swatted by the man',

they would understand that it concerns a man and a mosquito and the action of swatting. Because of their knowledge of men and mosquitoes, they would have no trouble figuring out who is doing what to whom. But a sentence such as, 'The cow was kicked by the horse' does not provide any extra cues; if the grammar is not understood, neither is the meaning of the sentence.

Other experiments have shown that people with non-fluent aphasia have difficulty carrying out a sequence of commands, such as 'Pick up the red circle and touch the green square with it' (Boller and Dennis, 1979). This finding, along with the other symptoms described in this section, suggests that an important function of the left frontal lobe may be sequencing, both physically in terms of muscle movement (for example, the muscles of speech-producing words) and semantically in terms of sequencing actual words (for example, comprehending and producing grammatical speech). As you saw in the section on working memory in Chapter 8, the frontal cortex may be important for allowing us to sequence stimuli correctly. This sequencing role of the frontal cortex is returned to in the next chapter in relation to reasoning and in Chapter 13 in relation to organising social and emotional behaviour.

Speech comprehension: evidence from receptive (Wernicke's) aphasia

Comprehension of speech obviously begins in the auditory system, which is needed to analyse sequences of sounds and to recognise them as words. Recognition is the first step in comprehension. As we saw earlier in this chapter, recognising a spoken word is a complex perceptual task that relies on memories of sequences of sounds. This task appears to be accomplished by neural circuits in the upper part of the left temporal lobe – a region that is known as **Wernicke's area**.

Brain damage in the left hemisphere that invades Wernicke's area as well as the surrounding region of the temporal and parietal lobes produces a disorder known as **Wernicke's aphasia**. The symptoms of receptive aphasia are poor speech comprehension and production of meaningless speech (Wernicke's aphasia is also known as sensory or receptive aphasia). Unlike non-fluent aphasia, speech in receptive aphasia is fluent and unlaboured; the person does not strain to articulate words and does not appear to be searching for them. The patient maintains a melodic line, with the voice rising and falling normally. When you listen to the speech of a person with receptive aphasia, it appears to be grammatical. That is, the person uses function words such as 'the' and 'but' and employs complex verb tenses and subordinate clauses. However, the person uses few content words, and the words that he or she strings together just do not make sense. For example:

Well this is . . . mother is away here working her work out o'here to get her better, but when she's looking, the two boys looking in other part. One their small tile into her time here. She's working another time because she's getting, too.

Or this example of a conversation between a patient and a speech therapist:

Therapist: What did you have (to eat)?

PH: Today I haven't touched a/maiwa/d^/David. He had beastly tomorrow.

Therapist: Was the food good?

PH: Yes, it was fine.

Source: R.C. Martin (2003).

The failure of patients with Wernicke's aphasia to comprehend their own speech typically renders them unaware of their language processing problems and they will continue to participate in conversations, nodding in the appropriate places and taking turns to speak, blissfully unaware of their disorder.

A commonly used test of comprehension for receptive aphasia assesses the patient's ability to understand questions by asking them to point to objects on a table in front of them. For example, they are asked to 'point to the one with ink'. If they point to an object other than a pen, they have not understood the request. When tested this way, people with severe Wernicke's aphasia show poor comprehension.

Because Wernicke's area is a region of the auditory association cortex, and because a comprehension deficit is so prominent in receptive aphasia, this disorder has been characterised as a receptive aphasia. Wernicke suggested that the region that now bears his name is the location of memories of the sequences of sounds that constitute words. This hypothesis is reasonable; it suggests that the auditory association cortex of Wernicke's area recognises the sounds of words, just as the visual association cortex in the lower part of the temporal lobe recognises the sight of objects.

Wernicke's aphasia, like non-fluent aphasia, actually appears to consist of several deficits. The abilities that are disrupted include recognition of spoken words, comprehension of the meaning of words, and the ability to convert thoughts into words. Recognition is a perceptual task; comprehension involves retrieval of additional information

from long-term memory. Damage to Wernicke's area produces a deficit in recognition; damage to the surrounding temporal and parietal cortex produces a deficit in production of meaningful speech and comprehension of the speech of others.

Brain damage that is restricted to Wernicke's area produces an interesting syndrome known as **pure word deafness** – a disorder of auditory word recognition, uncontaminated by other problems (Franklin *et al.*, 1994). Although people with pure word deafness are not deaf, they cannot understand speech. As one patient put it, 'I can hear you talking, I just can't understand what you're saying.' Another said, 'It's as if there were a bypass somewhere, and my ears were not connected to my voice' (Saffran *et al.*, 1976, p. 211). These patients can recognise non-speech sounds such as the barking of a dog, the sound of a doorbell, the chirping of a bird, and so on. Often, they can recognise the emotion expressed by the intonation of speech even though they cannot understand what is being said. More significantly, their own speech is excellent. They can often understand what other people are saying by reading their lips. They can also read and write, and, sometimes, they ask people to communicate with them in writing. Clearly, pure word deafness is not an inability to comprehend the meaning of words; if it were, people with this disorder would not be able to read people's lips or read words written on paper.

Wise *et al.* (2001) have suggested that the term 'Wernicke's area' has become meaningless because different research groups delineate the area in different ways and impute to it different functions. They re-analysed four brain imaging studies of Wernicke's area, defined generally as 'the left superior temporal cortex posterior to the primary auditory cortex'. The re-analysis identified two regions within 'Wernicke's area' which seemed to perform different functions. One part responded to speech and non-speech sounds, including the sound of the speaker's voice. The posterior part of this, near the parietal lobe, was active during speech production. The second part identified was more lateral and responded to external sources of speech; it was also active during the recall of word lists. This suggests that the functions of both parts are compatible with a hypothesis which states that the first region is involved in mimicking sounds and the second is involved in the transient representation of heard or internally generated phonetic sequences. Both processes, the authors argue, are important for the long-term memory of novel words.

If the region around Wernicke's area is damaged, but Wernicke's area itself is spared, the person will exhibit all of the symptoms of receptive aphasia except a deficit in auditory word recognition. Damage to the region surrounding Wernicke's area (the posterior language areas) produces a disorder known as **isolation aphasia**, an inability

ity to comprehend speech or to produce meaningful speech accompanied by the ability to repeat speech and learn new sequences of words. The difference between isolation aphasia and Wernicke's aphasia is that patients with isolation aphasia can repeat what other people say to them; thus, they obviously can recognise words. However, they cannot comprehend the meaning of what they hear and repeat; nor can they produce meaningful speech of their own. Apparently, the sounds of words are recognised by neural circuits in Wernicke's area, and this information is transmitted to Broca's area so that the words can be repeated. However, because the posterior language area is destroyed, the meaning of the words cannot be comprehended.

Damage to other regions of the brain can disrupt particular categories of meaning in speech. For example, damage to part of the association cortex of the left parietal lobe can produce an inability to name the body parts. This disorder is called **autotopagnosia**, or 'poor knowledge of one's own topography' (a better name would have been autotoponomia, 'poor naming of one's own topography'). People who can otherwise converse normally cannot reliably point to their elbows, knees or cheeks when asked to do so, and they cannot name body parts when the examiner points to them. However, they have no difficulty understanding the meaning of other words.

Psychology in action – The man who lost his language: the phenomenology of aphasia

On Tuesday, 28 July we went to a party in London. I drive home because John had had too much to drink. At a red light I glanced at him, and saw on his face the expression of a man crazed by an apocalyptic vision. He laughed it off: 'Is that what you go around saying at parties, "Good evening, you have a crazed apocalyptic look on your face?"' If I had known what that look meant, it is theoretically possible that I might have saved him . . .

Source: Sheila Hale (2002) *The Man Who Lost His Language*, p. 30.

On the morning of the 30 July 1992, just before nine o'clock, Sir John Hale, art historian and prolific author was found on his study floor, having the 'sweet witless smile of a baby' on his face and uttering only the words, 'the walls, the walls'. Hale had suffered a stroke. Sheila, his wife, had noted one of the signs just days before – a change in the musculature of his face. While most of the studies in this book emerge from academic journals, and are reported in the clinical way one would expect from such a source, Sheila Hale wrote a personal account of the disorder and its consequences, writing in careful and often touching detail about the day-to-day consequences of stroke and aphasia and how she coped with the virtual demolition of her husband's language.

Initially, John Hale was unable to speak or write or match written/spoken nouns to objects such as a razor, a chick, a pencil and some keys. He could surmise what people were saying from their gestures and tone of voice, laughing at jokes and following simple instructions. Reading for pleasure was difficult and he would turn over pages he could not follow. Curiously, he could understand academic journals and off-prints which suggested a dissociation between reading for pleasure and reading for information. John was written off by his original consultant – at the time of the stroke, Hale was in his 60s and was felt to be unable to benefit from rehabilitation

– but an independent neurologist suggested that his intelligence alone might help his recovery. Sheila Hale discovered a series of language puzzle books designed for Roald Dahl's wife, Patricia Neal – who had become aphasic following a stroke – by Valerie Eton Griffiths, and recruited family and friends to use them with her husband. At this point, he began introducing new sounds into his conversation: *the*, *da* or *whoah*. He could copy shapes and words and perform mental arithmetic but was unable to write words independently.

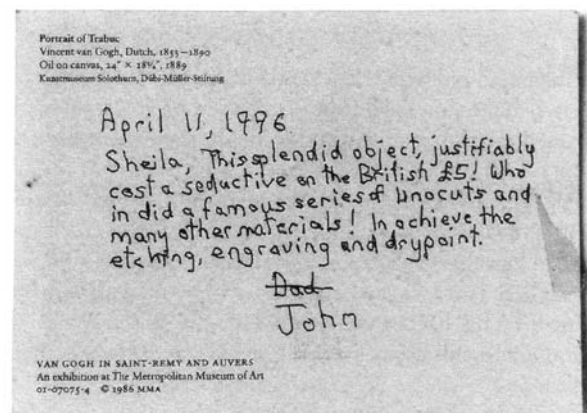

At a new hospital, he was given a pad to write on. One of his earliest spontaneous examples of writing involved writing 'f' in the centre of the page and 'o', 'r' and 'k' diagonally to the right. He could sort Scrabble tiles into words – often punning with them. He could play Boggle and he could reconstruct sentences that had been cut up. Proof-reading his most recent book, he missed some errors but was able to direct his editor to the location of the references needed for the book.

His speech therapist originally thought that John could not benefit from therapy – ironically, because he was too exuberant and that anyone with his degree of expressiveness would not be sufficiently motivated to help themselves through the difficult process of rehabilitation. This view changed when, at a dinner party, she lifted up her arm and asked John what it was: 'John said "*da woahs*". Elizabeth said, "No, John, listen to yourself. Now listen to me: *ahm*". John said *ahhmm*. "No, John, you're saying *ahhmm*. It's not quite right, is it? What is this? This is my . . . ?" John said *ahm*' (Hale, 2002, p. 191).

When Sheila asked the therapist how it could be that her husband could read German, English and French but not be able to write a sentence in any language, Elizabeth offered a series of illuminating metaphors: 'It is as though the road between Naples and Rome had been blown up. You can still travel between the two cities, but you have to make your way through the rubble to find an alternative route,' or 'The British Library has been shaken by an earthquake. The books have been

Psychology in action – Continued

RICARDO WENT OUT SHOPPING TO BUY SOME FRUIT. HE BOUGHT A POUND OF pears, AND A LARGE JUICY WATER melon. HE ALSO WENT INTO THE OFF-LICENCE AND BOUGHT THREE BOTTLES OF wine. HE WALKED HOME ALONG BY THE river AND WATCHED THE MEN ROWING THE boat. A VERY BEAUTIFUL girl WAS SITTING ON A bench SO HE SAT NEXT TO HER. SHE HAD LONG BLONDE hair AND BIG BLUE eyes. RICARDO SAID 'GOOD morning' IT'S A LOVELY day. SHE TURNED TO HIM AND smiled SHOWING LOVELY WHITE teeth. RICARDO OFFERED HER ONE OF HIS pears. THEY TALKED HAPPILY FOR HALF AN HOUR AND THEN RICARDO ASKED HER OUT TO dinner. SHE AGREED AND THEY MET OUTSIDE THE restaurant AT 7.30PM.

27 Oct. 1996.

Darling Polly,

I am glad John is all right. I am sure she was better for these three weeks. Sheila and I are well. We went to St. Petersburg with friends for a week.

Love,

John

20 September 1998

Dear Miranda,

Thank you for the delicious dance on Friday. I was flattered to be on your party list and to participate...

Love

John

Psychology in action – Continued

hurled off the shelves. They're all mixed up and the catalogues can't be found. The books are like your words: there they are, but you have no means of finding them' (Hale, 2002, p. 195).

John's understanding of words was excellent and he could recognise written and spoken reversed letter words, real words and non-words; he could match synonyms, and words to pictures. However, phonological segmentation was a problem: when presented with the words 'map' and 'gap' he was unable to indicate which sound had changed. He knew that both were different. He could identify the number of letters in a word and could fill in blanks in a story but sometimes made dysgraphic errors, writing 'borg' for 'dog'.

A curious deficit was his inability to recognise the subject of a sentence or picture. When presented with a picture of a boy on a bike and asked who was riding the bike, he would point to the word representing the verb ('riding' rather than the word 'boy'). He seemed to have lost understanding of 'who' words that stood for arguments. This lasted for two years. In 1995, his interest in reading for pleasure was rekindled, to such an extent that the house began to be over-run with biographies.

Three years after his stroke, John was able to speak the words: *haaloo, bye, I, fine, wine, bus, bow, bell, more, my, house and horse*. Sometimes, when trying to say one of these words, he would say 'arm' instead. Two years later, Sheila described a typical morning: 'Over lunch he tells me about his morning. *Mmmmmm* means walking along minding his own business. *Arrrr-up!* With his left hand describing an arc means that he has crossed a bridge. He meets a friend: broad smile, greeting gestures; they go into a pub; mime of conversation: *bahbahbahbahbah* – and drinking. Or John gets on a bus: sounds of changing gears, starting and stopping.'

Eventually, his non-language became less prosodic – he would introduce the words *um, oh, ah, aargh, gah, no* and *oh*

my God to stem the mellifluous aphasic flow. He took great pains to find the right word, a struggle observed in the brain-injured patient, Lt Zasetzky by Luria (1972) in his book, *The Man with a Shattered World*. 'It was so hard to write,' Zasetzky wrote, 'At last, I'd turned up a good idea. So I began to hunt for words to describe it and finally I thought up two. But by the time I got to the third word, I was stuck . . . Finally, I managed to write a sentence expressing an idea I had . . . sometimes I'll sit over a page for a week or two . . . But I don't want to give it up. I want to finish what I've begun. So I sit at my desk all day, sweating over each word.'

One October evening, Sheila Hale wrote, 'I was too weak to resist a quick, forbidden glance into the future. And what I saw was a succession of meals, sitting across a table from a husband who was no more, or less, companionable than an affectionate dog' (Hale, 2002, p. 61). John Hale hid his despair well until, one afternoon, his wife found him with his head bowed and his left hand covering his face: 'When I put my arms around him, I felt the tears on his face. He was crying for the first time since I had known him.'

Hale's book is testament to the support, love and care that can help an individual with aphasia deal with extreme communication difficulty. Despite the impairment in his speech, John continued to be charming, garrulous and intelligent company. David Chambers summed up the positive aspects of Hale when writing the historian's obituary in *The Times*: 'for those in his company, the infinitely modulated exclamations, chuckles and ironical groans which accompanied his enchanting smile seemed almost to amount to conversation. Gregarious as ever, he proved that, even in aphasia, life can be exhilarating.'

Specific language impairment

Some children have difficulties in producing or understanding spoken language, in the absence of known brain injury. The 3–4 per cent who exhibit this impairment are said to show **specific language impairment**. Grammar and phonology are the most affected aspects, but intelligence is within the normal range. When a 6-year-old with adequate hearing but specific language impairment is asked to repeat the sentence, 'Goldilocks ran away from the three bears because she thought they might chase her,' she says, 'Doedilot when away from berd. Them gonna chate her' (Bishop, 1997). A recent study suggests that one cause of these problems may be impaired auditory perception (B.A. Wright *et al.*, 1997). These researchers found that the children were impaired when perceiving tones that were brief, but not tones that were long.

Some language impairments, however, seem to occur in the absence of such auditory impairment. These impairments arise from a child's inability to acquire the rules of language early (Gopnik, 1997). One example of such a language impairment is the inability to produce the past tense. For example, in the following statement,

'Everyday he walks eight miles. Yesterday he . . .

some children would not be able to supply the past tense for 'walk' to complete the second sentence. These problems are seen in children who have normal auditory acuity and non-verbal and psychosocial skills, and, although they may have other difficulties such as dyslexia and depression, none of these factors has been reliably associated with these specific language impairments.

Table 10.10 The percentage of participants capable of marking novel words grammatically

Grammar	Language	Controls %	Impaired %
Past tense	English (in England)	95.4	38.0
	English (in Canada)	93.5	52.3
	Greek	87.1	20.0
	French	92.6	33.3
	Japanese	89.1	37.0
Plurals	English (in England)	95.7	57.0
	English (in Canada)	99.2	58.3
	Greek	79.8	42.1
Comparatives	English (in England)	74.0	21.0
Compounds	Japanese	80.5	20.2
	Greek	93.6	12.8
Diminutives	Greek	83.9	40.2

In each of these tests the subjects were given a context which required a grammatical rule to be applied to a novel word; for example, ‘This pencil is weff’ would require the participant to supply ‘This pencil is even . . . [weffer]’.

In a review and theoretical analysis of these impairments, Gopnik (1997) has suggested there may be a strong genetic influence on their development because they tend to cluster in families and seem to occur in families cross-culturally. Such impairments have also been found in languages such as English, Japanese, Greek and French. An example of the types of test used to determine specific language impairment is seen in Figure 10.10. Here, the participant is presented with a word they have never heard of (i.e. a non-word) and are given a grammatical rule to follow. The forms of impairment observed can be seen in Table 10.10.

Gopnik suggests that this specific impairment in the use of complex grammatical rules is universal, although critics have argued that auditory/articulation problems or general problems with cognition may be the source of the impair-

Figure 10.10 A task used to investigate a child’s ability to understand grammar using novel words.
Source: Reprinted from Gopnik, M., Language deficits and genetic factors. *Trends in Cognitive Sciences*, 1997, 1(1) p. 7. © 1997, with permission from Elsevier Science.

ment rather than a genetic, neural component. For example, children may leave off the /d/ sound when transforming an English word into the past tense. However, the problem does not seem to be specific to /d/ sounds. In languages where the past tense is transformed in a different way, the same specific language impairments have been observed. English, for example, has about four regular-form verbs; Greek has sixty. The number of mistakes in making past tenses seen in each language is proportional to the number of regular verbs they use. More to the point, as Gopnik notes, in French the final syllable is stressed so that it is not difficult to hear.

Speech and language disorders have been linked to chromosomes 3, 7, 13, 16 and 19. The genes underlying these are not fully identified, but one of these might be *FOXP2* located on chromosome band 7q31 (see Fisher, 2005 and Figure 10.11). Disruption of this gene leads to disruptions in articulation important for speech and seems to have evolved in the past 200,000 years. Striking evidence for this gene-linked disorder was found in a family where three generations were found to suffer from the impairment. Individuals with the genetic defect also have problems in expressing and understanding oral and written language. It is probably inaccurate to describe *FOXP2* as a ‘language’ gene, however, because it is also involved in other behaviour. To date, six chromosomes have been identified with links to specific learning impairment/dyslexia (Ramus, 2006).

Figure 10.11 Recent research suggests that the *FOX P2* gene may be responsible for the development of speech and language disorders.

Dyslexia

The term **dyslexia** refers to a disorder involving impaired reading and it is one of the most common language disorders seen in children and adults. The incidence of the disorder lies between 5 and 17.5 per cent (Shaywitz, 1998). Although boys are thought to be affected more than girls, the evidence is unclear (Flynn and Rahbar, 1994). Many different types of dyslexia have been described but there are two broad categories: acquired dyslexia and developmental dyslexia. **Acquired dyslexia** describes a reading impairment resulting from brain injury in individuals with previously normal language. **Developmental dyslexia** refers to a difficulty in learning to read despite adequate intelligence and appropriate educational opportunity (Brunswick, 2009). The types of dyslexia and their symptoms are described in Table 10.11.

Acquired dyslexia

The most important forms of dyslexia which result from brain injury are visual word form dyslexia, phonological dyslexia, surface dyslexia and deep dyslexia. Visual word form dyslexia describes an inability to recognise words immediately but gradually with the naming of each letter (Warrington and Shallice, 1980). Sometimes a patient might commit a letter-naming mistake, pronouncing ‘c, a, t . . . cat’ when the word to be read is ‘mat’. The disorder is thought to result from a disconnection between the region of the left hemisphere which mediates the recognition of word forms (Speedie *et al.*, 1982) and the visual input system. Reading ability may rely on the perceptual and visual skills of the right hemisphere.

Phonological dyslexia refers to an inability to read pseudowords and non-words and is relatively rare (although phonological deficits are also seen in developmental dyslexia, described below). Phonological dyslexia provides evidence that whole-word reading and phonological reading involve different brain mechanisms and provides some support for the dual-route model of reading outlined earlier in the chapter (see Figure 10.12). Phonetic reading, which is the only way we can read non-words or words we have not yet learned, entails some sort of letter-to-sound decoding. It also requires more than decoding of the sounds produced by single letters, because, for example, some sounds are transcribed as two-letter sequences (such as ‘th’ or ‘sh’) and the addition of the letter ‘e’ to the end of a word lengthens an internal vowel (‘can’ becomes ‘cane’).

Surface dyslexia is the inability to recognise and read words based on their physical characteristics. Individuals are able to apply the grapheme–phoneme correspondence rules, however (described earlier in the chapter), but have difficulties with irregular words, using inefficient spelling-to-sound strategies (so, ‘yacht’ is pronounced as it reads and sounds).

Deep dyslexia refers to a severe inability to read; concrete words can sometimes be read but are commonly replaced by semantically related words. For example, a patient would read ‘sleep’ when the word is ‘dream’ (Coltheart *et al.*, 1980). Abstract words are rarely pronounced accurately and neither are pronounceable non-words (indicating an inability to apply grapheme–phoneme correspondence rules).

Table 10.11 The dyslexias and the brain regions associated with them

Type of dyslexia	Primary symptoms	Brain regions implicated
Acquired dyslexia		
Visual word form dyslexia	Impaired sight reading; some decoding is possible	Disconnection between the angular gyrus of the dominant hemisphere and the visual input system
Phonological dyslexia	Deficits in reading pseudowords and non-words	Temporal lobe of the dominant hemisphere?
Surface dyslexia	Tendency to produce regularisation errors in the reading of irregular words	?
Deep dyslexia	Semantic substitutions, impaired reading of abstract words, inability to read non-words	Extensive damage to the dominant hemisphere
Developmental dyslexia		
	Impaired reading and spelling of words/non-words/pseudowords, poor phonological processing skills, sequencing and short-term memory, some visuo-perceptual defects	Temporo-parietal regions of the dominant hemisphere

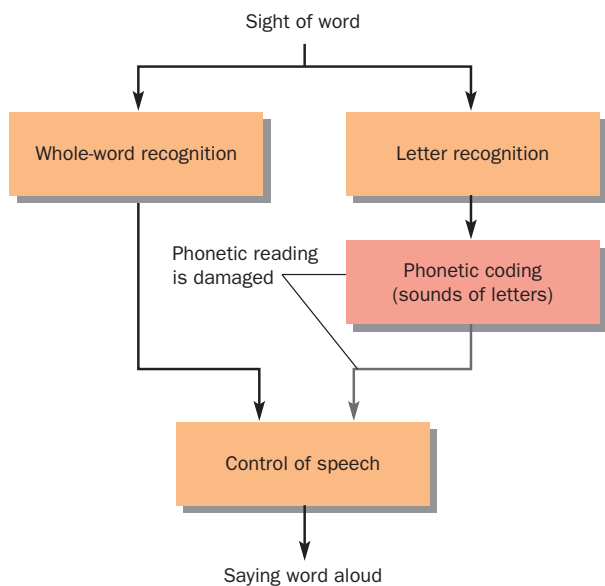

Figure 10.12 A hypothetical explanation of phonological dyslexia. Only whole-word reading remains.

Developmental dyslexia

The symptoms of developmental dyslexia resemble those of acquired dyslexias. Developmental dyslexia first manifests itself in childhood. It tends to occur in families, which suggests the presence of a genetic (and hence biological) component (Grigorenko *et al.*, 1997). Attempts have been made to categorise types of developmental dyslexia along the same lines as the acquired dyslexias. Such attempts usually distinguish between reading disorders which involve a deficit in ‘sounding out’ a word or in identifying words on the basis of visual form (Brunswick, 2009). Various names have been suggested for the two types such as dysphonetic v. dyseidetic (Fried *et al.*, 1981), phonological v. morphemic dyslexia (Temple and Marshall, 1983), and P (perceptual) and L (lingual) type (Bakker, 1992).

Although not all psychologists agree with such distinctions, a fairly constant factor in developmental dyslexia is poor awareness of the phonological features of sound, that is, poor phonological awareness (Stahl and Murray, 1994). The segmentation of words into sounds, being aware of alliteration, verbal repetition and verbal naming are all impaired in developmental dyslexia. For example, if children are asked to transpose the first sounds of the words ‘mustard’ and ‘salad’ (thereby producing ‘sustard’ and ‘malad’), those with developmental dyslexia are unable to do this. Similarly, individuals with developmental dyslexia may be unable to perform phonological tasks such as indicating what is left when you take either the first or last sound away from a word such as ‘mice’.

There also seems to be a deficit in the verbal or phonological memory of developmental dyslexics. For example, a number of studies have shown that these individuals have a poorer memory span than good readers for letter strings, words in a sentence and strings of digits. The stimuli do not have to be printed, the deficit is purely language-based; memory for unfamiliar faces or abstract patterns is intact (Lieberman *et al.*, 1982). Is this poor phonological memory the cause of the reading disorder?

Developmental dyslexia: possible neuropsychological causes

Visual pathway deficits

Some psychologists have argued that phonological impairments do not explain the persistent and severe nature of dyslexia (Hulme and Roodenrys, 1995). Reading is a complex task that requires phonology, memory and visual perception and there are various theories that attempt to explain developmental dyslexia in terms of dysfunctional neuronal systems in several areas of the brain (Habib, 2000). Stein and his colleagues (Stein, 1991; Stein and Walsh, 1997), for example, have suggested that developmental dyslexia is associated with poor visual direction sense, poor binocular convergence (described in Chapter 6), and visual fixation.

Stein’s view argues that dyslexics are unable to process fast, incoming sensory information adequately. Most information from the retina to the cortex via the thalamus travels through one of three visual system pathways. One of these systems – the magnocellular (M) pathway – is thought to carry visual information about space, such as movement, depth, and the relationships between the positions of stimuli. Some researchers have implicated a malfunctioning M pathway in dyslexia but have had difficulty in explaining why the defective pathway makes reading difficult.

Studies have shown that poor visual fixation, poor tracking from left to right and poor binocular convergence appear to hinder the development of normal reading (Eden *et al.*, 1994). In an fMRI study of developmental dyslexia and the ability to process visual motion, Eden *et al.* (1996) found that moving stimuli (such as dots) failed to activate the cortical area that is projected to by the magnocellular pathway (area V5). In competent readers, this area was activated in both hemispheres during the task. Furthermore, the presentation of stationary patterns did not produce different patterns of brain activation in dyslexic individuals and controls, suggesting that the dyslexic sample had difficulties specifically with attending to moving stimuli.

One hypothesis suggests that the M pathway plays an important role in selective attention. It acts as an atten-

tional spotlight which focuses on important stimuli and ignores all the clutter surrounding these stimuli. Vidyasagar and Pammer (1999) put this hypothesis to the test. They asked 21 reading-impaired children and age-matched normal readers to complete a standard visual search task in which they had to locate a stimulus that was characterised by a combination of colour and form (for example, looking for a grey triangle in a background of grey circles). The greater the number of distractors in

this task, the greater the number of errors made by the reading-impaired group. When there were fewer than 36 distractors, the impaired readers did as well as their age-matched counterparts. When the number increased to 70, a significantly greater number of errors were committed by the impaired reading group, suggesting to the authors that in the dyslexic group visual search mechanisms are compromised when a visual scene is cluttered. Because reading places great demands on the attentional spotlight

– which detects the conjunction of features – an impairment in this process may be explained by deficits in the system that turns on and operates the spotlight.

A challenge was reported in a study which tested this explanation (Stuart *et al.*, 2006). People with developmental dyslexia have an impairment in one of the two visual pathways, the magnocellular pathway, which means that they are not sensitive to rapidly changing stimuli. A deficit in the auditory equivalent means that they have difficulty in segmenting speech, making accurate phonological representations of what they read and making grapheme–phoneme correspondences. Stuart *et al.* measured auditory and visual contrast thresholds in adults with severe reading difficulties. This group showed normal ability to detect visual contrasts (and auditory contrasts). The data undermine the notion that the magnocellular pathway is defective in allowing a person to be sensitive to contrasts. Perhaps, the researchers suggest, the abnormality lies at the level of the interaction between this pathway and the other visual pathway, the parvocellular pathway.

Neural dysfunction

One of the consistent findings in neuroimaging studies of developmental dyslexia is that a decrease in blood flow is seen in temporal and inferior parietal areas, namely the areas involved in letter-to-sound conversion, the analysis of speech sounds and word form recognition (Brunswick *et al.*, 1999; Hoeft *et al.*, 2006, 2007; Aylward *et al.*, 2003; Horwitz and Braun, 2004). A study of 17 male dyslexics and a control group of 14 men, for example, found that blood flow to the superior part of the temporal lobe – a region called the angular gyrus – increased in normal readers with good reading performance: good reading skill was associated with greater blood flow to this area (Rumsey *et al.*, 1999). However, greater blood flow to this area was associated with poor reading skill in the dyslexic sample, suggesting that the good readers relied on this region to read and the region undertook the task adequately, but when the dyslexic readers also relied on the same region, it contributed to the task very poorly. Pugh *et al.* (2000) compared brain activation in impaired and normal readers who completed language tasks requiring minimal to considerable phonological processing. If tasks are print-related and involve no processing of the phonology of words, then there should be evidence of connectivity/activation between the angular gyrus and the superior temporal lobe in dyslexic participants. This is what Pugh *et al.* found.

Languages with fairly transparent reading systems, such as Italian, are less likely to present readers with difficulties. Paulesu *et al.* (2001) used PET to measure brain activation in French, English and Italian dyslexic participants and their respective control groups. Participants read either bisyllabic words or non-words aloud (an explicit reading

task) or as they made decisions about specific physical features of letters in words (an implicit reading task). Activity in the same region in the left hemisphere was reduced in all three dyslexic groups. The region included the left middle, inferior and superior temporal cortex.

A recent study has extended the study of dyslexia in other languages to Chinese. In logographic Chinese, graphic forms (characters) are mapped onto syllables whereas in English, units (letters) are mapped onto phonemes. For this reason, when Chinese people engage in working memory tasks, there is activation in the areas responsible for visuospatial manipulation and the left middle frontal gyrus. There is the reading of complex shapes and characters and orinunciation must be memorised by rote. Earlier studies had associated impaired reading in logographic Chinese with anomalous activation in the left middle frontal gyrus (Siok *et al.*, 2004). In a follow-up study, Siok *et al.* (2008) found reduced activation in the same area in people identified as dyslexic in Chinese. This finding is important because it suggests that the brain regions implicated in dyslexia depend on whether the language is alphabetic (e.g. English, Italian and so on) or non-alphabetic. See Figure 10.13.

Failure of lateralisation

One model of developmental dyslexia suggests that dyslexics have delayed or reduced left hemisphere function or have no lateralised preference (Bishop, 1990; Galaburda *et al.*, 1994). There is evidence that function and structure are more symmetrical in dyslexic samples.

When good and poor readers respond to visual or auditory stimuli, brain electrical activity is symmetrical in dyslexic readers but typically left-based in controls (Cohen and Breslin, 1984; Brunswick and Rippon, 1994; Rippon and Brunswick, 1998). A group of North American researchers has found that the size and type of brain region correlates with degree of reading difficulty (Leonard *et al.*, 2006). In an MRI study of 11–16-year-old boys and girls with reading and language impairments, they found that smaller and more symmetrical brain structures were associated with considerable reading and language difficulties, and that larger, more asymmetric structures were associated with poor word reading (but not comprehension). The study also found, however, that 75 per cent of the children with developmental dyslexia showed asymmetry in a very important region for dyslexia: planum temporale (it was longer in the left, in contrast to some studies).

The planum temporale (PT) is a small region corresponding to the auditory association cortex in the temporal lobe. Because of the PT's prominence in the left hemisphere (where it is longer) and because it contains an area that is functionally the same as Wernicke's area, some researchers have suggested that this structure is important for language (see Beaton, 1997, for a thorough discussion). This idea, however, is speculative (Galaburda, 1995). For example, the leftward asymmetry of the planum temporale may simply be nothing more than a physical feature of the brain; it simply happens to be larger on the left than the right. However, there do seem to be more anomalies in asymmetry in dyslexics than in normal-reading samples. Control readers have a larger planum temporale in the left hemisphere than the right whereas dyslexic readers show a similarly sized structure in both hemispheres.

Best and Demb compared the degree of planum temporale asymmetry in a group of young dyslexic adults having a known M-pathway deficit with a control group (Best and Demb, 1999). Using three methods of brain imaging, the authors found little difference between the controls and the dyslexics: both showed the typical leftward PT asymmetry. However, some methods did point towards greater symmetry in the dyslexics. What this, and other independent evidence, suggests, the authors conclude, is that a sub-type of dyslexia may have the characteristic leftward asymmetry but not the M-pathway deficits.

Cerebellar dysfunction

The cerebellum is best understood as the region which contributes to motor function, posture and balance, although recent research implicates it in a variety of non-motor functions such as reading, speech perception and even emotional expression (Desmond, 2001; Justus and Ivry, 2001). Damage to the structure, for example, results in impairments in grammatical morphology (see Table 10.12).

It has also been implicated in developmental dyslexia. Nicolson *et al.* (1999) found that activation in the cerebellum was significantly lower in dyslexic than normal readers during the execution of familiar and novel motor tasks. The authors suggest that this cerebellar dysfunction affects the learning of new skills and the 'performance of automatic, overlearned skills'. Reading, they argue, is a complex behaviour composed of a number of interacting motor behaviours which need to be learned and improved over time. The dysfunctional cerebellum is not a cause of dyslexia but is a key structure in dyslexia.

Right-sided reduction in the front of the cerebellum has correctly predicted over 72 per cent of children with dyslexia: that is, the reduction in the region was correlated with poor reading (Eckert *et al.*, 2003). Other studies find that activation is more diffuse in the cerebellum in dyslexic children who generate appropriate verbs to a noun (Baillieux *et al.*, 2009). Rae *et al.* (2002) found that the side of the cerebellum that controlled the writing hand was

Table 10.12 Some grammatical errors made by patients with cerebellar damage

Italian patient (translation): I was watching [the] television. One moment after, immediately after, to feel one-half not to go. To have an attack, to be unable to speak. Upstairs there was my wife sleeping because it was midnight. I suddenly to stand up, suddenly to fall down. Not to do anything because there was the carpet . . .

Silveri *et al.* (1994)

Italian patient (translation): Razor hand. First there was razor and brush. A brush was used now instead spray. Foam on the hands then palm cream razor hand I do like this. I repeat operation against the growth. Same blade twice. Or electric razor. Face well dry. To use before pre-shave lotion. Batteries or current same thing. But electric razor skin used to must be.

Zettin *et al.* (1997)

less well developed in dyslexic adults than controls. However, as Bishop (2002) argues, the development of the cerebellum depends on the degree of experience a person has with writing: a child with literacy problems is less likely to pick up a pen and use it frequently. Consequently, the cerebellum does not show the same strength of development seen in individuals who have a history of well-practised writing (Bishop, 2002).

Word recognition and production: neuroimaging studies

Neuroimaging studies of normal readers generally conclude that the left hemisphere participates in language-related tasks more actively than does the right hemisphere and that specific regions of the left hemisphere are involved in the different components of language such as speech production, comprehension, processing of sound, meaning, and so on (Brunswick, 2004).

Petersen *et al.* (1988) were the first to conduct a PET investigation of language processing in healthy individuals. They found that the left posterior temporal cortex (including the primary auditory cortex and Wernicke's area) was significantly more active during passive listening of words than during a control condition. Repeating the nouns activated the primary motor cortex and Broca's area.

When people were asked to think of verbs that were appropriate to use with the nouns, even more intense activity was seen in Broca's area. Price *et al.* (1994) have also reported that greater activation in the left inferior and middle frontal cortices was found during performance of a lexical decision task whereas more temporal regions were activated during reading aloud and reading silently.

An important aspect of language analysis is, as you saw earlier in the chapter, phonological processing – the putting together of sounds to make meaningful words. Neuroimaging studies have found that when individuals discriminate between spoken words on the basis of phonetic structure, when they discriminate between consonants and when they make judgements about rhyme or engage in phonological memory tasks, activation in the left frontal cortex near Broca's area is found (Fiez *et al.*, 1995; Paulesu *et al.*, 1996; Zatorre *et al.*, 1996). Other studies report involvement of the temporal cortex and angular gyrus especially during tasks involving drawing analogies, repeating words and in reading words and pseudowords (Nobre *et al.*, 1994; Karbe *et al.*, 1998).

This evidence suggests that Broca's area and the frontal cortex are necessary for the phonetic manipulation of language but that the posterior temporal cortex is responsible for the perceptual analysis of speech (Zatorre *et al.*, 1996).

However, the picture may be a little more complex. Binder *et al.* (1997) compared the analysis involved in the phonetic and semantic perception of aurally presented words with the analysis of non-linguistic stimuli such as tones. A large network of left-hemisphere regions was activated during the semantic analysis, including areas in the frontal, temporal and parietal cortex. Activation, therefore, was not limited to one specific region.

Damasio *et al.* (1996), in a comprehensive study of its kind, evaluated the effects of language processing in individuals with brain lesions in both hemispheres, inside and outside the temporal regions. Damasio *et al.* hypothesised that there is no single mediating site for all words, but there are separate regions within a larger network that are activated by different kinds of word. There were three categories of words: persons, non-unique animals and non-unique tools, each of which should be processed by different parts of the frontal and temporal lobe. Although 97 individuals showed normal language, 30 did not; 29 of these had brain injury to the left hemisphere. While impaired retrieval of words was associated with temporal cortex damage, abnormal retrieval of animal words was found in patients with left interior temporal lobe damage and abnormal retrieval of tools was associated with posterolateral inferior temporal cortex damage.

Because we cannot infer normal function from brain damage, Damasio *et al.* conducted a second experiment in which healthy individuals performed the same language tasks while undergoing a PET scan. Although all words activated the left temporal cortex, specific categories were associated with activation of specific regions of the brain. Naming of tools activated the posterior, middle and inferior temporal gyri, for example, and animal naming activated other parts of the inferior temporal cortex. These results are similar to those of Martin *et al.* (1996), which showed that different categories of words appeared to activate different parts of the brain. A recent study has even suggested that silently naming the use of tools activates Broca's area and the left premotor and supplementary motor area (Grafton *et al.*, 1997). This suggests that even the naming of a tool's use can activate those parts of the brain that would be activated during the actual movement involved in using those tools.

There is significant overlap between neuroimaging and lesion studies in what they reveal about localisation of language processes. However, in neuroimaging experiments, it is unclear whether the activation in specific regions is necessary for the aspects of language processing studied. According to Price *et al.* (2003), one method of determining the necessity of these areas is to examine lesion data and investigate whether lesions to different areas are associated with different deficits.

Price *et al.* used fMRI to study two patients with acquired dyslexia. One patient had damage to all of the left temporal regions that are usually activated during

normal reading. He was able to read some highly imageable words but was unable to read pseudowords and made meaning errors when reading others (saying 'wrong' when trying to read the word 'error'). The pattern is consistent with deficits seen in deep or phonological dyslexia and suggests that he relies on semantics when translating written words into sounds. The second patient also showed left temporal lobe damage but the lesion did not affect the superior temporal lobe (but did affect the inferior and anterior region). She could read regular words and most pseudowords but had greater difficulty in reading irregularly spelled words, a pattern typical of surface dyslexia. She had difficulty in reading words that required semantic processing, suggesting that the areas damaged might be important for semantic processing.

The first patient was asked to read highly imageable words during scanning; the second was asked to read one of a triad of regular three-letter words. For example, the word BUS would appear under two identical words. The first patient showed activation in all the language areas one would expect to be activated during normal reading, except for the area damaged. The second patient activated all the typical language areas but showed a reduction in areas associated with semantic processing. On the basis of these single-case studies, Price *et al.* suggest that translating written words to sounds is mediated by the left mid-fusiform gyrus in the temporal cortex. But, when semantic processing is impaired, the posterior part of this region and left frontal areas tries to undertake the function of translating the written word into phonology via semantics.

Is there a visual word form area?

People with visual word form dyslexia are unable to recognise the form of words presented visually. Studies with healthy individuals have localised the ability to identify visual letter strings as words – visual word form – in the left fusiform gyrus. Consequently, this area has been known as the visual word form area (Warrington and Shallice, 1980) because it responds to the visual, rather than auditory, forms of words (Giraud and Price, 2001).

Studies have suggested that damage to the ventral temporal lobe and fusiform gyrus are associated with an inability to recognise words while the ability to recognise individual letters is intact (Binder and Mohr, 1992); patients with fusiform gyrus damage engage in letter by letter reading (Beversdorf, *et al.*, 1997). Neuroimaging studies show that this region is active during the perception of word and word-like forms but it is less active during the perception of strings of letters that are unfamiliar such as consonant-string non-words (Buchel *et al.*, 1998). Polk and Farah (2002) found that the left ventral visual cortex was active during the recognition of pseudowords and words presented in normal case. Words and non-words which had alternating case letters activated the area just as strongly as did the pseudowords and words presented in regular form. The findings suggest that this region may respond to abstract letter identities rather than the font, size or case of the letters. The results were supported by the findings of another fMRI study which showed that activation in the left inferotemporal area was stronger during alphabetic letter strings than to chequerboards and was greater during word perception than during the perception of consonants (Cohen *et al.*, 2002).

Cutting edge – Irony—a look inside the brain

As neuroimaging methods and machinery become more complicated, so do the topics studied by psychologists who measure neural correlates of behaviour. Psychology has come a long way since the late 1980s when PET was used to measure brain activation during simple exercises such as reading or speaking single words. An example of the new complexity is a study in which researchers compared brain activation during the comprehension of literal, metaphoric or ironic sentences (Eviatar and Just, 2006). The aim was to discover whether different brain regions or systems were involved in these different types of comprehension.

Sixteen healthy adults read three-sentence stories that ended with a literal, metaphoric or ironic sentence. When utterances were metaphoric, activation was higher in the left inferior frontal gyrus and in both sides of the inferior temporal

lobe than when utterances were ironic or literal. Irony was associated with more activation in the right superior and middle temporal gyri than were the literal statements (the metaphor condition fell in between the two).

The data suggest that different types of semantic information recruit different regions of the brain, especially the right temporal lobe. Irony is especially associated with right hemisphere activation, and this might reflect the 'processing of communicative intent or the construction of a coherent narrative.' (p. 2355). Metaphor processing has been associated with right hemisphere activity. The researchers suggest that when a task is more 'lexical', as theirs was, this would recruit the left hemisphere. If the participant had to make a judgement about the plausibility of a metaphor (a more 'holistic' task), this would recruit the right hemisphere.

Neuroimaging and language – An international perspective

Deep orthographies such as those found in English and French are a minefield of rules and linguistic irregularities. In English there are 1,120 ways of using graphemes (letters and strings of letters) to form 40 sounds (phonemes). Italian, on the other hand, has 33 graphemes representing 25 phonemes. When psychologists talk about the localisation of language, it is easy to forget that language is not a standard, unitary process but is heavily culture-bound. English, Russian and French, for example, all have different orthographical and phonological rules. Some authors have suggested that this explains the differences in word reading speed in English and Italian individuals (Italians are faster).

A recent meta-analysis of behavioural lateralisation studies (e.g. dichotic listening, visual field studies) of bilingualism has found differences between early and late bilinguals (Hull and Vaid, 2007). Early bilinguals (who acquired both languages before the age of 6), showed evidence of bilateral language representation; late bilinguals (who acquired language after the age of 6) showed greater left hemisphere dominance. In this second group, left hemisphere dominance was greater if participants were not proficient at the second language and if the second language was English.

Neuroimaging studies suggest more left hemisphere involvement in language by bilingual individuals and that similar cortical areas may be recruited during the processing of both languages. A study of French and English speakers, for example, found that performing language tasks in both languages was associated with activity in the left inferior frontal cortex (Klein *et al.*, 1995). Another study found that there was activation in different parts of Broca's area when people performed language tasks using a language learned in adulthood, but this activation was absent in those who had learned the language in childhood (Kim *et al.*, 1997). There was no difference in activation in Wernicke's area.

Some researchers have argued that such differences might reflect participants' proficiency in using language rather than the age at which the second language was acquired (Perani *et al.*, 1998). If there is an overlap in the language areas that mediate both tongues, this may be due to the similarity of the two languages spoken. Most studies, for example, have studied bilinguals who speak Indo-European languages (English, French, Italian and so on). Perani *et al.* (1996) compared brain activation in Italian–English speakers, where English was learned later in life, and Spanish–Catalan speakers, where Catalan was learned concomitantly with Spanish. Focal activity in the left hemisphere language regions was determined by expertise and not age of acquisition, a finding that has been replicated (Chee *et al.*, 1999; Dehaene *et al.*, 1997). Would the same overlap be seen if the two languages spoken were different in terms of syntax (meaning and grammar), morphol-

ogy (physical construction of the language) and phonology (the sound of the language)?

To test this hypothesis, Klein *et al.* (1999) measured cerebral blood flow in seven native speakers of Chinese (Mandarin) who had acquired English during adolescence. Mandarin uses pitch and tone to a greater extent than does English. The participants' task was to repeat words in Mandarin and English and to generate a verb in response to a noun in Mandarin and English. All words were presented auditorily and participants were asked to respond vocally. Klein *et al.* (1999) found that an area in the left frontal cortex was activated during speech production in Mandarin and English. A similar area was found to be active during French and English language processing in a previous study of Klein *et al.*'s (1995). Such findings can even extend to speakers of four or more languages.

Breilman *et al.* (2004), for example, used fMRI to measure the response of six quadrilingual participants who were asked to generate appropriate verbs to nouns; if the word 'fish' was presented, the participant might respond with 'swim'. Participants had knowledge of four to five common languages (English, German, Italian, French or Spanish) and completed the verbal task in each of their languages. As previous studies would predict, the task was associated with left-sided activation but, curiously, this activation was more pronounced in the languages in which participants were least proficient. This suggests that when people speak languages in which they are proficient the brain expends less energy – the process is more automatic and requires fewer cognitive resources for this reason. If people are not proficient in a language, there has to be a greater attempt at producing and understanding that language; this, in turn, recruits greater neural resources in order for the process to succeed.

In two PET studies, Paulesu *et al.* (2000) asked six English and six Italian university students either to read aloud words and non-words (experiment 1) or to perform a feature detection task (experiment 2) which involved paying attention to physical aspects of words presented visually rather than to the words themselves. They were not asked to read the words in experiment 2. The authors found that, across both experiments, the Italian speakers showed greater activation in those areas responsible for processing phonemes (left temporal regions) whereas the English speakers showed greater activation in other areas of the temporal cortex and frontal cortex (areas activated during word retrieval and naming). The areas activated can be seen in Figure 10.14.

This study was the first to show cultural effects on brain function related to language in healthy individuals and suggests that the neurophysiological difference may underpin the behavioural findings from word reading speed studies.

Neuroimaging and language – *Continued*

Figure 10.14 The different strategies used by English and Italian speakers are reflected in different types of brain activation.

Source: Fiez, J., Sound and meaning: How native language affects reading strategies. *Nature Neuroscience*, 2000, 3 (1), 3–5, reprinted by permission of the author and Nature Publishing Group.

The result is in keeping with studies of aphasia patients among different ethnic Chinese groups. Yu-Huan *et al.* (1990), for example, have reported that unilateral stroke leads to greater incidence of aphasia in dextrals with right-sided lesions (crossed aphasia) but only among the majority ethnic group called the Han. Crossed aphasia is rare among the minority ethnic group (the Uighur-Kazaks) and Wernicke's aphasia is generally rare in the Han. One explanation for this dissociation may lie in the way in which the languages of the groups differ: the Uighur-Kazak language is Indo-European-based and phonological in nature; the Han language,

conversely, is non-phonetic ('ideographical') where one sound can have multiple meanings.

A similar distinction is found in Japanese. Phonetic-based symbols (Kana) and logographic symbols (Kanji) are used routinely in written Japanese. Left-sided lesions are associated with impaired Kana reading in Japanese participants but preserved Kanji reading (Sasanuma, 1975). When healthy individuals are exposed to the different symbols in a typical visual field experiment, a left visual field advantage for Kanji is reported, suggesting right hemisphere involvement (Elman *et al.*, 1981).

Braille and Sign language

Gesturing preceded the sophisticated vocal communication of evolutionary modern times but, as you saw earlier, we still use gesture to communicate. More seriously, the congenitally deaf use American or British Sign Language. But to what extent does the brain have different systems for understanding the different types of communication – those that rely on our ability to hear and one that relies on our ability to decipher symbols or actions?

These questions assume an absolute definition of language. Goldberg has suggested that instead of referring to language per se, we should adopt the more general term 'descriptive systems' (Goldberg, 1989). Under this umbrella he includes various cognitive systems ('super-structures') which are normally employed to assemble the 'codes' received via the elementary 'feature detection' systems such as the visual and auditory cortices. Language,

as traditionally defined, is one such system. Others include mathematical or computational languages and musical notation. Early encounters with these systems are characteristically tentative, but gradual familiarity develops into automatic processing.

Schlesinger (1988) has observed a specific inability in some deaf children to manipulate the linguistic code, i.e. they experience difficulty in understanding questions, they are unable to formulate hypotheses, they have difficulty in conceptualising superordinate categories, and they appear to exist in a 'preconceptual, perceptual world'. In short, these people display precisely the syntactic and semantic deficits associated with isolated right hemisphere speech in those who have experienced left hemisphere damage in later life. Perhaps these deficits are caused by a shift from an initial stage of right hemisphere language to mature left hemisphere language. Neville *et al.* (1989), for example, have found that only deaf people with a perfect grasp of English

grammar displayed ‘normal’ left hemisphere specialisation, concluding that both in the deaf and in those with normal hearing, grammatical competence is necessary and sufficient for left hemisphere specialisation if it occurs early. Early competence in spoken or signed language brings about this development of the left hemisphere and bestows an advantage on the right side of perceptual space, i.e. the right visual field and the right ear, via the dominant contralateral sensory pathways. Obviously, this perceptual advantage is grossly impaired following left hemisphere damage.

Unfortunately, this early exposure to signed language which brings about the shift of language functions to the left hemisphere is not always available to deaf children. Evidence has shown that hearing children of deaf parents and deaf children of deaf parents acquire sign language in infancy as a primary language and tend to show the shift to left hemisphere mediation of language (Grossi *et al.*, 1996). Many deaf children of hearing parents, however, have only restricted exposure to sign language during the critical period of development, a privation which may lead to a total arrest or delay, depending on the degree of deficiency of the linguistic experience, of cerebral maturation. In this situation, the child would continue to display signs of predominantly right hemisphere language as predicted in the absence of a shift to left hemisphere dominance.

Individuals who are deaf but have learned sign language appear to show activation in areas of the right hemisphere while signing. Using fMRI, Neville *et al.* (1998) measured brain activation in three groups of people: monolingual speakers of English who could hear; native deaf signers of American Sign Language (ASL); and bilingual users (of English and ASL) who could hear. Participants watched a videotape recording of a deaf signer producing sentences in ASL, and read English sentences presented on a computer monitor. The study found that although all groups activated the typical left hemisphere areas (Broca’s and Wernicke’s) when they processed English sentences, the native speakers of ASL also showed corresponding increases in the right hemisphere.

Could the results be due to the reorganisation of the cortex in the deaf participants? This is unlikely because both the hearing and deaf participants who were fluent ASL signers showed the same right hemisphere activation. Paulesu and Mehler (1998) have suggested that this pattern of activity may, instead, reflect the possibility that the right hemisphere holds the grammar for sign language because it requires representations of both sides of the body.

In the first brain imaging study of the perception of British Sign Language, nine hearing and nine congenitally deaf individuals had their brain activity measured by fMRI during the perception of sentences presented in BSL (MacSweeney *et al.*, 2002). An analogous auditory task in English was completed by hearing individuals. Regardless of the modality of communication, there was activation in

Broca’s area and in Wernicke’s area – both bilaterally – during the language perception tasks. However, differences did emerge between tasks in temporal and occipital areas. The auditory task in hearing individuals was associated with increased activity in the auditory cortices. This activation was not found during BSL. BSL, on the other hand, was associated with activity in an area called V5 at the junction of the temporal and occipital cortex. V5 is the region of the visual cortex which responds to movement and so activation here is consistent with what we know of the neurology of visual perception.

When hearing and deaf people’s responses to BSL were explored, however, deaf signers showed greater activation in the left superior temporal cortex than did hearing signers. This result is intriguing because it suggests that the auditory cortex of the temporal lobe is active during an auditory language task in hearing individuals but that it may respond to visual input in congenitally deaf individuals.

This part of the temporal lobe has been described as a multi-modal language area (Buchel *et al.*, 1998) because it can be activated by language processed in different modalities. The MacSweeney study indicated that this was so for sign language. Buchel *et al.* observed a similar phenomenon when studying blind participants reading Braille. When people engaged in tactile reading, the posterior left temporal area (Area 37) was active. Buchel *et al.* proposed that this area in blind, Braille-reading participants promotes activity in other parts of the brain that allows participants access to words. However, this area was active only during written word recognition, not spoken word recognition.

Neuropsychological models of language: a summary

A recent review of neuropsychological models of language suggests that there are four competing and plausible frameworks for understanding the role of the brain in speech production and comprehension (Shalom and Poeppel, 2008).

- 1 **Price’s (2000) model.** This is a descendant of the Broca–Wernicke–Lichtheim model embodied in the aphasia sections. The Broca–Wernicke–Lichtheim model is an umbrella term used to describe the way in which the brain organises language comprehension and production, and is named after three neuropsychological figures. Price’s model suggests that acoustic analysis occurs in the superior temporal cortex, visual analysis in the posterior inferior frontal cortex and temporal cortex, and semantic representation in a network of frontal and temporal regions. She suggests that there are two routes to retrieving the sounds and sights of words – a non-semantic route (posterior superior temporal

cortex) and a semantic route (via posterior/inferior temporal cortex). Speech planning is governed by the anterior part of Broca's area and actual output is the responsibility of the motor cortex. The emphasis in Price's model is on semantic processing.

- 2 *Friederici's (2002) model.* This model makes two claims. The first is that the temporal lobe is responsible for semantic identification (such as the retrieval of memorised semantic information) and the frontal lobe constructs semantic relationships. The second is that the structure of syntax is built before semantic processing occurs and that these two interact later on in the processing stream.
- 3 *Hickok and Poeppel's (2004) model.* This utilises the distinction drawn in visual processing between the ventral and the dorsal streams (which you read about in Chapter 6 and also in the dyslexia section). They propose a visual and an auditory stream. The visual stream has two substreams, one (ventral) projecting to the temporal lobe and which is responsible for visual object recognition (the 'what') and a dorsal one projecting to the parietal and frontal lobes, which are involved in the visual representations of spatial attributes of language (the 'where'). The auditory stream is analogously conceptualised in the same way. The model, however, has little to say about the role of Broca's area.
- 4 *Indefrey and Levelt's (2004) model.* This proposes that Wernicke's area is involved in lexical analysis and in the representation of words but the posterior middle temporal lobe is involved in the phonological aspects of retrieval. It sees word production as involving five main types of representation (from appreciating the idea that a stimulus is lexical, to the breakdown of phonological output into syllables to production) each of which is processed at different times (from 175 ms after stimulus onset to 600 ms).

Although each says something slightly different about language processing and how it occurs in the brain, there are similarities between them. They suggest that:

- memorisation (learning and retrieval) occurs in the temporal lobe;
- analysis occurs in the parietal lobe;
- synthesising (creating combinations of representations) occurs in the frontal lobe;

and that:

- the inferior parietal lobe, inferior frontal lobe and the whole of the temporal lobe are involved in phonological processing;
- the middle areas are involved in syntactic processing;
- inferior areas are involved in semantic processing.

Caveats and complications

Sex differences

Early studies of language differences in men and women, utilising fairly basic methods, reported a greater right visual field (RVF) advantage when responding to words presented to the left and right visual fields in men. That is, information received by the left hemisphere (via the right visual field) is processed more quickly in men (Boles, 1984). Early neuroimaging studies showing greater left hemisphere activation in men when completing language tasks but a more symmetrical pattern of activation found in women (Pugh *et al.*, 1996), but the literature is mixed. Knaus *et al.* (2004), for example, found greater leftward asymmetry in the planum temporale in women whereas Sommer *et al.*'s (2004) meta-analysis of 14 functional imaging studies comprising 377 men and 442 women found no evidence for a sex difference in brain activity during language processing. The most recent review has found no differences in proficiency between the sexes: there is an early advantage for girls but this disappears into adulthood (Wallentin, 2009). There is no difference in brain activation or structure.

Language and the right hemisphere

The right side of the brain is not neglected in language. It takes on especial importance when the left hemisphere is damaged and may compensate for the language function lost after such damage. It is involved in the appreciation of metaphors (Bottini *et al.*, 1994) and in the processing of prosody and the affective tone of speech (Pell and Baum, 1997).

How good is the right hemisphere at processing language? And does it compensate well when the left hemisphere is damaged or removed during childhood? Evidence suggests that it does. Vanlancker-Sidtis (2004) examined the language and communication skills of an adult who had undergone a hemispherectomy at age 5. Consistent with what has previously been reported, the participant performed at normal levels on neuropsychological tests: he was able to pronounce, understand grammar, and understand word and sentence meaning at the levels we would expect of a control participant. However, slight impairments were found on three tests: the patient had difficulty in pronouncing phonemically complex words, comprehending linguistic contrasts in prosody (i.e. understanding the difference between the pronunciation of 'moving van' and 'moving van' when the stress is on 'moving' or 'van') and in deciding whether one of two line drawings matched a sentence spoken by the experimenter.

Interestingly, these impairments in prosody did not manifest themselves in the patient's everyday life. He could converse, use humour and take turns when in conversation at a level which belied his surgery. The research suggests, how-

ever, that although removal of the ‘language’ hemisphere does not impair most language functions, specific testing picks up on specific deficits. The author, however, could not rule out the possibility that the patient was naturally left-handed, and, therefore, had ‘right-hemisphere’ speech.

Handedness

Handedness refers to the degree to which individuals preferentially use one hand for certain activities (such as writing, unscrewing a jar, throwing a ball). It can also refer to the strength of hand skill. It is found in a variety of species and in most primates (from old/new world monkeys to great apes). Evidence of handedness or laterality goes back 2 million years; we seem to be the most lateralised of the primates. The right-left hand ratio in chimps is 2:1; in humans, it is 9:1 (Hopkins and Cantaloupo, 2008).

Handedness may be relevant to language because left- and right-handers may have speech localised in different hemispheres. According to a pioneering study by Rasmussen and Milner (1977), 96 per cent of right-handers and 70 per cent of left-handers in their study had left-hemisphere speech. Other, recent estimates place the figures at 95.3 per cent and 61.4 per cent, respectively (Segalowitz and Bryden, 1983). There are more men who are left-handers than women (Papadatou-Paston *et al.*, 2008), possibly due to an X-linked allele.

The implication of these figures is that a proportion of left-handers do not have left-hemisphere speech but may have right-hemisphere or bilateral speech (this is why most neuroimaging studies of language indicate that their participants were all right-handed; this reduces the likelihood of variability in brain asymmetry). Right-handers are called dextrals and right-handedness is referred to as dextrality. Left-handers are called sinistrals and left-handedness is referred to as sinistrality. You can quickly see from these terms, that left-handers have not been treated

particularly fairly by language (‘dextrous’ means skilled; ‘sinister’ means menacing and evil; the French for left is *gauche*, which can also mean clumsy). There is even a theory that left-handers die sooner than right-handers (you can find more on this controversy in Martin, 2006).

A large neuroimaging study ($N=188$) of moderate and strong right-handers found that approximately 92 per cent of the sample showed left hemisphere language, with around 7 per cent showing right hemisphere activation during a language task (Knecht *et al.*, 2000a, b). There was no difference in lateralisation between men and women and there were no differences in task performance between the sexes.

The degree of activation in the right hemisphere during a word-generation task increases with the left-handedness of the participant (Knecht *et al.*, 2000a, b). Some psychologists have argued that human language evolved from gesture and that these gestures are ‘behavioural fossils’ which accompany speech. Corballis (1999), for example, argues that the proposition that language is gestural in origin might explain the relationship between handedness and cerebral asymmetry for language (of which, more later). Corballis cites evidence showing that right-handers primarily gesture with their right hand (which may not be surprising), but that left-handers (who have primarily left-hemisphere-based speech but show a more diverse pattern of localisation with some having speech in both hemispheres, or the right hemisphere), gesture with both hands. The logical consequence of the gestural hypothesis is that it was not language which distinguished *Homo sapiens* from other primates, but our ability to vocalise our communication instead of gesturing it.

The right shift theory

One theory of handedness suggests that the distribution of differences between the skills of both hands is determined by a single gene (Annett, 1985). Individuals who possess the $rs+$ allele have their hand distribution shifted to the right; their left hemisphere becomes dominant for speech. Individuals with the $rs++$ gene show an even greater shift to the right hand (these individuals are called homozygotes) whereas those with the $rs+-$ gene show a lesser degree of hand dominance (these individuals are called heterozygotes). Those without the $rs+$ allele (who express the $rs-$ genotype) will show no overall bias in hand dominance.

This theory is called the **right shift theory** because it suggests that a single gene shifts dominance to one hand (this oversimplifies a complex theory but it is basically correct). Annett’s theory is important because it suggests a relationship between hand skill and language (and even cognitive) ability. For example, Annett’s theory predicts that heterozygotes (those with the $rs+-$ allele) will be more advantaged on some skills than others, and that homozygotes (those with the $rs++$ or the $rs--$ allele) and those with the $rs+$ gene absent, will be disadvantaged.

Ronald Reagan, George Bush Snr, Bill Clinton and, now, Barak Obama . . . the latest in a run of left-handed US Presidents’.

Source: Press Association Images/Molly Riley/AP

Annett and her colleagues (Annett and Manning, 1989; Annett, 1992) have shown that extreme left- and right-hand dominance in hand skill is associated with poorer reading ability than is intermediate hand skill. Annett (1993) also reported that children with intermediate hand skill were more likely to be selected for elite schools in the UK. Individuals with the least bias to dextrality perform better in terms of arithmetical ability and spatial skill (Annett and Manning, 1990; Annett, 1992).

However, research from other laboratories has not found unequivocal evidence for Annett's theory. For example, McManus *et al.* (1993) assessed the handedness and intellectual ability of medical students and examined differences between three degrees of right-handedness, from weak to strong preference. He found no evidence of cognitive advantage or disadvantage between weak, intermediate and strong right-handers. Similarly, Resch *et al.* (1997) administered a series of cognitive ability tests to 545 students whose hand preference they also measured. They found that although those at the left end of the handedness continuum showed the poorest spelling, non-verbal IQ and educational success, there was no significant difference between this group and an intermediate and right-handed group, whereas Annett's theory might predict that strong right-handers would also exhibit poorer language ability. Palmer and Corballis (1996) have also found no relationship between hand preference and reading ability in 11–13-year-old children. Instead, read-

ing ability was predicted by the overall level of hand skill rather than by the skill difference between hands.

Others have criticised Annett's model for other reasons. For example, Provins (1997) argues that handedness is a product of motor learning and environmental pressure. What is genetically determined, Provins argues, is not handedness but the motor capacity which could produce left- and-right hand preference, depending on the environment. Other critics such as Corballis (1997) have queried whether a single gene locus for handedness is reasonable: although the data would seem to fit a single-gene model, most genes have several loci, as we saw in Chapter 3 and will see again in Chapter 11 when we discuss the role of genetics in intelligence.

McManus (1985) has proposed that what is important is not hand skill, as Annett's model suggests, but hand preference. He proposes that a dextral allele (D) predisposes us towards right-hand preference while a chance allele (C) produces no directional bias. Individuals with the D allele (DD genotype) will develop a right-hand preference whereas those with the C allele (CC genotype) are equally likely to show left- or right-hand preference. Both models have attracted interest from researchers investigating the relationship between handedness and cognitive/language ability. Neither has fully explained this relationship but they provide an explanatory framework in which such relationships could operate.

Chapter review

Speech and comprehension

- Language can be defined as an orderly system of communication that involves the understanding or interpretation of vocal or written symbols.
- Phonemes are the basic elements of speech but research has also shown that the primary unit of analysis is not individual phonemes but groups of phonemes, perhaps syllables.
- Recognition of words in continuous speech is far superior to the ability to recognise them when they have been isolated. We use contextual information in recognising what we hear.
- Meaning is a joint function of syntax and semantics. All users of a particular language observe syntactical rules that establish the relations of the words in a sentence to one another. These rules are not learned explicitly. People can learn to apply rules of an artificial grammar without being able to say just what these rules are.
- The most important features that we use to understand syntax are word order, word class, function words, affixes, word meanings and prosody. Content words refer to objects, actions and the characteristics of objects and actions, and

thus can express meaning even in some sentences having ambiguous syntax.

- Chomsky has suggested that speech production entails the transformation of deep structure (ideas, thoughts) into surface structure (actual sentence).
- Speech comprehension requires more than an understanding of syntax and semantics: it also requires knowledge of the world. We must share some common knowledge about the world with a speaker if we are to understand what the speaker is referring to.
- Speech errors, although incorrect, follow syntactical rules; the errors lie in the content of the speech.

Reading

- Recognition of written words (reading) is a complex perceptual task which involves scanning text, perceiving and understanding symbols and sounding out these visual symbols.
- The eye-tracking device allows researchers to study people's eye movements and fixations and to learn from these

behaviours some important facts about the nature of the reading process. For example, we analyse a sentence word by word as we read it, taking longer to move on from long words or unusual ones.

- Once a word has been perceived, recognition of its pronunciation and meaning takes place. Long or unfamiliar words are sounded out, that is, they are read phonologically by a process called phonic mediation.
- Short, familiar words are recognised as wholes. In fact, only whole-word reading will enable us to know how to pronounce words such as 'cow' and 'blow', or 'bone' and 'one', which have irregular spellings.
- The dual-route model of reading suggests that we have two routes for reading: one which does not rely on grapheme–phoneme correspondence rules and another which does.

Language acquisition

- Studies using the habituation of a baby's sucking response have shown that the human auditory system is capable of discriminating among speech sounds soon after birth.
- Human vocalisation begins with crying, then develops into cooing and babbling, and finally results in patterned speech. During the two-word stage, children begin to combine words creatively, saying things they have never heard.
- Child-directed speech is very different from that directed towards adults; it is simpler, clearer and generally refers to items and events in the present environment. As young children gain more experience with the world and with the speech of adults and older children, their vocabulary grows and they learn to use adult rules of grammar.
- Children seem to pay less attention to phonetic detail of language as they grow older, presumably because the process of acquiring vocabulary and understanding of objects and situations is computationally complex.
- Although the first verbs children learn tend to have irregular past tenses, once they learn the regular past tense rule (add '-ed'), they apply this rule even to irregular verbs they previously used correctly.
- A language acquisition device contains universal grammatical rules and motivates language acquisition. Although children's verbal performance can be described by complex rules, it is possible that simpler rules – which children could reasonably be expected to learn – can also be devised.
- Deliberate reinforcement is not necessary for language learning, but a controversy exists about just how important child-directed behaviour is.
- A critical period for language learning may exist which occurs between the ages of 5 and 14 years old; learning a new language after this is more difficult.
- Bilingualism refers to competence in two or more languages that are used to communicate with significant others. The languages activate similar brain areas, regardless of age of acquisition.
- Studies of other primates suggest that apes can be taught at least some of the rudiments of language.

Brain development and language

- Damage to either hemisphere is associated with better recovery of language when it occurs in childhood than adulthood.
- Some researchers have suggested that the lateralisation of language – left hemisphere dominance for language processing – is complete by around age 6; others argue that it continues until puberty.
- The ability of the brain to reorganise itself following injury in infancy and childhood, together with its ongoing development, is referred to as its plasticity.
- Children who have experienced surgical removal of an entire hemisphere, for medical reasons, do not experience significant impairments in function later in life.
- The ability of the child's brain to recover better than that of the adult's has been attributed to the ongoing development of lateralisation as well as the capacity of the right hemisphere to undertake the role of the language functions if disrupted.

Neuropsychology of language and language disorders

- The effects of brain damage suggest that memories of the sounds of words are located in Wernicke's area and that memories of the muscular movements needed to produce them are located in Broca's area.
- Wernicke's area is necessary for speech perception and Broca's area is necessary for its production.
- Wernicke's aphasia (caused by damage that extends beyond the boundaries of Wernicke's area) is characterised by fluent but meaningless speech that is lacking in content words but rich in function words.
- Broca's aphasia (caused by damage that extends beyond the boundaries of Broca's area) is characterised by non-fluent but meaningful speech that is lacking in function words but rich in content words.
- Damage restricted to Wernicke's area does not produce aphasia but produces pure word deafness, a deficit in speech comprehension unaccompanied by other language difficulties. Damage to the temporoparietal region surrounding Wernicke's area produces isolation aphasia – loss of the ability to produce meaningful speech or to comprehend the speech of others but retention of the ability to repeat speech.
- Dyslexia refers to an inability to read. There are two general types: acquired and developmental.
- Acquired dyslexia refers to reading disorder arising from brain injury and there are various types of dyslexia that result from brain injury such as deep dyslexia, phonological dyslexia and visual word form dyslexia. Although some regions of the brain are known to be involved in these disorders, their exact neural basis is unknown.

- Developmental dyslexia refers to a disorder of reading that occurs without brain injury and manifests itself in delayed reading development. Phonological processing (the ability to break down words into sounds and appreciate how they relate to each other) is severely impaired in developmental dyslexia.
- No one knows the exact causes of developmental dyslexia. Theories include delayed or disorganised left hemisphere development, an impairment in the function of the magnocellular pathway, a dysfunctional cerebellum, an inability to scan text efficiently and neuronal degeneration in the temporal cortex.

Neuroimaging and language

- Neuroimaging studies of language production and comprehension suggest that no one brain region is involved in

language processing. Instead, there is a complex mosaic of regions which contributes to language and which interacts in a way which we only partially understand.

- Evidence suggests that Broca's area and the frontal cortex is necessary for the phonetic manipulation of speech but that the temporal cortex is necessary for the perceptual analysis of speech.
- The language areas of men and women are differently activated, with more bilateral activation in women, but the evidence is inconsistent.
- Handedness also interacts with degree of language proficiency, but in slightly irregular ways. Most right- and left-handers have left-hemisphere speech.

Intelligence and thinking

Explore the accompanying videos, simulations, and animations on MyPsychLab. This chapter includes activities on: Standard intelligence measure • Gardner's theory of intelligence • An experiment in mental rotation • The mind's organisation of conceptual knowledge • Check your understanding and prepare for your exams using the multiple choice, short answer and essay practice tests also available.

Lessons from a tragedy

St Anne's College, Oxford, 1962. I am on the sofa reading an essay to my English literature tutor. The door opens slowly and a woman with large blue-grey eyes and a helmet of rope-thick, not-so-clean hair appears with an old army blanket around her shoulders. She has a reputation for brilliance, eccentricity and lots of affairs of the heart. She is Iris Murdoch, distinguished philosopher, bestselling author, a noted teacher and student of human nature. As I expand on the character of Milton's Satan, I begin to quake under her gaze.

Cambridge University Department of Neurology, 2005. I am peering at a set of MRI scans of the grey matter belonging to the woman who once owned those fantastic blue-grey eyes . . . To a professional brain scientist's eye, the scans show that her neocortex is remarkably shrunken compared with a normal brain's. Slices of Iris Murdoch's brain, stored in a tissue bank in the same department, show protein deposits known as 'plaques' and 'tangles'.

It is probable that Iris Murdoch had Alzheimer's at 42 when, craving a cigarette, she walked into my tutor's room.

WHAT YOU SHOULD BE ABLE TO DO AFTER READING CHAPTER 11

- Describe the ways in which intelligence has been defined.
- Understand the principles of intelligence testing.
- Describe the various models of reasoning.
- Evaluate the contribution of heredity and environment to intelligence.
- Be aware of and describe individual differences in intelligence.
- Describe and understand the effects of ageing on cognitive ability.
- Define and give examples of inductive and deductive reasoning.
- Appreciate the biases in human reasoning and why they occur.

QUESTIONS TO THINK ABOUT

- What is intelligence?
- How can intelligence be measured?
- Is it useful to invoke the concept of intelligence?
- Is there more than one 'intelligence'?
- Is there a difference between 'clever' and 'intelligent'?
- What factors contribute to the development of intelligent thought?
- Is intelligence inherited?
- What are the effects of ageing on functions such as language and remembering?
- What is dementia and are there different types of dementia with different symptoms?
- What causes dementia?
- How do we reason?
- Are there different ways of reasoning?
- In which ways can our reasoning be irrational?
- Why do we sometimes violate various logical rules?
- What is creativity? Can we measure and facilitate creativity experimentally?

What is intelligence?

In general, if people do well academically or succeed at tasks that involve their heads rather than their hands, we consider them to be intelligent. If a politician makes a useful policy decision, we call it an intelligent decision. If an author writes an erudite book on an arcane subject, we might describe him as having written an intelligent appraisal. But if asked to give a precise definition of intelligence, psychologists – in common with non-scientists – come slightly unstuck. Sternberg and Detterman (1986) asked a dozen theorists to provide definitions of intelligence and received a dozen different descriptions. Even according to one of psychology's historians, writing in the 1920s, intelligence has come to represent whatever intelligence tests measure (Boring, 1923).

In general, however, psychologists agree that the term **intelligence** describes a person's ability to learn and remember information, to recognise concepts and their relations, and to apply the information to their own behaviour in an adaptive way (Neisser *et al.*, 1996a). Where they diverge is in describing the nature of intelligence and how it works. For example, some psychologists argue that there is a general factor called intelligence but no different subtypes of intelligence; others argue intelligence is a series of abilities; yet others adopt a combinative approach arguing that there is general intelligence but there are also specific abilities. The number of these abilities depends on the theory one examines.

Theories of intelligence

Most theories of intelligence are based on the analysis of performance on tests which seek to measure specific abilities such as non-verbal and verbal intellectual competence. Much of the debate in the psychology of intelligence has focused on whether there is a single intelligence or there are multiple intelligences. Is our intellectual ability a unitary factor or is it made up of a number of different abilities? Are these abilities, if they do exist, completely separate from each other or are they related?

Intelligence tests yield a single number, usually called an IQ score, although this does not itself mean that intelligence is a single, general characteristic. Some investigators have suggested that certain intellectual abilities are completely independent of one another. For example, a person can be excellent at spatial reasoning but poor at solving verbal analogies. But psychologists disagree over whether specific abilities are totally independent or whether one general factor influences all

abilities. The next sections consider some influential theories of intelligence.

Spearman's two-factor theory

Charles Spearman (1927) proposed that an individual's performance on a test of intellectual ability is determined by two factors: the **g factor**, which is a general factor, and the **s factor**, which is a factor specific to a particular test. Spearman did not call his **g** factor 'intelligence'; he considered the term too vague. He defined the **g** factor as comprising three 'qualitative principles of cognition': apprehension of experience, eduction of relations and eduction of correlates. A common task on tests of intellectual abilities – solving analogies – requires all three principles (Sternberg, 1985). For example, consider the following analogy:

LAWYER:CLIENT:DOCTOR: _____

This problem should be read as 'LAWYER is to CLIENT as DOCTOR is to _____'.

Apprehension of experience refers to people's ability to perceive and understand what they experience; thus, reading and understanding each of the words in the analogy requires apprehension of experience. Eduction (not 'education') is the process of drawing or bringing out, that is, making sense of, given facts. In this case, eduction of relations refers to the ability to perceive the relation between lawyer and client; namely, that the lawyer works for and is paid by the client. Eduction of correlates refers to the ability to apply a rule inferred from one case to a similar case. Thus, the person whom a doctor works for and is ultimately paid by is obviously a patient. Because analogy problems require all three of Spearman's principles of cognition, he advocated their use in intelligence testing.

Empirical evidence for Spearman's two-factor theory comes from correlations among various tests of particular intellectual abilities. The governing logic is as follows. If we administer ten different tests of intellectual abilities to a group of people and each test measures a separate, independent ability, the scores these people make on any one test will be unrelated to their scores on any other; the correlations among the tests will be approximately zero. However, if the tests measure abilities that are simply different manifestations of a single trait, the scores will be related; the intercorrelations will be close to 1.

In fact, the intercorrelations among a group of tests of intellectual abilities are neither zero nor 1. Instead, most of these tests are at least moderately correlated, so that a person who scores well on a vocabulary test also tends to score better than average on other tests, such as arith-

metic or spatial reasoning. The correlations among various tests of intellectual ability usually range from 0.3 to 0.7, which means that they have between 9 per cent and 49 per cent of their variability in common (Ozer, 1985).

Spearman concluded that a general factor (g) accounted for the moderate correlations among different tests of ability. Thus, a person's score on a particular test depends on two things: the person's specific ability (s) on the particular test (such as spatial reasoning) and their level of the g factor, or general reasoning ability.

Evidence from factor analysis

Factor analysis is a statistical procedure developed by Spearman and Pearson that permits investigators to identify common factors among groups of tests. It is a form of data reduction in the sense that a large number of data can be reduced and explained by reference to two or three factors (Kline, 1993). In the case of intelligence tests, these common factors would be particular abilities that affect people's performance on more than one test. If a group of people take several different tests of intellectual ability and each person's scores on several of these tests correlate well with one another, the tests may (at least partly) be measuring the same factor. A factor analysis determines which sets of tests form groups. For example, Birren and Morrison (1961) administered the Wechsler Adult Intelligence Scale (WAIS, an intelligence test described in the next section) to 933 people. This test consists of 11 different subtests. Birren and Morrison calculated the correlations between subtests and then subjected these correlations to a factor analysis. Table 11.1 shows the results of the analysis.

Table 11.1 Three factors derived by factor analysis of scores on WAIS subtests

Subtest	Factors		
	A	B	C
Information	0.70	0.18	0.25
Comprehension	0.63	0.12	0.24
Arithmetic	0.38	0.35	0.28
Similarities	0.57	0.12	0.27
Digit span	0.16	0.84	0.13
Vocabulary	0.84	0.16	0.18
Digit symbol	0.24	0.22	0.29
Picture completion	0.41	0.15	0.53
Block design	0.20	0.14	0.73
Picture arrangement	0.35	0.18	0.41
Object assembly	0.16	0.06	0.59

Source: Adapted from Morrison, D.F. (1967) *Multivariate Statistical Methods*, New York: McGraw-Hill.

The factor analysis revealed three factors, labelled A, B and C. The numbers in the three columns in the table are called factor loadings; they are somewhat like correlation coefficients in that they express the degree to which a particular test is related to a particular factor. For the various subtests on factor A, the largest factor loading is for vocabulary, followed by information, comprehension and similarities. In the middle range are picture completion, arithmetic, picture arrangement and digit symbol. Digit span, object assembly and block design are the smallest. Verbal subtests make the most important contribution to factor A, so we might be tempted to call this factor verbal ability. But almost all tests make at least a moderate contribution, so perhaps this factor may reflect general intelligence. Digit span has a heavy loading on factor B (0.84), and arithmetic and digit symbol have moderate loadings. Factor B, therefore, is related to maintaining information in short-term memory and manipulating numbers. Factor C appears to be determined mainly by block design, object assembly, picture completion and picture arrangement, and might, therefore, represent the factor, spatial ability.

Although factor analysis can give hints about the nature of intelligence, it cannot provide definitive answers. The names given to factors are determined by the investigator and, although the names may appear to be quite appropriate, the process inevitably has a subjective element to it. There is also the danger of reification when conducting factor analysis. That is, the factors may wrongly be seen as concrete entities and not simply as labels used to describe a set of data as concisely and accurately as possible. Furthermore, factor analysis can never be more meaningful than the individual tests on which it is performed. To identify the relevant factors in human intelligence, one must include an extensive variety of tests in the factor analysis. The WAIS, for example, does not contain a test of musical ability. If it did, a factor analysis would undoubtedly yield an additional factor. Whether musical ability is a component of intelligence depends on how we decide to define intelligence; this question cannot be answered by a factor analysis.

Other psychologists employed factor analysis to determine the nature of intelligence. Louis Thurstone's study (1938) of students' performance on a battery of 56 tests extracted seven factors, which he labelled verbal comprehension, verbal fluency, number, spatial visualisation, memory, reasoning and perceptual speed. At first, Thurstone thought that his results contradicted Spearman's hypothesised g factor. However, Eysenck suggested a few years later that a second factor analysis could be performed on Thurstone's factors. If the analysis found one common factor, then Spearman's g factor would receive support. In other words, if Thurstone's seven factors themselves had a second-order factor in common, this factor might be conceived of as general intelligence.

Cattell performed a second-order factor analysis and found not one but two major factors. Horn and Cattell (1966) called these factors fluid intelligence (g_f) and crystallised intelligence (g_c). Fluid intelligence is reflected by performance on relatively culture-free tasks, such as those that measure the ability to see relations among objects or the ability to see patterns in a repeating series of items. Crystallised intelligence is defined by tasks that require people to have already acquired information, such as vocabulary and semantic information, and is therefore more culture-bound. Cattell regards fluid intelligence as closely related to a person's native capacity for intellectual performance; in other words, it represents a potential ability to learn and solve problems. In contrast, he regards crystallised intelligence as what a person has accomplished through the use of their fluid intelligence – what they have learned. Horn (1978) disagrees with Cattell by citing evidence suggesting that both factors are learned but are also based on heredity. He says that g_f is based on casual learning and g_c is based on cultural, school-type learning.

Figure 11.1 shows examples from five of the subtests that load heavily on fluid intelligence.

Tests that load heavily on the crystallised intelligence factor include word analogies and tests of vocabulary, general information and use of language. According to Cattell, g_c depends on g_f . Fluid intelligence supplies the native ability, whereas experience with language and

exposure to books, school and other learning opportunities develop crystallised intelligence. If two people have the same experiences, the one with the greater fluid intelligence will develop the greater crystallised intelligence. However, a person with a high fluid intelligence exposed to an intellectually impoverished environment will develop a poor or mediocre crystallised intelligence. Table 11.2 presents a summary of tests that load on g_f and g_c .

No two investigators agree about the nature of intelligence. However, most believe that a small number of common factors account for at least part of a person's performance on intellectual tasks.

Sternberg's triarchic theory of intelligence

Sternberg (1985) has devised a theory of intelligence that derives from the information-processing approach used by many cognitive psychologists. Sternberg's theory has three parts; he calls it a **triarchic theory** (meaning 'ruled by three'). The three parts of the theory deal with three aspects of intelligence: componential intelligence, experiential intelligence and contextual intelligence. Taken together, these three components go beyond the abilities measured by most common tests of intelligence. They include practical aspects of behaviour that enable a person to adapt successfully to their environment. Table 11.3 provides a summary of the key concepts of Sternberg's triarchic theory.

Table 11.2 Summary of tests with large factor loadings on g_f or g_c

Test	Approximate factor loadings	
	g_f	g_c
<i>Figural relations:</i> Deduction of a relation when this is shown among common figures	0.57	0.01
<i>Memory span:</i> Reproduction of several numbers or letters presented briefly	0.50	0.00
<i>Induction:</i> Deduction of a correlate from relations shown in a series of letters, numbers, or figures, as in a letter series test	0.41	0.06
<i>General reasoning:</i> Solving problems of area, rate, finance, and the like, as in an arithmetic reasoning test	0.31	0.34
<i>Semantic relations:</i> Deduction of a relation when this is shown among words, as in an analogies test	0.37	0.43
<i>Formal reasoning:</i> Arriving at a conclusion in accordance with a formal reasoning process, as in a syllogistic reasoning test	0.31	0.41
<i>Number facility:</i> Quick and accurate use of arithmetical operations such as addition, subtraction and multiplication	0.21	0.29
<i>Experimental evaluation:</i> Solving problems involving protocol and requiring diplomacy, as in a social relations test	0.08	0.43
<i>Verbal comprehension:</i> Advanced understanding of language, as measured in a vocabulary reading test	0.08	0.68

Table 11.3 An outline of Sternberg's triarchic theory of intelligence

Componential intelligence

Metacomponents (e.g. planning)
Performance components (e.g. lexical access)
Knowledge acquisition components (e.g. ability to acquire vocabulary words)

Experimental intelligence

Novel tasks
Automated tasks

Contextual intelligence

Adaptation (adapting to the environment)
Selection (finding a suitable environment)
Shaping (changing the environment)

Componential intelligence consists of the mental mechanisms people use to plan and execute tasks. The components revealed by the factor analyses of verbal ability and deductive reasoning are facets of componential intelligence. Sternberg suggests that the components of intelligence serve three functions. Metacomponents (transcending components) are the processes by which people decide the nature of an intellectual problem, select a strategy for solving it, and allocate their resources. For example, good readers vary the amount of time they spend on a passage according to how much information they need to extract from it (Wagner and Sternberg, 1985; cited in Sternberg, 1985). This decision is controlled by a meta-component of intelligence. Performance components are the processes actually used to perform the task, for example word recognition and working memory. Knowledge acquisition components are those the person uses to gain new knowledge by sifting out relevant information and integrating it with what they already know.

The second part of Sternberg's theory deals with experiential intelligence. **Experiential intelligence** is the ability to deal effectively with novel situations and to solve automatically problems that have been previously encountered. According to Sternberg's theory, a person with good experiential intelligence is able to deal more effectively with novel situations than is a person with poor experiential intelligence. The person is better able to analyse the situation and to bring mental resources to bear on the problem, even if they have never encountered one like it before. After encountering a particular type of problem several times, the person with good experiential intelligence is also able to 'automate' the procedure so that similar problems can be solved without much thought, freeing mental resources for other work. A person who has to reason out the solution to a problem every time it occurs will be left behind by people who can give the answer quickly and automatically. Sternberg suggests that this distinction is closely related to the distinction between fluid and crystallised intelligence (Horn and Cattell, 1966). According to Sternberg, tasks that use fluid intelligence are those that demand novel approaches, whereas tasks that use crystallised intelligence are those that demand mental processes that have become automatic.

The third part of Sternberg's theory deals with **contextual intelligence** – intelligence reflecting the behaviours that were subject to natural selection in our evolutionary history. Contextual intelligence takes three forms: adaptation, selection and shaping. The first form, adaptation, consists of fitting oneself into one's environment by developing useful skills and behaviours. In different cultures, adaptation will take different forms. For example, knowing how to distinguish between poisonous and edible plants is an important skill for a member of a hunter-gatherer tribe. Knowing how to present oneself in a job interview is an important skill for a member of an industrialised society. The second form of contextual intelligence, selection, refers to the ability to find one's own niche in the environment. That is, individuals will decide on careers or activities which they both enjoy doing and do well.

The third form of contextual intelligence is shaping. Adapting to the environment or selecting a new one may not always be possible or profitable. In such cases, intelligent behaviour consists of shaping the environment itself. For example, a person whose talents are not appreciated by their employer may decide to start their own business.

Gardner's multiple intelligences theory

Gardner's theory of intelligence is based on a neuropsychological analysis of human abilities (Gardner, 1983). It argues that intelligence falls into seven categories: linguistic intelligence,

musical intelligence, logical/mathematical intelligence, spatial intelligence, bodily/kinesthetic intelligence, and two types of personal intelligence. Bodily/kinesthetic intelligence includes the types of skill that athletes, typists, dancers or mime artists exhibit. Personal intelligence includes awareness of one's own feelings (intrapersonal intelligence) and the ability to notice individual differences in other people and to respond appropriately to them – in other words, to be socially aware (interpersonal intelligence).

Three of Gardner's types of intelligence – verbal intelligence, logical/mathematical intelligence and spatial intelligence – are not unusual, having been identified previously by many other researchers. The other four are rather unusual. According to Gardner, all seven abilities are well represented in the brain, in that specific brain damage can impair some of them but leave others relatively intact. For example, people with damage to the left parietal lobe can show apraxia, an inability to perform sequences of voluntary skilled movements. In contrast, people with damage to the right parietal lobe develop the spatial neglect described in Chapter 6. Individuals with frontal lobe damage, as you saw in Chapter 4 and will see later in this chapter and in Chapter 13, have difficulty evaluating the significance of social situations and making decisions about social matters (the frontal lobes used to be regarded as the region of the brain responsible for intelligence). These examples illustrate bodily/kinesthetic intelligence and both intrapersonal and interpersonal intelligence.

Gardner's theory has the advantage of being based on neuropsychological reality. It also accommodates the views of intelligence held by some non-Western cultures. For example, he would recognise the ability of a member of the Puluwat culture of the Caroline Islands to navigate across the sea by the stars as an example of intelligence.

Emotional intelligence

A different type of intelligence, one not based on any particular cognitive ability, was proposed by Goleman (1995, 1998). This type of intelligence refers to the social and emotional components of interactions with others: the more socially sensitive and emotionally sensitive you were to the needs and behaviours of others, the more successful your interaction would be. Goleman referred to this as **emotional intelligence** but there is some controversy over whether this is a separate, valid and reliable type of intelligence (Sjoberg, 2001).

There is certainly evidence that social skill is a key factor in understanding others' thoughts and feelings and this is one of the factors that Goleman cites as being important to success in business. A recent study suggests

that an interaction between intelligence and social skill may underlie some differences in job performance (Ferris *et al.*, 2001). Having low ability and social skill will do nothing for your career, but what if you had low ability and great social skill or great ability and low social skill?

The study asked 106 software engineers and programmers to complete a general ability scale which measured vocabulary, arithmetic, reasoning and spatial ability and also to rate their social skills, job performance and job dedication. These employees, their supervisors and their

personnel managers were interviewed. A measure of personality was taken and salary level and sex were noted.

Neither high general mental ability nor high social skill was individually associated with high levels of performance or high salaries. Each factor seemed to influence the other. Social skill was highly correlated with performance and salary when workers were very mentally able; mental ability was highly correlated with job success when social skill was high. Having good social skills but low mental ability, however, resulted in lower salary levels. 'Perhaps individuals low in GMA [General Mental Ability]', the authors suggest, 'may attempt to overcompensate for their lack of intelligence by focusing a disproportionate amount of time and effort on social aspects of the job.'

They conclude that while the results suggest that social skill and intelligence interact and predict job performance and salary independently of personality, the next logical step would be to explore these relations by asking people – other than the employees themselves – to rate the employees' social skills.

It has been pointed out that Goleman's concept of emotional intelligence involves both social and emotional intelligence and that these may be separable. Measures of emotional intelligence seem to predict job success better

than does interview performance (itself not a difficult achievement given the low correlation between interview performance and job performance), but empirical support for the concept is mixed (Mayer and Cobb, 2000).

Because the two factors involved in emotional intelligence may predict different behaviours, some researchers have developed specific scales to measure the emotional component only. Mayer *et al.* (1999), for example, have constructed such a scale and have defined emotional intelligence as 'the ability to perceive and express emotion, assimilate emotion in thought, understand and reason with emotion and regulate emotion in the self and others'. This scale seems to correlate well with questionnaires measuring empathy – a key feature of emotional intelligence – but its reliability and validity await more extensive testing. Some studies show that brief emotional intelligence measures predict commitment to a career but other authors have argued that the concept may not be as separate as some psychologists state. Sjöberg (2001), for example, argues that emotional intelligence may not be a measure of anything separate but is a factor that is 'secondary' to other concepts (which may be personality or cognitive ability).

Estimating intelligence – An international perspective

Although the proposition that men and women differ in intelligence is controversial, there is a great deal of evidence to suggest that males estimate their own IQ more highly than do females their own (Beloff, 1992; Byrd and Stacey, 1993). These beliefs seem to be unrelated to actual cognitive performance. The performance of males is significantly lower than their IQ estimate whereas that of females is also lower but not significantly so (Reilly and Mulhern, 1995).

A consistent finding is that participants of both sexes rate their fathers' IQ as being higher than their mothers' (Beloff, 1992; Furnham and Rawles, 1995). Not only are fathers rated as more intelligent than mothers, but boys are also rated as having a greater IQ than girls by their parents (Furnham and Gasson, 1998). These findings appear to generalise across the cultures studied to date.

To determine whether such sex differences in estimates are global (general IQ) or specific (related to specific abilities), Furnham *et al.* (1999a) asked 400 participants from the UK, Hawaii and Singapore to estimate their own parents' and siblings' IQ score for each of Gardner's multiple intelligences, using the test described in Figure 11.2. There were no sex differences in the estimated intelligence of siblings and parents but men estimated their own mathematical, spatial and bodily/kinetic intelligence as well as their overall intelligence to be higher than did women.

A similar study asked 140 Belgian, 227 British and 177 Slovakian students to estimate their multiple intelligence as well as that of their parents and siblings (Furnham *et al.*, 1999b). Men rated their own general intelligence, but not those of their parents or siblings, more highly than did women. When the researchers looked at specific types of intelligence, men rated their numerical (but not verbal or cultural) IQ higher than did women.

Few national differences were reported but those that were appeared to be attributable to the Slovakian women. They rated their own and their fathers' IQ more highly than did Slovakian men. They also rated their verbal intelligence more highly than numerical and cultural IQ (Slovakian men rated their cultural and numerical IQ to be similar but higher than their cultural IQ). This is the first study of its kind to find that women rate their own intelligence more highly.

A study comparing British and Turkish respondents found that men rated their father's intelligence as being higher than their mother's (based on Gardner and Sternberg's models) and men rated their overall, verbal, logical, spatial, creative and practical intelligence higher than did women (Furnham *et al.*, 2009). Cultural differences were more pronounced than sex differences, however, with Turks rating their musical, body-kinesthetic, interpersonal, intrapersonal, naturalistic, creative, emotional and practical intelligence higher than did the Brits.

Estimating intelligence – Continued

How intelligent are you?

Intelligence tests attempt to measure intelligence. The average or mean score on these tests is 100. Most of the population (about $\frac{2}{3}$ people) score between 85 and 115. Very bright people score around 130 and scores have been known to go over 145.

The following graph shows the typical distribution of scores.

Figure 11.2 Example of a test used to examine individuals' perception of their own and their relatives' intelligence.

Using the same intelligence measures, von Stumm *et al* (2009) compared estimates of men and women from 12 nations – Australia, Austria, Brazil, France, Iran, Israel, Malaysia, South Africa, Spain, Turkey, UK and USA. All nations overestimated their intelligence compared with actual scores

obtained for each of the nations and men overestimated their own intelligence pretty universally (see Figure 11.3).

Finally, in an intriguing study, Furnham *et al.* (2002) asked British and American students to estimate their own overall intelligence and different types of intelligence, but also that of

Figure 11.3 Self-estimates of intelligence and national IQ scores across nations

Source: von Stumm, S., Chamorro-Premuzic, T. & Furnham, A. (2009). Decomposing self-estimates of intelligence: Structure and sex differences across 12 nations. *British Journal of Psychology*, 100, 429–42.

Estimating intelligence – Continued

well-known figures such as Tony Blair, Bill Gates, Prince Charles and Bill Clinton. Men, as expected, estimated their verbal, logical and spatial IQ more highly than did women and women rated their male partners as having lower verbal IQ but higher spatial IQ than themselves. Of the famous figures, participants rated Bill Clinton and Prince Charles as less intelligent than themselves but Tony Blair and Bill Gates to be more intelligent.

These sex differences in the perception of relatives' intelligence perhaps underlie the sex differences seen in intellectual ability. There has been some controversy in psychology over whether men and women (and boys and girls) are better than each other on tests of cognitive ability. In fact, there do seem to be consistent sex differences in the performance of specific types of test (see below).

Are there consistent sex differences in cognitive ability?

Take a look at Figure 11.4. At the moment, the glass is empty but imagine that it is half full. Using a pencil, draw a line across the glass where you think the top of the water should be. Do that now before you read on.

If you were a man, you probably drew the line horizontally across the glass; if you were a woman, you probably drew the line parallel to the direction in which the water glass is tipped. The correct line would be the horizontal one.

This phenomenon illustrates one of the most consistent sex differences in cognitive ability. The task is Piaget's Water Level Test, and men tend to be better at it than women (Halpern, 1992; Rilea, 2008). Other tests showing sex differences are summarised in Table 11.4.

Figure 11.4 The Water Level Test. The glass is meant to be half full of water. The participant's task is to indicate where the top of the water should be.

Source: Kalichman, S.C., The effects of sex and context on paper and pencil spatial task performance, *Journal of General Psychology*, 1989, 116, 133–9. Reprinted with permission of the Helen Dwight Reid Educational Foundation. Published by Heldref Publications, 1319 Eighteenth St., NW, Washington, DC, 20036–1802, www.heldref.org, copyright © 1989.

Why should males tend to be better at this task? One explanation for the Water Level Test result is that men and boys are intrinsically superior at tests of spatial ability than are women and girls (we will come on to reasons why this should be a little later). Spatial ability refers to 'skills in representing, transforming, generating and recalling symbolic, nonlinguistic information' (Linn and Petersen, 1985). The test of spatial ability which shows the most consistent and reliable sex difference is mental rotation (Masters and Sanders, 1993). In this task, individuals are presented with three sets of cubes and have to match the target set with one of the other two. The task is not straightforward because the cubes have to be mentally rotated before a match can be made, as you saw in Chapter 8 (Figure 8.6).

The three-dimensional nature of the stimuli appears to be important. In one experiment the performance of 3- and 6-year-old boys and girls were compared on a two-dimensional task (a jigsaw puzzle) or a three-dimensional task (constructing Lego). It was found that although there was no difference between boys and girls on the two-dimensional task, boys performed better than girls at the three-dimensional task (McGuinness and Morley, 1991).

Is this sex difference consistent across all spatial ability tests? The answer is no. In other types of visuospatial test, women tend to outperform men. For example, women have been found to be consistently superior to men at tests involving visual recognition. It has been suggested that this may be so because of women's superior linguistic ability. Women, for example, are better than men at tests involving verbal fluency, such as naming as many objects as possible beginning with a specific letter (Halpern, 1997), and boys tend to be diagnosed with reading and speech disorders more commonly than are girls (Flynn and Rahbar, 1994).

The stimuli used can also be important. Rilea (2008) found that men were better at the Water Level Task but showed no advantage on mental rotation or paper folding. However, men were better at rotating polygons than stick figures (and they showed a right hemisphere advantage for the task; there was no right hemisphere advantage shown by women for either stimulus type).

Table 11.4 Cognitive tests and tasks that usually show sex differences

Type of test/task	Example
<i>Tasks and tests on which women obtain higher average scores</i>	
Tasks that require rapid access to and use of phonological, semantic and other information in long-term memory	Verbal fluency – phonological retrieval Synonym generation – meaning retrieval Associative memory Spellings and anagrams Mathematical calculations Memory for spatial locations
Knowledge areas	Foreign languages
Production and comprehension of complex prose	Reading comprehension Writing
Fine motor skills	Mirror tracing – novel, complex figures Pegboard tasks Matching and coding tasks
Perceptual speed	Multiple speeded tasks
Speech articulation	Tongue-twisters
<i>Tasks and test on which men obtain higher average scores</i>	
Tasks that require transformations in visual working memory	Mental rotation Piaget Water Level Test
Tasks that involve moving objects	Dynamic spatiotemporal tasks
Motor tasks that involve aiming	Accuracy in throwing balls or darts
Knowledge areas	General knowledge Maths and science knowledge
Test of fluid reasoning (especially in maths and science domain)	Promotional reasoning tasks Mechanical reasoning Verbal analogies Scientific reasoning

Contreras *et al.* (2007) suggest a stimulus-specific complicating factor: the tests of spatial ability used are static, not dynamic. Therefore, they set up a study in which men and women performed a dynamic test of spatial ability – guiding two dots towards a destination in the shortest time. They found that even when performance factors were taken into account, men outperformed women (i.e. differences in performance style did not explain the sex difference). On average, men took longer to decide on the first move of the dots, then guided the dots more quickly. These data suggest that ‘spatial ability’ is not an all-or-nothing concept but multidimensional. Different types of spatial ability test and different types of spatial stimuli produce sex differences; others do not.

Can sex differences be eliminated? There are some interesting answers. An experiment by McLoy and Koonce (1988, cited in Halpern, 1992) trained men and

women on a standard simulated flight task and found that men were better at learning this task than were women. They also found that given sufficient training, women performed at about the same level as men; they simply needed more training to achieve this level of competence. Recently, a study manipulated participants’ belief in performance and observed the consequences for behaviour. Men and women (in same sex groups) were asked to perform a mental rotation test but different groups were given different instructions (Moe, 2009). One group was told: ‘Men are better than women at this task’; another: ‘women are better than men’; and a third were given instructions with no reference to sex. Each group was also told that the test was either quite easy or very difficult. Women performed better when given the sex-positive instruction but task difficulty priming had no discernible effect. Men performed better when given sex-

positive instructions, when told the test was easy and, if given control instructions, when the task was described as difficult. The sex-negative instructions had no effect on performance of either sex.

Sex differences in visuospatial ability might also be due to different processing styles. Pena *et al.* (2008) asked men and women to complete a visuospatial exercise in which they had to guide two differently coloured dots on a monitor to a colour-appropriate target area. Participants did this by using a cursor to alter the direction of an arrow button which guided the dots. Two interesting findings emerged. Men, as expected, performed better than women but the type of strategy employed during the task affected success on the task. They also found that when one type of strategy was adopted, sex differences were reduced; when the other was employed, sex differences remained strong.

The two strategy styles were described as 'segmentary' or 'planned and feedback-dependent holistic'. Segmentary strategy involved focusing on a particular portion of the task, to the exclusion of other aspects of the task or the screen (hence, 'segment'). Followers of this strategy would change the course of the dot frequently. Holistic strategists did not make as many course changes. Some of these planned their actions before the task ('planned') and some acted on feedback from the screen ('feedback-dependent'). Men used the holistic strategy more often than did women; women were more likely to adopt the segmentary strategy. When men used planned holistic and segmentary strategies, they performed better than women using the same strategies. However, when both sexes employed the planned strategy, this sex difference narrowed.

Why should men outperform women on spatial tasks? Theories of sex differences in cognitive ability fall into four general categories: evolutionary, psychosocial, biological and cognitive.

Evolutionary theories

The evolutionary point of view suggests that spatial superiority in men is a throwback to the evolution of men and women as hunters and gatherers (Eals and Silverman, 1994). This theory suggests that because men originally roamed and hunted (activities which rely on the manipulation of visuospatial features in the environment), and because women stayed 'at home' and gathered, it is not surprising that men are spatially superior. The greater visual recognition performance seen in women is meant to reflect women's evolutionary role as foragers (Tooby and DeVore, 1987).

According to evolutionary psychologists, one reason why men are better at spatial cognition than women is that men were the hunters who ranged far and wide for

their prey and would, therefore, need to develop a well-tuned set of navigational skills. Women, the child-bearers and rearers, stayed at home and foraged. Some argue that women's ranging was limited to picking plants; men would hunt for game.

According to Ecuyer-Dab and Robert (2004), however, this dichotomy suggests that rather than showing a superior spatial advantage by men over women it shows how context can affect the way in which each sex expresses its specific spatial skills: spatial cognition in men would be used to navigate the environment for a mate and food whereas women's spatial cognition developed to deal with the immediate environment because they were more concerned with the survival of their offspring in the home. They, therefore, had no need to develop the navigational spatial skills that men did. In short, men developed and evolved large-scale navigation mechanisms and women evolved small-scale ones.

Ecuyer-Dab and Robert cite evidence from recent studies to support the hypothesis. Women, for example, were more likely than men to use landmarks when giving map directions. Men were more likely to provide more detail on direction and distance – although women are capable of doing this, they simply do not use these references as their primary source of information.

One objection to the theory that males are intrinsically superior to females on tests of mental rotation is that the results may be attributable to other causes. For example, because the task is timed, it has been argued that this is detrimental to women, who are more cautious when making decisions about rotation (Goldstein *et al.*, 1990). To test this hypothesis, Masters (1998) allowed male and female undergraduates either a short or unlimited time to perform a mental rotation task. She also used three different scoring procedures because previous studies had been criticised for basing their findings on using correct answers only (without looking at the number of incorrect responses too). Masters found that regardless of scoring procedure or time limit, men performed better than women. (Interestingly, however, some sex differences, such as female self-reported confusion over left and right, may be attributable to women rating themselves more critically than do men (Jordan *et al.*, 2006).)

However, as you saw in Chapter 3, evolutionary theories such as these are so broad as to be untestable. As Halpern (1997) also notes, you can explain almost any finding by indicating how it would be advantageous to hunters and gatherers.

Psychosocial theories

Psychosocial theories suggest that sex differences are learned through experience or imitation. Children, it is

argued, fulfil sex-role stereotypes: boys are encouraged to play with toys which involve visuospatial manipulation; girls are not (we will come back to this in Chapter 12). It has also been suggested that boys and girls receive different models, rewards and punishment. One researcher has suggested that peer interaction is more likely to lead to stereotypical sex-role behaviour than is parent-child interaction, although this idea is controversial (Harris, 1995).

Another study, investigating the effect on spatial performance of the degree to which men and women internalise their sexual identity or behave in a stereotypically male or female way, on spatial test performance found a weak relationship between spatial ability and sex roles although the actual sex difference remained (Saucier *et al.*, 2002).

Halpern (1992) cites fairly strong evidence against a psychosocial explanation for sex differences in cognitive ability. She noted that among individuals with high reasoning ability, right-handed men outperformed left-handed men on tests of spatial ability but were poorer than left-handed men at verbal tasks. Conversely, left-handed females were better at spatial tasks than were right-handers but the opposite pattern applied to verbal tasks. Any theory of psychosocial influence would have difficulty in explaining these findings: why should right- and left-handed boys and girls be socialised differently? It would also have difficulty in explaining why boys are more likely than girls to suffer from stuttering and reading disorders.

Biological theories

Biological theories suggest that sex differences in cognitive ability may be due to biological factors such as hormonal regulation and brain organisation. There is evidence that anatomical differences exist between the brains of boys and girls and between men and women (Martin, 2006). Witelson *et al.* (1995) reported that the number of neurons found in a structure thought to be important for language – the planum temporale (described in Chapter 10) – was 11 per cent greater in women than in men. A part of the tract of fibres that connects the two cerebral hemispheres (the corpus callosum) has also been found to be larger in women (Elster *et al.*, 1990; Holloway *et al.*, 1993). Some researchers have suggested that whereas men rely predominantly on one or other hemisphere to perform a specific function, women use both (Jancke and Steinmetz, 1994). The processing of phonemes – the constituent sounds of words – is associated with greater activation in both hemispheres in women than men (Shaywitz *et al.*, 1995).

Apart from neuroanatomical differences, there may also be differences in the amount of, or sensitivity to, hormones (Collaer and Hines, 1995). Cognitive ability, for example, appears to fluctuate across the menstrual cycle (Hampson, 1990), and the amount of testosterone appears to correlate with spatial skill (Moffat and Hampson, 1996). In two interesting experiments, groups of individuals were given certain hormones for reasons other than enhancing cognitive ability. In one study, normal ageing men given testosterone to enhance their sex drive showed increased visuospatial performance (Janowsky *et al.*, 1994). In another, transsexuals given testosterone as part of their preoperative sex change programme were found to show increased visuospatial ability and decreased verbal ability over a period of three months (Van Goozen *et al.*, 1995).

Some studies have also found no relationship between hormone level and spatial ability (Liben *et al.*, 2002). This may not mean that steroids are not involved. ‘It may be’, as the authors suggest, ‘that such effects do occur but only under some as yet unidentified additional setting conditions (be they biological or experiential).’

An fMRI study has found that activation in the brain during mental rotation varies depending on a woman’s point in her menstrual cycle and with hormone secretion in both sexes (Schoning *et al.*, 2007). Twelve men and twelve women completed a three-dimensional mental rotation task and had their levels of testosterone and/or estradiol measured. Women were tested during the early follicular and midluteal phase of their cycle. Men and women showed activation in frontal and parietal regions. In men, greater testosterone was associated with greater left parietal lobe activation. In women, there was also a correlation between testosterone levels and activation in the follicular phase. Women’s estradiol levels in both phases were associated with increased activation in frontal and parietal areas.

The study suggests that important factors, such as hormone level and point at the menstrual cycle, can significantly influence brain activation in neuroimaging studies of cognition.

Although appealing and persuasive in explaining the mechanism of some cognitive abilities, biological theories cannot account for some of the findings in sex differences research. If, for example, spatial ability is ‘hard-wired’ in the brain, how can improvements in spatial ability be brought about by training? Is the capacity there but the strategy for using this capacity absent?

Cognitive theories

Empathising and systemising are two ways of processing information, described by Simon Baron-Cohen (2003), in which people work at identifying someone’s thoughts and

feelings (perspective-taking, altruism, cooperativeness) or analysing relationships in non-social interactions (an interest in science, technology, the natural world, etc.). The approaches can be measured by two questionnaires, called the empathy quotient and the systemising quotient. Women are thought to be better at the former; men, the latter.

In a recent study, men were found to engage in higher levels of systemising than were women and non-heterosexual women higher than heterosexual women (Nettle, 2007). There were no differences between heterosexual and non-heterosexual men. Women did show a greater interest in the arts and culture, however, which may not be related to sociability/empathy.

Sex differences in general knowledge

When the most commonly used test of intelligence (the Wechsler Adult Intelligence Scale, described later) was validated, a curious finding emerged. The men scored more highly than did women. The same difference was found when the WAIS was revised 25 years later. The general knowledge section of the WAIS is quite short and so any sex difference in scores may not be entirely conclusive. The difference may be restricted to the narrow range of subjects in that subtest of the WAIS.

Whether sex differences exist in general intelligence is controversial. Investigating any differences between boys and girls is complicated by the fact that girls mature more quickly than boys, and that the growth spurt in boys is seen in late adolescence and this correlates with higher IQ. Researchers at the University of Western Ontario (Jackson and Rushton, 2006) examined the performance of 46,509 male and 56,007 female 17–18-year-olds on the 1991 Scholastic Assessment Test, a measure of academic success that correlates well with general intelligence.

They found that the boys/men scored, on average, 3.63 IQ points higher than the girls/women. This effect was found regardless of ethnic group and socio-economic status. The authors caution, however, that the results from this one test cannot be generalised to the general population.

To examine whether such sex differences in general knowledge could be replicated, Lynn and Irwing administered a much larger set of general knowledge questions to 1,047 science and arts undergraduates at the University of Ulster, Northern Ireland (Lynn and Irwing, 2003).

Tests were constructed which covered 19 areas of general knowledge and yielded six factors covering (1) Physical health and recreation, (2) Current affairs, (3) Family (this included, oddly, cookery and medicine), (4) Science, (5) Fashion, and (6) Arts. The experimenters also took measures of general intelligence and reasoning.

Some of the questions asked included, ‘Who wrote *The Republic*?’, ‘What is the hardest substance?’, ‘What organ

is impaired by glaucoma?’, ‘In what game is the best score 21?’, ‘Who is the leading black British model?’ and ‘What is the currency of Greece?’

Men scored, on average, better than women on questions covering literature, general science, games and finance. Women outscored men on questions involving medicine and fashion. In general, the men scored half a standard deviation (see Appendix) higher than women. When scores on the general intelligence measure were compared, there was no significant difference between men and women. Neither general intelligence, nor A level grades, appeared, therefore, to explain this difference.

The authors argue, on the basis of these results, that general knowledge ought to be considered an intelligence factor in its own right. They call it ‘semantic memory’.

Intelligence testing

Assessment of intellectual ability, or intelligence testing, is a controversial topic because of its importance in modern society. Unless people have special skills that suit them for a career in sports or entertainment, their economic success may depend heavily on formal education. Many employers use specialised aptitude tests to help them select among job candidates. Test scores correlate with school and university grades, the number of years in education and adult occupational status (Neisser *et al.*, 1996a). There are hundreds of tests of specific abilities, such as manual dexterity, spatial reasoning, vocabulary, mathematical aptitude, musical ability, creativity and memory. All these tests vary widely in reliability, validity and ease of administration.

Early intelligence tests

Intelligence testing has a long and chequered history. As early as 2200 BC, Chinese administrators tested civil servants (mandarins) periodically to be sure that their abilities qualified them for their job. In Western cultures, differences in social class were far more important than individual differences in ability until the Renaissance, when the modern concept of individualism came into being.

The term ‘intelligence’ is an old one, deriving from the Latin *intellectus* (meaning ‘perception’ or ‘comprehension’). However, its use in the English language dates only from the late nineteenth century, when it was revived by the philosopher Herbert Spencer (1820–1903) and by the biologist/statistician Sir Francis Galton (1822–1911). Galton was the most important early investigator of individual differences in ability. He was strongly influenced by his cousin Charles Darwin, who stressed the importance of

inherited differences in physical and behavioural traits related to a species' survival. Galton observed that there were family differences in ability and concluded that intellectual abilities were heritable. Having noted that people with low ability were poor at making sensory discriminations, he decided that tests involving such discriminations would provide valid measures of intelligence.

In 1884, Francis Galton established the Anthropometric Laboratory (meaning 'human-measuring') at the International Health Exhibition in London. His exhibit was so popular that afterwards his laboratory became part of the South Kensington Museum. He tested over 9,000 people on 17 variables, including height and weight, muscular strength, and the ability to perform sensory discriminations. One task involved detecting small differences in the weights of objects of the same size and shape.

Galton made some important contributions to science and mathematics. His systematic evaluation of various large numbers of people and the methods of population statistics he developed served as models for the statistical tests now used in all branches of science. His observation that the distribution of most human traits closely resembles the normal curve (developed by the Belgian statistician Lambert Quételet, 1796–1874) is the foundation for many modern tests of statistical significance and can be seen in Figure 11.5.

Galton also outlined the logic of a measure he called correlation: the degree to which variability in one measure is related to variability in another. From this analysis, the British mathematician Karl Pearson (1857–1936) derived the correlation coefficient (r) used today to assess the degree of statistical relation between variables. In addition, Galton developed the logic of twin studies and adoptive parent studies to assess the heritability of a human trait.

Modern intelligence tests

The Binet–Simon Scale

Alfred Binet (1857–1911), a French psychologist, and a colleague (Binet and Henri, 1896) suggested that a group of simple sensory tests could not adequately determine a person's intelligence. They recommended measuring a variety of psychological abilities (such as imagery, attention, comprehension, imagination, judgements of visual space, and memory for various stimuli) that appeared to be more representative of the traits that distinguished people of high and low intelligence.

To identify children who were unable to profit from normal classroom instruction and needed special attention, Binet and Theodore Simon assembled a collection of tests, many of which had been developed by other investi-

Figure 11.5 The normal curve and data from intelligence testing. **(a)** A mathematically derived normal curve. **(b)** A curve showing the distribution of IQ scores of 850 children two-and-a-half years of age.

gators, and published the **Binet–Simon Scale** in 1905. The tests were arranged in order of difficulty, and the researchers obtained norms for each test. **Norms** are data concerning comparison groups that permit the score of an individual to be assessed relative to his or her peers. In this case, the norms consisted of distributions of scores obtained from children of various ages. Binet and Simon also provided a detailed description of the testing procedure, which was essential for obtaining reliable scores. Without a standardised procedure for administering a test, different testers can obtain different scores from the same child.

Binet revised the 1905 test in order to assess the intellectual abilities of both normal children and those with learning problems. The revised versions provided a procedure for estimating a child's **mental age** – the level of

intellectual development that could be expected for an average child of a particular age. For example, if an 8-year-old child scores as well as average 10-year-old children, their mental age is 10 years. Binet did not develop the concept of IQ (intelligence quotient). Nor did he believe that the mental age derived from the test scores expressed a simple trait called ‘intelligence’. Instead, he conceived of the overall score as the average of several different abilities.

The Stanford–Binet Scale

Lewis Terman of Stanford University translated and revised the Binet–Simon Scale in the USA. The revised group of tests, published in 1916, became known as the Stanford–Binet Scale. Revisions by Terman and Maud Merrill were published in 1937 and 1960. In 1985, an entirely new version was published. The **Stanford–Binet Scale** consists of various tasks grouped according to mental age. Simple tests include identifying parts of the body and remembering which of three small cardboard boxes contains a marble. Intermediate tests include tracing a simple maze with a pencil and repeating five digits orally. Advanced tests include explaining the difference between two abstract words that are close in meaning (such as fame and notoriety) and completing complex sentences.

The 1916 Stanford–Binet Scale contained a formula for computing the intelligence quotient (IQ), a measure devised by Stern (1914). The **intelligence quotient (IQ)** represents the idea that if test scores indicate that a child’s mental age is equal to their chronological age (that is, calendar age), the child’s intelligence is average; if the child’s mental age is above or below their chronological age, the child is more or less intelligent than average. This relation is expressed as the quotient of mental age (MA) and chronological age (CA). The result is called the **ratio IQ**. The quotient is multiplied by 100 to eliminate fractions. For example, if a

child’s mental age is 10 and the child’s chronological age is 8, then their IQ is $(10 \div 8) \times 100 = 125$.

The 1960 version of the Stanford–Binet Scale replaced the ratio IQ with the deviation IQ. Instead of using the ratio of mental age to chronological age, the **deviation IQ** compares a child’s score with those received by other children of the same chronological age (the deviation IQ was invented by David Wechsler, whose work is described in the next section). Suppose that a child’s score is one standard deviation above the mean for their age. The standard deviation of the ratio IQ scores is 16 points, and the score assigned to the average IQ is 100 points. If a child’s score is one standard deviation above the mean for their age, the child’s deviation IQ score is $100 + 16$ (the standard deviation) = 116. A child who scores one standard deviation below the mean receives a deviation IQ of 84 ($100 - 16$), as Figure 11.6 illustrates.

Wechsler Adult Intelligence Scale

When David Wechsler was chief psychologist at New York City’s Bellevue Psychiatric Hospital he developed several popular tests of intelligence. The Wechsler–Bellevue Scale, published in 1939, was revised in 1942 for use in the armed forces and was superseded in 1955 by the **Wechsler Adult Intelligence Scale (WAIS)**. This test was revised again in 1981 (the WAIS-R) and in 1997 (the WAIS-III). The **Wechsler Intelligence Scale for Children (WISC)**, first published in 1949 and revised in 1974 (the WISC-R), closely resembles the WAIS. Various versions of the WAIS-R have been devised for use with various populations (such as Irish, Scottish, Welsh and so on).

The current version, the WAIS-III, has widened age range for norms, is culturally up-to-date and includes more easy and difficult items. It is a large collection of individual tests (the test is called a ‘battery’) validated

Figure 11.6 Calculating the deviation IQ score.

on 2,450 individuals from 13 age groups (from 16–17 years to 89). It was also administered to African American and Hispanic respondents, and rarely answered items were removed, thus giving the test a degree of culture-free face validity.

The WAIS-III comprises 14 subtests (11 are included from the WAIS-R) including vocabulary, arithmetic, block design, comprehension, object assembly and so on. Both the adult and children's versions comprise two major scales: verbal IQ (VIQ) and performance IQ (PIQ) which contribute to Full-Scale IQ (FS-IQ). Each major scale has various subscales (or subtests). For example, subtests of the verbal scale include tests of:

- information;
- comprehension (practical reasoning/interpretation of proverbs);
- similarities (abstraction and verbalisation of properties common to objects);
- arithmetic reasoning;
- digit span (repetition and reversal of numbers presented aurally);
- vocabulary (definitions).

Subtests of the performance scale include:

- digit symbols;
- picture completion (identification of missing features from line drawings);
- picture arrangement (arrangement of cartoon pictures in a meaningful order);
- block designs (block construction from a given design);
- object assembly (timed construction of puzzles).

The performance scale relies less on the retention of previously acquired information than does the verbal scale. As such, it is less dependent on formal education but is more vulnerable to ageing and conditions which impair perceptual and motor skills and speed (Rao, 1986). It is also susceptible to practice effects, as is the verbal scale but more so. An example of one of the performance scale tests can be seen in Figure 11.7. The norms obtained for the WAIS permit the tester to calculate a deviation IQ score.

The WAIS is the most widely administered adult intelligence test. An important advantage is that it tests verbal and performance abilities separately. Neuropsychologists often use it because people with brain damage tend to score very differently on the performance and verbal tests. In fact, it is so widely used that Lezak (1995) has called it the 'workhorse of neuropsychological assessment'. Comparisons of performance and verbal test scores suggest the presence of undiagnosed brain damage. Because people who have had few educational and cultural opportunities often do worse on the verbal tests

Figure 11.7 The block design subtest similar to that illustrated here is part of both of Wechsler's Scales, the WISC-R for children and the WAIS-R for adults.

than on the performance tests, the WAIS is useful in estimating what their score might have been had they been raised in a more favourable environment.

Reliability and validity of intelligence tests

The adequacy of a measure is represented by its reliability and validity (terms described in Chapter 2). In the case of intelligence testing, reliability is assessed by the correlation between the scores that people receive on the same measurement on two different occasions; perfect reliability is 1. High reliability is achieved by means of standardised test administration and objective scoring: all participants are exposed to the same situation during testing, and all score responses in the same way. The acceptable reliability of a modern test of intellectual ability should be at least 0.85. Validity is the correlation between test scores and the criterion – an independent measure of the variable that is being assessed.

However, most tests of intelligence correlate reasonably well with such measures as success in school

(between 0.40 and 0.75). Thus, because intellectual ability plays at least some role in academic success, IQ appears to have some validity.

Are intelligence scores improving?

One of the most curious phenomena of intelligence measurement is that people appear to be getting significantly more intelligent or, more accurately, their IQ scores are increasing. This is called the Flynn effect after the psychologist James Flynn who noticed that the average level of intelligence has risen since the beginning of the twentieth century (Flynn, 1984, 1987). This is illustrated in Figure 11.8. It has been estimated that people living in the 1930s would have IQ scores that were one to two standard deviations below those living in 2000. The US population appears to have made a 20-point acceleration in IQ in 60 years. Scores on tests of fluid intelligence have doubled compared with scores on crystallised intelligence. In one Dutch study, an 18–20 point increase in IQ was observed within a generation (Flynn, 1999). There has also been an increase in semantic and episodic memory performance (Rönlund *et al.*, 2008). Why?

Figure 11.8 IQ increase over the twentieth century.

Source: Blair, C., Gamson, D., Thorne, S. and Baker, D., Rising mean IQ: Cognitive demand of mathematics education for young children, population exposure to formal schooling and the neurobiology of the prefrontal cortex, *Intelligence*, 2005, 33, 93–106, p. 94, figure 1.

The most obvious explanation would be improved schooling and education, especially in primary or elementary school where the focus has shifted towards teaching cognitive skills that reflect fluid intelligence (Blair *et al.*, 2005).

There is a significant association between national IQ and educational achievement. Lynn and Mikk (2007) correlated published national IQs scores in 2002 and 2006 with the educational attainment scores of children in 25 (10-year-olds) and 46 (14-year-olds) countries. Maths and science achievement correlated significantly with national IQ. IQ was also associated with per capita income: the greater the IQ, the greater the income.

The roles of heredity and environment

Abilities – intellectual, athletic, musical and artistic – appear to run in families. Why? Are the similarities owing to heredity, or are they solely the result of a common environment, which includes similar educational opportunities and exposure to people having similar kinds of interests?

According to Sternberg and Grigorenko (1997), we know three facts about the roles of heredity and environment in intelligence: (1) both contribute to intelligence, (2) they interact in various ways, and (3) poor and enriched environments influence the development of intellectual ability regardless of heredity.

What these facts illustrate is that the typical nature–nurture debate in intelligence is no longer valid. The nature–nurture argument suggests that, in its most stark form, behaviour or function is determined solely by the environment or solely by genetics/heredity. Psychologists have discovered that this argument is too simplistic. In fact, it is inaccurate. Almost all psychologists agree that

Cutting edge – Do you have to be smart to be rich?

This is the question Jay Zagorsky of Ohio State University asked when he examined IQ and income generation data from over 7,000 Americans born between 1957 and 1964 (Zagorsky, 2007). He found that although each point increase in IQ was associated with between \$234 and \$616 additional income per year, there was no statistically significant relationship between them. That is, while greater IQ was associated with greater income, the increase was not large enough to be statistically meaningful.

A slightly different finding was found in a study of IQ and career success (Strenze, 2007). This study found that intelligence measured before respondents had left formal schooling was significantly associated with later career/socio-economic success. However, parents' socio-economic status and school achievement was also associated with their offspring's success.

intelligence has a hereditary (as well as environmental) component. The debate now focuses on the degree to which each contributes to intelligence and the ways in which they interact to influence intellectual development.

The meaning of heritability

When we ask how much influence heredity has on a given trait, we are usually asking what the heritability of the trait is. **Heritability** is a statistical measure that expresses the proportion of the observed variability in a trait that is a direct result of genetic variability. The value of this measure can vary from 0 to 1. The heritability of many physical traits in most cultures is very high; for example, eye colour is affected almost entirely by hereditary factors and little, if at all, by the environment. Thus, the heritability of eye colour is close to 1.

Heritability is a concept that many people misunderstand. It does not describe the extent to which the inherited genes are responsible for producing a particular trait; it measures the relative contributions of differences in genes and differences in environmental factors to the overall observed variability of the trait in a particular population. An example may make this distinction clear. Consider the heritability of hair colour in the Eskimo culture. Almost all young Eskimos have black hair, whereas older Eskimos have grey or white hair. Because all members of this population possess the same versions of the genes that determine hair colour, the genetic variability with respect to those genes is in essence zero. All the observed variability in hair colour in this population is explained by an environmental factor – age. Therefore, the heritability of hair colour in the Eskimo culture is zero.

As with hair colour, we infer the heritability of a person's intelligence from their observed performance. Thus, looking at a person's IQ score is equivalent to looking at the colour of a person's hair. By measuring the correlation between IQ score and various genetic and environmental factors, we can arrive at an estimate of heritability. Clearly, even if hereditary factors do influence intelligence, the heritability of this trait must be considerably less than 1 because so many environmental factors also influence intelligence. The branch of psychology called behaviour genetics, which we came across in Chapters 1 and 3, predicts the degree of parental influence via genetic and environmental transmission on the development of the child's intellectual development. The proportion of the variance associated with genetic differences among individuals is called h ; the remaining variation which is associated with environmental influences is referred to as $1-h$ (Neisser *et al.*, 1996a). The features which families share and have in common (such as choice of home) is sometimes referred to as c . Factor h

can be subdivided into two types: additive h , which refers to the amount of hereditary variance that is passed from parent to child, and non-additive h which refers to new, unique genetic expression in each generation. As children grow older, h increases and c decreases (McGue *et al.*, 1993). In childhood, the contribution of h and c to intelligence is similar; by adolescence h predicts about three-quarters of intellectual ability.

The heritability of a trait depends on the amount of variability of genetic factors in a given population. If there is little genetic variability, genetic factors will appear to be unimportant. Because the ancestors of people living in developed Western nations came from all over the world, genetic variability is likely to be much higher there than in an isolated tribe of people in a remote part of the world. Therefore, if a person's IQ score is at all affected by genetic factors, the measured heritability of IQ will be higher in, say, Western European culture than in an isolated tribe.

The relative importance of environmental factors in intelligence depends on the amount of environmental variability (EV) that occurs in the population. If environmental variability is low, then environmental factors will appear to be unimportant. In a society with a low variability in environmental factors relevant to intellectual development – one in which all children are raised in the same way by equally skilled and conscientious carers, all schools are equally good, all teachers have equally effective personalities and teaching skills, and no one is discriminated against – the effects of EV would be small and those of GV (genetic variability) would be large. In contrast, in a society in which only a few privileged people receive a good education, environmental factors would be responsible for much of the variability in intelligence: the effects of EV would be large relative to those of GV.

Although h and c give an indication of the degree of variance attributable to heredity and environment, they do not explain the mechanism by which intelligence is transmitted or developed (Neisser *et al.*, 1996a).

Sources of environmental and genetic effects during development

Biological and environmental factors can affect intellectual abilities prenatally and post-natally. Newborn infants cannot be said to possess any substantial intellectual abilities; rather, they are more or less capable of developing these abilities during their lives. Therefore, prenatal influences can be said to affect a child's potential intelligence by affecting the development of the brain. Factors that impair brain development will necessarily also impair the child's potential intelligence.

As the axons of developing neurons grow, they thread their way through a tangle of other growing cells, responding to physical and chemical signals along the way. During this stage of prenatal development, differentiating cells can be misguided by false signals. For example, if a woman contracts German measles during early pregnancy, toxic chemicals produced by the virus may adversely affect the development of the foetus. Sometimes, these chemicals can misdirect the interconnections of brain cells and produce mental retardation. Thus, although development of a human organism is programmed genetically, environmental factors can affect development even before a person is born.

Harmful prenatal environmental factors include physical trauma injury to the mother (for example, in a car accident) and toxic effects. A developing foetus can be exposed to toxins from diseases contracted by the mother during pregnancy (such as German measles) or from other sources. A pregnant woman's intake of various drugs can have detrimental effects on foetal development. Alcohol, opiates, cocaine and the chemicals present in cigarettes are harmful to foetuses. One of the most common drug-induced abnormalities, **foetal alcohol syndrome**, is seen in many offspring of women who are chronic alcoholics. Children with foetal alcohol syndrome are much smaller than average, have characteristic facial abnormalities, and, more significantly, are mentally retarded. Figure 11.9 shows the face of a child with foetal alcohol syndrome as well as the faces of a normal mouse foetus and of a mouse foetus whose mother received alcohol during early pregnancy.

Development can also be harmed by genetic abnormalities. Some of these abnormalities cause brain damage and consequently produce mental retardation. The best-

known example of these abnormalities is Down syndrome, described in Chapter 3. Although Down syndrome is a genetic disorder, it is not hereditary; it results from imperfect division of the 23 pairs of chromosomes during the development of an ovum or (rarely) a sperm. Chapter 3 also described phenylketonuria (PKU), an inherited metabolic disorder that disrupts normal brain development. If left untreated, PKU can result in severe mental retardation.

From birth onwards, a child's brain continues to develop. Environmental factors can either promote or impede that development. Post-natal factors such as birth trauma, diseases that affect the brain, or toxic chemicals can prevent optimum development and thereby affect the child's potential intelligence. For example, encephalitis (inflammation of the brain), when contracted during childhood, can result in mental retardation, as can the ingestion of poisons such as mercury or lead.

Educational influences in the environment, including (but not limited to) schooling, enable a child to attain their potential intelligence. By contrast, a less than optimum environment prevents the fullest possible realisation of intelligence. Experience with mentally retarded people demonstrates this point. Known environmental causes account for only about 25 per cent of observed cases of mental retardation. In addition, people whose mental retardation has no obvious physical cause are likely to have close relatives who are also mentally retarded. These findings strongly suggest that many of the remaining 75 per cent of cases are hereditary. However, environmental causes (such as poor nutrition or the presence of environmental toxins) can produce brain damage in members of the same family; thus, not all cases of familial mental retardation are necessarily hereditary.

Results of heritability studies

Estimates of the degree to which heredity influences a person's intellectual ability come from several sources. As you saw in Chapter 3, the two most powerful methods are comparisons between identical and fraternal twins and comparisons between adoptive and biological relatives.

Identical and fraternal twins

Scarr and Weinberg (1978) compared some specific intellectual abilities of parents and their adopted and biological children and of children and their biological and adopted siblings. They administered four of the subtests of the Wechsler Adult Intelligence Scale: arithmetic, vocabulary, block design and picture arrangement. The correlations between biological relatives were considerably higher than those between adoptive relatives, indicating that genetic factors played a more significant role than shared environmental factors. In fact, with the exception of vocabulary, adopted children showed little resemblance to other members of their family.

These results suggest that a person's vocabulary is more sensitive to their home environment than are other specific intellectual abilities. Presumably, such factors as the availability of books, parental interests in reading, and the complexity of vocabulary used by the parents have a significant effect on the verbal skills of all members of the household, whether or not they are biologically related.

A comprehensive survey of the differences between identical (monozygotic) and fraternal (dizygotic) twins on tests of spatial and verbal ability is illustrated in Figure 11.10 (reported in Plomin and DeFries, (1998)).

The figure illustrates the differences between the intelligence of groups across the lifespan from childhood to old age. What is remarkable about these data is that, across the lifespan, the similarity between identical twins is significantly greater than that between fraternal twins. Compare these results with those seen in Table 11.5. The table summarises data from a number of published studies of biological and adoptive families and adolescent and adult twins (Scarr, 1997). The table also shows that although identical twins reared in the same home show a higher concordance rate than identical twins reared apart, these concordance rates are still higher (significantly so) than those of fraternal twins reared together.

Recent studies have indicated that not only are monozygotic children closer in intellectual ability than their fraternal counterparts but that this difference extends to old age. Petrill *et al.* (1998) studied the degree of heritability of general intelligence in monozygotic and dizygotic twins longitudinally during infancy and early childhood. The researchers found that h^2 increases from zero at 14 months to 0.64 at 36 months and begins to exert a significant effect by 24 and 36 months. The influence of shared environment began to attenuate at 36 months. One reason for the pronounced influence of

Table 11.5 Intelligence test correlations of siblings from five behaviour-genetic studies of biological and adoptive families and twins (adolescents and adults).

Genetic r (correlation)	Relationship	Same home?	IQ correlation	Number of pairs
1.00	Same person tested twice	Yes	0.90	–
1.00	Identical twins	Yes	0.86	4672
1.00	Identical twins	No	0.76	158
0.50	Fraternal twins	Yes	0.55	8600
0.50	Fraternal twins	No	0.35	112
0.50	Biological siblings	Yes	0.47	26473
0.50	Biological siblings	No	0.24	203
0.00	Adoptive siblings	Yes	0.02	385

heredity at 36 months (and the attenuation of the influence of environment) may be the development of language, a function that is thought to be highly heritable.

The contribution of h to intelligence appears to increase from 0.3 in early childhood (Cherny *et al.*, 1994) to 0.8 in middle age (Finkel *et al.*, 1995). However, this influence may extend to very old age (over 80 years of age). In the first study of its kind, Petrill *et al.* (1998) examined the influence of h in monozygotic and dizygotic twins greater than 80 years of age taken from the OctoTwin sample of the Swedish Twin Registry which contains details of 90 per cent of the twins born in Sweden. The mean age of the participants was 82.7 years and all were free from dementia and motor handicap. Petrill *et al.* (1998) found that there was a significant influence of h on ability, especially on memory performance.

At least half the total variance in IQ scores is accounted for by genetic variance (Chipuer *et al.*, 1990; Plomin *et al.*, 1997). The fact that, by most estimates, genetic factors account for approximately 50 per cent of the variability in IQ scores means that the other half of the variability is accounted for by environmental factors. However, when the data are taken from tables such as Table 11.5, contribution of the environment is less than 25 per cent. Some estimates, based on comparisons of parents and their offspring raised together or apart, suggest a value of only 4 per cent. Why are these figures so low?

Plomin (1988, 1990) suggests that estimates of the importance of environmental factors tend to be low because the environment in a given family is not identical for all its members. Some environmental variables within a family are shared by all members of the family, such as the number of books the family has, the examples set by the parents, the places the family visits on holiday, the noisiness or quietness of the home, and so on. But not all of the environmental factors that affect a person's development and behaviour are shared in this way. For

example, no two children are treated identically, even by family members; differences in their appearances and personalities affect the way other people treat them. Different members of a family will probably have different friends and acquaintances, attend different classes in school, and, in general, be exposed to different influences. And once people leave home, their environments become even more different.

Estimates of the contribution of environmental variability to intelligence based on measurements made during childhood tend to be higher than similar estimates based on measurements made during adulthood. The reason for this difference may be that, during childhood, family members share a more similar environment, whereas during adulthood their environments become less similar. As Plomin (1997) notes, studies of genetically unrelated children (of a mean age of under 10 years) adopted and raised in the same families, suggest that up to 30 per cent of the variability in IQ scores is due to common environmental factors. However, when the comparison is made among young adults, the figure drops to less than 3 per cent. This can be seen in Figure 11.11, which summarises the correlations between children and their birth parents, adopted children and their birth parents, and adopted children and their adoptive parents for verbal and spatial ability from the time when the child was 3 years of age to adolescence (Plomin and DeFries, 1998). Adopted children appear to become more like their birth parents but do not become more like their adoptive parents, findings that were also reported in a study of the development of antisocial behaviour in twins (Pike *et al.*, 1996).

Thus, once children leave home and are exposed to different environmental variables, the effect of a common family environment almost disappears. What is left, in the case of related individuals, is their common genetic heritage.

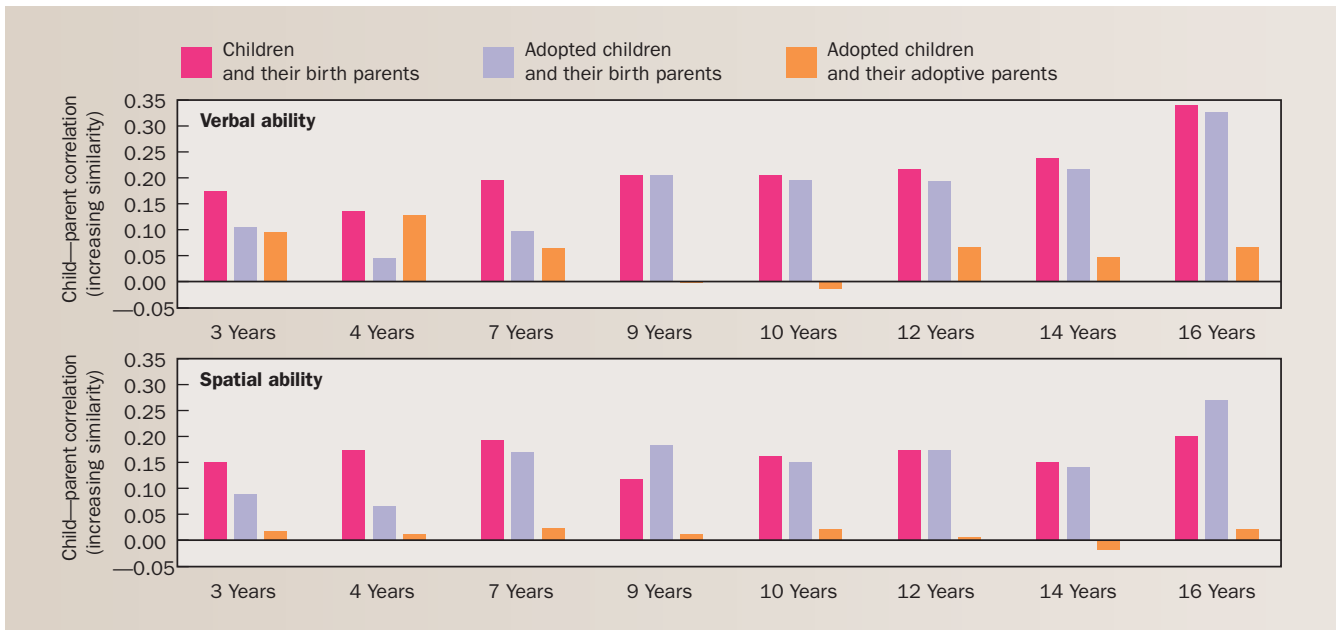

Figure 11.11 The Colorado Adoption Project monitored the spatial and verbal ability of (1) children and their birth parents; (2) adopted children and their birth parents; and (3) adopted children and their adoptive parents, from the child's third birthday to its sixteenth birthday. Notice how closely the adopted children's intelligence resembles that of their birth parents but that there is little resemblance between adopted children and their adopted parents.

If intelligence is inherited, how does inheritance occur?

Given that our DNA is what makes us what we are, the first and most obvious locus of any genetic cause would be our chromosomes (Plomin, 1997). The DNA contains sequences of information which are divided into sections by enzymes (called restriction enzymes). Sometimes these sequences are repeated. These enzymes act as markers which can be used to locate chromosomes and defects on chromosomes. Some genetic disorders of behaviour are single-gene disorders, that is, only one chromosome is affected (such as that seen in PKU, as you saw in Chapter 3). More complex behaviours, however, are likely to have multiple genetic loci called quantitative trait loci. The question, therefore, is whether intelligence is inherited through one gene or multiple genes.

Plomin and his colleagues have pioneered research in this, one of the most difficult areas in behaviour genetics. Plomin *et al.* (1994a, b, 1995) have made an extensive study of DNA markers from Caucasian children of varying intelligence – from low IQ (less than 59) to high IQ (over 142) – and have found small genetic differences in intelligence between those with low and high IQ. Several of 100 identifiable DNA markers have been associated with intelligence, but no one marker has been consistently

associated with it. A recent study has located a DNA marker for the gene on chromosome 6 which appears with greater frequency in a high IQ group (IQ over 136) than a control group (IQ = 103) (Chorney *et al.*, 1998). This is an exciting finding because it was replicated in a group with even higher IQ (over 160). The researchers caution, however, that the gene accounted for only a small portion of the genetic influence on intelligence and that many more genes may be implicated. Nonetheless, this new area of research may hold the key to identifying the genetic basis of intelligent behaviour.

Giftedness

Although having a high IQ may seem less of an intellectual impediment than having a low IQ, gifted children encounter equally serious but different problems at school (Winner, 1997). Gifted children are frequently described as bored in classes of children of the same age (Gross, 1993) and there is little provision in most schools for the teaching of the very bright and able (Westberg *et al.*, 1993).

Gifted children have been found to be able to induce the rules of algebra at 4–5 years (Winner, 1996), memorise musical scores (Feldman and Goldsmith, 1991), and identify prime numbers (Winner, 1996). Are there specific features of the gifted child, apart from high IQ, which

Psychology in action – Can low intelligence be improved?

Various projects, predominantly but not exclusively in the USA, have sought to discover whether early intervention in the schooling of poor children can lead to educational benefits beyond the period of intervention. In a recent review of the evidence for the long-term success of such programmes, Campbell *et al.* (2001) conclude that interventions are generally beneficial.

Some intervention programmes have shown that intervening early in a poor child's education can enhance their success at school (Johnson and Walker, 1991; Reynolds, 1994). Two such interventions include the Cognitive Acceleration Through Science Education programme (Adey and Shayer, 1994) and the Practical Intelligence for Schools Project (Sternberg and Wagner, 1986; Williams *et al.*, 1996). The former involves teaching children the pattern of thinking seen in science. In a two-year intervention study of 11–12-year-old children, there was a significant increase in science achievement test scores at the end of the intervention. The latter helps the child to build coping strategies based on knowing the strengths, weaknesses and demands of a task and applying the appropriate steps and strategies to complete these tasks. Again, intervention improved the intellectual skill of children when measured on practical and academic measures of writing, homework and test-taking. However, it is unclear whether these interventions make children think better or make them more intelligent.
