Campbell *et al.* (2001) also draw attention to numerous other studies that have shown the positive benefit in middle childhood of early educational intervention. They also highlight the lack of studies beyond adolescence. They cite two studies in which children who received intervention were less likely to be placed in special needs classes while in school but (1) were not intellectually superior and (2) did not graduate any more quickly (Gray *et al.*, 1982). The second study, conversely, found that although intervention groups were less likely to be placed in special needs classes in school, they also performed better at school and, at 19 years old, performed better than the non-intervention group on tests of literacy (Weikart *et al.*, 1978).

The picture is clearly mixed, but if intervention programmes do show some evidence of success, why should this be? Campbell *et al.* suggest that intervention programmes directly affect a child's cognitive abilities by enabling it to 'meet the

challenges of school'. The evidence, they argue, points towards a stronger role for these direct factors rather than indirect ones such as changes in motivation or the parents' perception of the child. The researchers explored some of these factors in a cohort of 104 largely African American children (98 per cent of total) from the Abecedarian project.

The Abecedarian project involved the study of the effects of educational intervention in children from low-income families. Fifty-seven of the infants were randomly assigned to the intervention group; the remainder to the control group. Intervention took the form of early education programmes in infancy for 8 hours a day, 5 days a week, 50 weeks a year. A special curriculum was designed to promote cognitive, perceptual and social development. The control group did not receive such consistent education and attended various day-care centres for different periods, with no experimental intervention. The researchers (Campbell *et al.*, 2001) conducted follow-up assessments when the participants were 21 years old and these assessments included tests of intelligence and evaluations of achievement.

The researchers found that cognitive test performance increased more steeply in the treated group during early childhood when compared with controls. From 3 to 21 years, however, there was a generally better performance in the treated group than in the controls. Reading and mathematics performance was better in the treated group but both groups' performance remained fairly stable from middle childhood onwards: performance showed little change over time and both groups' achievement developed in parallel. It was evident, however, that both groups showed a gradual decline in scores between 12 and 21 years, when compared with standardised scores for the general population. While the treated group performed better than the untreated group, both groups' performance compared unfavourably with the population average.

The results suggest that early intervention in a child's education can be beneficial for children from low-income families with poor maternal education compared with no intervention at all. The period from birth to 3 years or 5 years may be the key to explaining why other intervention programmes do not show such success (Gray *et al.*, 1982). These intervention programmes began when the children were 3 or 4 years old; they were also less time-intensive than the Abecedarian project.

distinguish them from a child of average intelligence? According to Davidson and Sternberg (1984), insight is a frequent characteristic of scholastic achievement; gifted children appear adept at selecting information and selectively encoding it. Similarly, gifted children may use the

same memory strategies as other children but use them more effectively (Jackson and Butterfield, 1986). They also appear to think more independently and persistently than other children and require less structure in their work (Rogers, 1986).

What makes the brain of an intellectually gifted individual different from that of a less gifted one? Is there something about the way in which a gifted person's brain functions that distinguishes him or her?

A group of researchers from the USA and Australia used fMRI to compare brain activation in mathematically gifted adolescent males and control individuals while participants completed a three-dimensional mental rotation task (O'Boyle *et al.*, 2005). The same task is described in Chapter 8, Figure 8.6. In the gifted sample, activation was more bilateral during mental rotation while the control group showed more right-sided activation. Bilateral activation was especially prominent in the parietal lobes and was accompanied by bilateral activation in parts of the frontal lobe, such as the anterior cingulate. Activation in this region was almost completely absent in the control group.

The researchers suggest that this network might be activated or relied upon by the intellectually gifted or by individuals who are mathematically gifted. The prefrontal cortex, as you will see in this chapter, is more greatly activated during performance of tests of fluid intelligence.

Another MRI study has shown that the posterior parietal cortex is significantly more active in intellectually superior Korean adolescents than in Korean children of average intelligence (Lee *et al.*, 2006). The children completed two reasoning tasks, one which relied heavily on general intelligence (*g*), and another which relied on *g* less heavily. The study found that although both groups of adolescents recruited the prefrontal cortex and posterior parietal cortex during the task which relied heavily on *g*, activation was greater in the gifted children. The researchers suggest that superior intelligence is facilitated by activation in a fronto-parietal network which is itself facilitated by activation in the posterior parietal cortex.

IQ and nutrition

There is a clear, obvious and important link between intelligence and nutrition. Malnutrition can impair brain function (Brown and Pollitt, 1996) and IQ in the long term; iodine deficiency during pregnancy can lead to retardation and cretinism. In the late 1980s and early 1990s, a series of studies reported significant differences in non-verbal IQ between schoolchildren who received vitamin and mineral supplements (VMS) and those who received a placebo (Benton, 1992; Haller, 1995; Eysenck and Schoenthaler, 1997). Those who received the supplements scored significantly better.

Benton and Roberts (1988) administered either VMS or a placebo to 60 12-year-old Welsh schoolchildren and measured verbal and non-verbal IQ before and after the trial which lasted 9 months. They found that the non-verbal IQ of those children receiving VMS was significantly higher at the end of the trial compared with those receiving a placebo. In fact, non-verbal IQ was, on average, nine points higher. Schoenthaler *et al.* (1991a) also reported those receiving supplements had significantly higher non-verbal IQ (the placebo group's average IQ actually dropped a point). Two other studies confirmed the general findings from these reports (Benton and Buts, 1990; Benton and Cook, 1991). The largest study involved 615 Californian children (Schoenthaler *et al.*, 1991b). A placebo, VMS at the recommended daily allowance, VMS at half the RDA or VMS at twice the RDA was administered to the children each day for 12 weeks. As predicted, non-verbal IQ increased in all VMS groups.

Do these studies indicate that supplementation does have a genuine effect on cognitive performance? Do all studies agree? The answer, to the second question at least, is no. Some studies have failed to replicate the Benton

Cutting edge – The effect of intelligence on health

In recent years, psychologists have turned to an unusual factor as a predictor of long-term good health: intelligence. Studies have shown that people with lower IQ are more likely to die earlier than those with higher IQ, whatever socio-economic class they belong to (Batty *et al.*, 2007). A new study of 1,181 Scottish people born in 1936 and followed by researchers from 1963 to 2003 has confirmed this finding (Deary *et al.*, 2008).

People with higher intelligence and who were most dependable had a significantly lower rate of mortality. The 'hazard ratio' was 0.8 for intelligence and 0.77 for dependabil-

ity (i.e. very low). Children who were in the lower half of the dependability/intelligence dimension were twice as likely to die as those in the upper half. The hazard ratio was 2.82. Smoking, high cholesterol and high blood pressure in middle age is associated with a hazard ratio of 2.34 in women and 3.2 in men (Lowe *et al.*, 1998).

The researchers suggest that a number of explanations could account for this association. There is a relationship between genetics and intelligence and longevity, for example. This relationship may be mediated by socio-economic status and engaging in healthy behaviour.

and Schoenthaler findings. Nelson *et al.* (1990), for example, examined the effect of VMS and placebo on 227 7–12-year-old children over four weeks and found no evidence of significant improvement in non-verbal IQ. Benton (1992) and Eysenck and Schoenthaler (1997), in a review of these studies, suggest that a number of methodological differences could account for the contrary results. Differences in the length of trials, the types of test used, the method of administering tests, interpreting the results of tests, and the type of VMS may explain the results of those studies reporting no significant improvement in non-verbal IQ. More recently, researchers have found a significant relationship between iron and folate intake and total IQ and non-verbal IQ (Arija *et al.*, 2006). The greater the intake, the better the IQ. The results suggests that even in children who are well-nour-

ished and intelligent, some nutritional intervention might lead to better cognition.

If the effect seen in children is robust, why should VMS affect only non-verbal IQ? In all the published studies there has been no reported improvement in verbal IQ. Cast your mind back to the sections on types of intelligence earlier in this chapter. Verbal intelligence, as measured on the standard types of test, usually relies on information that has already been learned through experience. This type of intelligence is called ‘crystallised’ intelligence. Non-verbal intelligence, however, does not rely on previous knowledge and has been described as ‘fluid’. If fluid intelligence reflects the potential to perform, it seems reasonable that administering VMS should affect this type of intelligence more than the type which is fixed and crystallised.

Controversies in Psychological Science – Is there a relationship between race and intelligence?

The issue

Of all the controversies in psychological science discussed in this book, perhaps the most controversial is that of the contribution of race to intelligence. *The Bell Curve*, a book written by a psychologist and a sociologist (Herrnstein and Murray, 1994), provoked a furore among psychologists and in the media across the world. The book asserted that psychologists agree that a general intelligence factor exists; that IQ tests measure what most people think of as intelligence; that IQ is almost impossible to modify through education and special training; that IQ is genetically determined; and that racial differences in IQ are the result of heredity. Whereas the chapter has so far discussed the first four assertions, this section addresses the last: whether race can influence IQ.

The evidence

Many studies have established the fact that there are racial differences in scores on various tests of intellectual abilities. For example, people who are identified as black generally score an average of 85 on IQ tests, whereas people who are identified as white score an average of 100 (Lynn, 1991; Jensen, 1985; Rushton, 1997). Although many blacks score better than many whites, on average whites do better on these tests. A statement endorsed by 52 professors indicated that, on average, whites’ average IQ score is 100, African Americans’ is 85, American-Hispanics’ is somewhere between whites and African Americans’, and Asians’ is above 100 (*Mainstream Science*, 1994, cited in Suzuki and Valencia (1997)). Lynn’s study (1996) of 2,260 children between 6 and

17 years of age found that Asian children scored an average of 107 IQ points, white children an average of 103 and black children an average of 89. Interestingly, black infants are more advanced than their white counterparts in the first 15 months of life (Lynn, 1998).

The controversy lies not in the facts themselves but in what these facts mean. Some authors have argued that the racial differences in scores on the tests are caused by heredity (Lynn, 1993; Rushton, 1995, 1997). *The Bell Curve* highlighted other racial aspects of intelligence such as the failure of intervention programmes to improve the IQs of black children.

The assertions made in *The Bell Curve* have not gone unchallenged. In response to the book and issues surrounding intelligence, the American Psychological Association set up a taskforce to report on the current state of knowledge regarding the nature and determinants of intelligence (Neisser *et al.*, 1996a). The evidence we have reviewed so far in the chapter has helped to clarify some of the issues raised in *The Bell Curve*.

Some investigators have attempted to use statistical methods to remove the effects of environmental variables, such as socio-economic status, that account for differences in performance between blacks and whites. However, these methods are controversial, and many statisticians question their validity. On the other hand, a study by Scarr and Weinberg (1976) provides unambiguous evidence that environmental factors can substantially increase the measured IQ of a black child. Scarr and Weinberg studied 99 black children who were adopted into white families of higher-than-average educational and socio-economic status. The expected average

Controversies in Psychological Science – *Continued*

IQ of black children in the same area who were raised in black families was approximately 90. The average IQ of the adopted group was observed to be 105.

Other authors have flatly stated that there are no racial differences in biologically determined intellectual capacity. But this claim, like the one asserting that blacks are inherently less intelligent than whites, has not been determined scientifically. It is an example of what Jensen (1980) has called the egalitarian fallacy – the ‘gratuitous assumption that all human populations are essentially identical in whatever trait or ability the test purports to measure’ (p. 370). Although we know that blacks and whites have different environments and that a black child raised in an environment similar to that of a white child will receive a similar IQ score, the question of whether any racial hereditary differences exist has not been answered. When we point to group differences in races we are referring to general, average differences in intellectual performance; there are considerable within-group differences which may even be larger than between-group differences (Suzuki and Valencia, 1997).

There is also a problem with what we mean by race. We can define race biologically by gene frequencies (Loehlin *et al.*, 1975) or we can define it as a social construct. For many people, race is whatever they believe it to mean; they themselves ascribe meaning to it (Omi and Winant, 1994). In this sense, the concept of race makes very little scientific sense.

Conclusion

Although the issue of race and intelligence as currently conceived does not appear to be meaningful, it would be scientifically interesting to study the effects of different environments on inherited intellectual capacity. The interesting and more valid questions concerning race are those addressed by social psychologists and anthropologists – questions concerning issues such as the prevalence of prejudice, ethnic identification and cohesiveness, fear of strangers (xenophobia), and the tendency to judge something (or someone) that is different as inferior.

Intelligence, thinking and ageing

Ageing and cognitive ability

As the body and the brain grow older, certain changes occur. The acuity of the senses may begin to decline, the ability to move quickly is reduced. On the cognitive level, there is also a decline in various functions such as the manipulation of information in working memory, retrieval of names, reaction time, declarative memory, information processing. Functions such as vocabulary, however, see some improvement with age (Woodruff-Pak, 1997). General IQ scores will peak at around 25 years of age and decline up to 65 years. After 65, the score drops rapidly (Woods, 1994). At the most severe end of cognitive decline, there is dementia – the gradual and relentless loss in intellectual function as the individual reaches the sixth decade of life and beyond. There may be great difficulty in separating the effects of normal ageing from the effects of dementia on cognitive ability (Alzheimer’s disease, for example, can only be diagnosed with certainty post-mortem when the brain can be examined). Data from a Canadian sample suggest that the degree of cognitive impairment that is not related to dementia is around 16.8 per cent (the usual prevalence of dementia is 8 per cent) (Graham *et al.*, 1997).

Our categorisation of individuals into age groups is fairly arbitrary. In most developed countries, the age of

retirement is set at 65 (an age originally set by Otto von Bismark, the German chancellor from 1871 to 1890), although this does not mean that those people who are 65 or older are incapable of holding down a job or lack the cognitive and physical capacity to hold down such a job. The distribution of the elderly population in the Western world in 1950 was pyramid-shaped, that is, there were fewer people reaching old and very old (over 80 years) age. It has been estimated that by 2030, this distribution will be pillar-shaped, with roughly equal numbers in the old and very old categories.

Improvements in health care, sanitation, crime prevention and nutrition are thought to be responsible for this increase in the number of years we are living. Psychologically, therefore, the more we learn about the effects of ageing – and in reversing its negative effects – the more important this information will become in countries where we are living longer.

What is ageing?

From a strict point of view, we age as soon as we emerge from the womb. We are born with all the neurons we will have in life and they begin dying as soon as we grow. There is a massive shedding of neurons and synapses during childhood; this continues to old age. Of course, this shedding does not leave us intellectually helpless. Although neurons are lost, new connections are formed between existing neurons (this is why, although neurons

are lost, the brain increases in weight during childhood) and the existing neurons work more efficiently. It has been suggested that psychological ageing begins after maturity and that this is measured by behaviour that includes the ability to acquire, remember and retrieve words, people and events and the ability to process and manipulate information. This scientific study of the ageing process is called **gerontology**.

One problem with studying the ageing process, however, is the large variability between and within samples. For example, during a long period of study, older participants become susceptible to disease processes and illnesses which could directly affect the variables that gerontologists are interested in studying. This within-subject variation can also be seen in another capacity. If we take one age group, say the 50–60-year-old, and compare it with another on some cognitive measure, we are defining a group of individuals by an age category but all individuals within this group may not show the same degree of ageing. For example, although the ability to remember strings of digits declines with age, some individuals perform badly, some stay the same and some actually get better (Holland and Rabbitt, 1991). Group variation becomes more of a problem when we look at data from cross-sectional studies.

Cross-sectional studies, you will remember from Chapter 2, compare independent groups on some measure. In ageing research, a cross-sectional design would involve assigning individuals to age categories such as 18–25, 26–35, 36–45, 46–55 and so on. These groups would then complete a series of tests of cognitive ability, and differences between groups would be examined. If a difference in memory was found between the younger groups and the older groups, however, we could not attribute this finding to ageing and cite ageing as a cause. Can you see why? (This question was posed in Chapter 2.) The reason is that we are not really looking at the effects of ageing but at the effect of age groups. We are not following one individual across all age ranges, but have sampled from several different age ranges. Because of this, our groups may differ on variables that we had not anticipated, such as improvement in nutrition and healthcare. When one group influences the results in this way, the study is said to show a cohort effect. The conclusion we can draw is that age groups differ from each other.

A different type of design looks at age change and this is called a longitudinal design. Here, individuals are assessed across the lifespan and each individual acts as his/her own control (we could combine the two designs as well and compare individuals within one age group which vary on another characteristic, such as occupation or education level). A problem here is that with repeated testing, the individual will become increasingly familiar with the measures employed. When longitudinal and cross-

sectional measures are compared, the longitudinal assessments show least decline in ability (Schaie, 1990).

However, recent studies suggest that cross-sectional designs such as these can be meaningful and provide similar data to longitudinal studies. For example, Salthouse (2009) has summarised data showing the (fairly relentless decline) in cognitive ability as we get older, in a number of domains apart from vocabulary and general knowledge (which increase). You can see these data illustrated in Figure 11.12. The decline begins in adulthood and progresses thenceforth.

Memory decline

There is a gradual loss in performance for certain types of memory task with age. For example, older individuals have difficulty in retrieving names (Rabbitt *et al.*, 1995) and putting names to famous faces (Burke *et al.*, 1991). In Burke *et al.*'s experiment, participants were allowed one minute in which to name famous faces. The number of tip-of-the-tongue responses as people tried to put names to faces increased with age. When participants were allowed to try to remember the names on the tips of their tongues, however, 95 per cent of their responses were correct, which suggests that the information had been stored but that the participants had difficulty in retrieving it.

Older people also have difficulty in recalling where, when or how an event occurred, despite knowing that an event has occurred. This type of memory is called **source memory** because the emphasis is on the recall of the context in which an event occurred, rather than of the content/knowledge of the event (Johnson *et al.*, 1993). This type of memory seems more affected in the elderly than is memory for facts or items (Trott *et al.*, 1997), possibly because it relies on the integrity of the frontal lobe and the integrity of this brain region is challenged in elderly individuals, as you will see later.

Age-related impairments have been reported for declarative memory, efficiency of processing information and metamemory (Woodruff-Pak, 1997). **Metamemory** refers to 'knowing about knowing'; this knowledge of skills necessary to complete a task may be absent in the elderly. For example, elderly individuals may not spend sufficient amounts of time on a task that requires time to be spent on it (recall of digit names in serial order, for example). When they are instructed to spend a certain length of time on this task, however, they can recall accurately just as many series of digits as younger participants.

Prospective memory

Recent research on ageing and memory has focused on **prospective memory**, that is, remembering to perform an activity in the future (Maylor, 1996). This type of

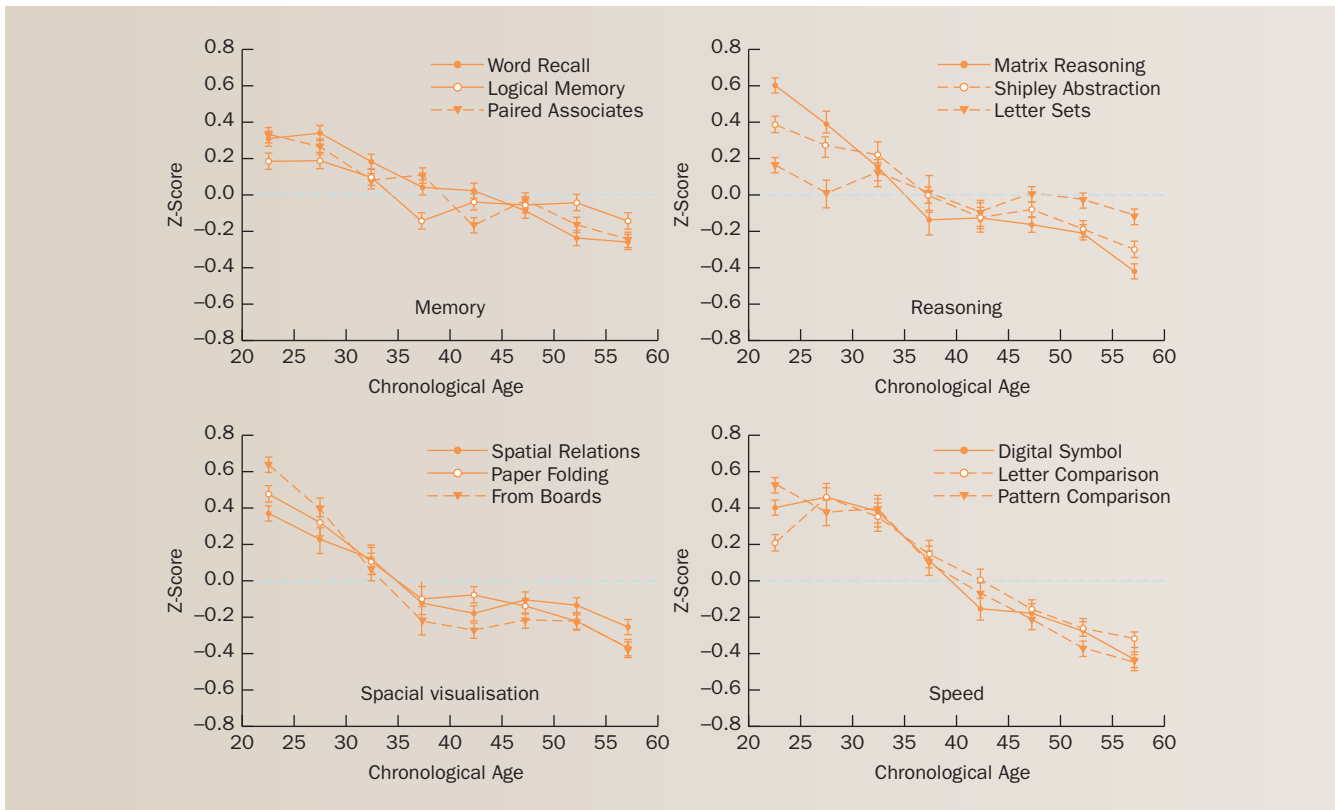

Figure 11.12 Mean scores and standard errors for 12 cognitive variables at 5-year age intervals.

Source: Salthouse, T.A. When does age-related cognitive decline begin? *Neurobiology of Aging*, 2009, 30, 507–14, figure 2.

memory may be especially important to the elderly given that such monitoring is essential for taking medicine at particular times, for example (Park and Kidder, 1996; Einstein *et al.*, 1998). In experiments where a handkerchief or comb is borrowed by the experimenter at the beginning of a test session and/or hidden in a drawer and the individual has to remember to ask for the return of the item, there is an age-related decline in memory.

Studies of prospective memory can be either ‘time based’ or ‘event based’. In time-based experiments, the participant engages in a task and has to inform the experimenter when a certain time has elapsed (Einstein *et al.*, 1995). This may be analogous to remembering to telephone someone in an hour’s time (Maylor, 1996). In one study, Maylor (1990) asked 52–95-year-olds to telephone her once a day for a week. Three-quarters of those who adopted a memory strategy or used external cues for remembering were more reliable at telephoning than were those who did not use such mnemonics. In event-based experiments, participants must make a response when a particular event occurs in a sequence of events.

Although age-related impairments have been observed for time-based tasks, event-based tasks show mixed results. Einstein *et al.* (1998), for example, gave a group of

young (mean age 19.8 years) and old (mean age 70.73 years) individuals 11 tasks to complete. The participants were told that during each task they should press a key on a keyboard once, thereby encouraging habitual prospective memory. In a divided attention condition, some participants were also told that they would hear a series of digits and were asked to press a hand-held counter when they heard two odd numbers. The young group performed the prospective memory task more effectively than did the old group and performance was worse in the divided attention condition, as expected. However, the impairment in the old group was made worse by divided attention. They omitted to make a response in 42 per cent of the first trials, and 12 per cent of the trials contained repetition errors. For trials occurring at the end of the experiment, 16 per cent contained omission errors whereas 42 per cent contained repetition errors.

During the experiment, participants were also presented with an external cue as a reminder that they should press the key. This cue resulted in the old group committing a greater number of omission errors, especially on later trials. One reason for this unexpected finding is that the old group came to rely on this (ineffective) external cue and not on an internal memory strategy.

The poor performance on prospective memory tasks may be attributable to reduced or impaired functioning of the frontal lobes (we will see later that there is some frontal lobe impairment with ageing). Given that prospective memory involves a considerable degree of planning, and that frontal lobe function declines with age, perhaps these two factors are related.

A study by Kliegel *et al.* (2000), however, suggests that the tests of prospective memory used in these experiments are not particularly realistic. These tests, they argue, usually require participants to make a single, isolated act within an experimental session. Everyday life, on the other hand, often involves more complicated planning than this. From cooking a three-course meal to air traffic control, the prospective memory required to perform these acts is complex.

The researchers asked 31 young (average age 26.5 years) and 31 older (average age 71.3 years) individuals to remind the experimenter to return to them a personal belonging (e.g. a wristwatch) at the end of the experiment. After having been given this instruction, participants were told that at some point they would complete a personal information questionnaire in the second part of the experiment after a short break and some tasks. This would be the cue for reminding the experimenter to return the belonging. Participants then completed various cognitive tasks that required them to follow a plan in order to perform these tasks successfully. They were then presented with the questionnaire.

While there was no difference between the two groups in their ability to remind the experimenter about the belonging, the older participants were significantly less likely to remember to initiate intended actions during the cognitive task phase of the experiment. The faithfulness with which participants executed their plans was no different between groups and both groups retained these plans equally well. The older participants, however, had difficulties in planning, initiating and executing the set of tasks.

The authors suggest that the findings may reflect superior working memory in the younger participants – the tasks required the maintenance and rehearsal of material in mind while undertaking other tasks, the critical feature of working memory and, as we have seen, a function of the frontal cortex.

A caveat

One note of caution, however, should be struck when interpreting these data. Some studies show that when memory instructions in some experiments are de-emphasised, age differences in performance disappear (Rahal *et al.*, 2001). Age is also affected by the content of the test. So, for example, if people have to recall a narrative that is

character-based, older people perform more poorly at it than if they recalled a narrative that was based on perceptual features – referring to a man or a woman, rather than to a character (Fung and Carstencens, 2003). Older people also appear to perform better between 8 a.m. and 11 a.m. whereas younger participants give of their best between 1 p.m. and 5 p.m. (Hasher *et al.*, 1999).

Language

There are certain aspects of language processing that may not decline with age and may actually improve. One of the greatest gains is seen in vocabulary (Bayley and Oden, 1955; Jones, 1959). However, older individuals have difficulty in retrieving or accessing these words and exhibit a greater number of tip-of-the-tongue responses than do young individuals during retrieval (Bowles and Poon, 1985). According to LaRue (1992), the types of linguistic error made by elderly participants include: circumlocutions (giving inaccurate multi-word responses), nominalisations (describing functions not objects), perceptual errors (misidentifying stimuli) and semantic association errors (naming an object/feature associated with a target object). The elderly may also have difficulty in comprehending and initiating grammatically complex sentences (Kemper, 1992). Reasons for these, and other memory impairments, are discussed below.

Why does cognitive ability decline?

The evidence above indicates that cognitive ability, especially certain types of memory, declines with age. But is this the case? Ritchie (1997), for example, distinguishes between behaviour that is ageing-related and age-related. Ageing-related processes are the result of ageing; age-related processes occur only at a specific age. Huntington's disease, which was discussed in Chapter 3, is age – not ageing – related, for example. Is the decline seen in the elderly, therefore, not the result of ageing but of other age-related illnesses? Some European longitudinal data suggests that ageing may not be a factor (Ritchie *et al.*, 1996; Leibovici *et al.*, 1996). These researchers found that when controlling for physical illness, depression and signs of dementia, participants' cognitive performance improved over three years. They suggest that the decline that is commonly reported is due to pathology not ageing per se.

Processing speed and ageing

Several studies have shown a strong, positive association between our speed at processing information and intelligence. A new review of 172 studies, featuring

over 53,000 participants, has now confirmed this association (Sheppard and Vernon, 2008). Intelligence measures were significantly associated with mental speed, an association which became stronger as the information processing task became more complex. Men and women also differed on some tests of information processing.

Over many years and several studies, Timothy Salthouse (1992, 1993; Craik and Salthouse, 2000) has argued that the elderly perform more poorly at cognitive tasks because they become slower at performing them. Older people have difficulty in activating, representing or maintaining information 'in mind', in attending to relevant stimuli in the environment and ignoring the irrelevant ones and in processing information speedily. If individual differences in speed are partialled out of these studies, then age-related differences disappear (Salthouse and Babcock, 1991). In fact, ageing could account for less than 1–2 per cent of the variance seen in such studies (Salthouse, 1993). This is a theory that has strong currency in gerontology. For example, several researchers have proposed that the cognitive decline seen in ageing may be attributable to reduced functioning of the frontal lobe (Parkin and Walter, 1992; West, 1996). The density of dopamine receptors declines in this area and dopamine is an important neurotransmitter in the performance of working memory tasks. The frontal cortex is also important for efficient information processing.

If there is significant frontal cortex decline with ageing, we might expect executive function, a key function of the frontal cortex, to be more significantly compromised in older participants. The support for this hypothesis, however, is mixed with some cross-sectional studies showing no differential decline and others showing decline on specific frontal lobe tests (one of these, a card sorting task, is described in the next major section on thinking) (Crawford *et al.*, 2000).

The problem with suggesting that executive function may be specifically impaired, however, is that executive and non-executive task performance may be difficult to distinguish in elderly samples. The reason for this is the one cited by Salthouse (1996): all of these tasks may draw on a common resource such as speed of information processing.

The speed of processing explanation, however, may not account for the findings from prospective memory studies. Prospective memory tasks do not rely on speed but on retention of information for future use. It is possible that timed tasks impair the ability of the elderly. This was evident in experiments where participants could name famous faces if given enough time. Training also appears to be an important factor. In one study, older participants played video games for two hours a week for seven weeks or played no such games. Those who had played were faster at an experimental reaction time task

than those who had not, and were also faster on several difficulty levels (Clark *et al.*, 1987).

Another factor which can help to protect against certain types of cognitive impairment is education. In one Australian study of elderly blue-collar workers and academics, degree of education was associated with stable crystallised intelligence but not other types of cognitive ability (Christensen *et al.*, 1997). A Dutch study has also shown that education was associated with a slower rate of memory decline (Schmand *et al.*, 1997). However, more recent studies (see, e.g. Andel *et al.*, 2006) suggest that high levels of education and having a complex occupation accelerates cognitive decline, arguably because the person's 'cognitive reserve' has been expended.

The environment of the individual also contributes to the stability or decline of cognition. Individuals with cognitive impairment were three times as likely to be living in community healthcare institutions (Graham *et al.*, 1997). Holland and Rabbitt (1991) found that when elderly participants were allowed ten minutes to recall autobiographical memories from each third of their lives, participants living in the community recalled significantly more memories from the recent than the remote period, in contrast to those in residential care who recalled more memories from the earliest period.

But why does such slowing occur in the first place? Why is memory performance one of the most consistently affected cognitive abilities? One suggestion is that cognitive decline is the result of changes in the central nervous system (Lowe and Rabbitt, 1997). In particular, researchers have focused on the hippocampus and the frontal cortex. There is a considerable loss in frontal lobe tissue over the course of the lifespan – around 17 per cent between the ages of 20 and 80 (Mittenberg *et al.*, 1989; West, 1996). One PET study compared the encoding and retrieval of word pairs in young (mean age 26) and old (70 and over) adults (Cabeza *et al.*, 1997). The young participants showed greater left prefrontal activation during encoding and right prefrontal activation during retrieval compared with the old sample. In fact, the old sample showed little frontal activation during encoding and more bilateral activation during retrieval. This pattern of activity suggested to the experimenters that the stimuli had been inefficiently processed or encoded. An fMRI study of recognition and encoding in young, middle-aged and older adults found that activation in brain areas involved in these memory processes declines across age groups but activation in areas that are irrelevant to the specific tasks increases (Grady *et al.*, 2006). Other cognitive studies show that when material is learned thoroughly, then ageing has little effect on retrieval (Woodruff-Pak, 1997), although no neuroimaging study has explored this yet.

At the neural level, one might expect gross changes in the language areas. This would explain the deficits seen on some language tasks. However, little change occurs in the language areas of the elderly. This has led some researchers to suggest that this ageing-related impairment is not due to ineffective language processing but to deficiencies in attention, perception, speed, memory and executive function (Glosser and Deser, 1992).

An alternative (or complementary) view to the frontal lobe hypothesis suggests that ageing results in an impairment of cognitive differentiation – the degree to which behaviour is specialised for specific tasks. The decline, which is domain-independent, is reflected in neurons' inability to perform such differentiation. The cortical basis of visual differentiation may be the ventral visual cortex – this responds to faces, orthography and places – and shows less atrophy than other areas with age. In an fMRI study where 12-year-olds and 70-year-olds were asked to view faces, houses, pseudowords and chairs, less specialisation in activation in the ventral visual cortex was found in the elderly sample (Park *et al.*, 2004). Given that perceptual processing speed declines with age, perhaps such a slowness might be the result of a ventral visual cortex that shows less differentiation. Because there is less differentiation, older participants who are asked to make the same/different decisions about geometric pairs or digits (a standard perceptual processing speed task) are slower at doing so.

Dementia

Dementia refers to the gradual and relentless decline in cognitive ability and is characterised by impairment in short-term and long-term memory. There may also be confusion, change in personality and impaired abstract thinking and judgment. There are various types of dementia such as **dementia of the Alzheimer type** (DAT, the commonest type), vascular dementia (the second commonest, caused by stroke), Pick's disease dementia and Lewy body dementia (both are characterised by neural abnormality). There are many causes of dementia: the most common is **Alzheimer's disease**. It is important to differentiate between Alzheimer's disease and DAT: the former is the disease, the latter is the psychological consequence of this illness. It has been estimated that 24.3 million people worldwide suffer from dementia and that the number of people diagnosed with the illness is expected to double every 20 years until 2040 (Ferri *et al.*, 2005). In the EU, it is estimated that 1–2 million people over 65 years of age have dementia and 54 per cent of these cases are due to Alzheimer's disease (Lobo *et al.*, 2000).

Dementia of the Alzheimer type

According to **DSM-IV TR**, dementia of the Alzheimer type is characterised by:

- Cognitive decline exemplified by memory impairment (learning new information and recalling previously learned information) and one or more of: aphasia, apraxia, agnosia and executive function problems.
- Symptoms which cause significant decline from previous level of functioning.
- Gradual onset and continuing cognitive decline.
- Symptoms that are not due to other progressive CNS diseases or conditions causing dementia.

(DSM-IV TR is the manual used by the majority of the world's clinicians to diagnose mental illness and mental disorder (you'll find this described in more detail in Chapter 18).)

Although there are no completely accurate figures, it is estimated that between 5 per cent and 10 per cent of individuals over 65 years of age will develop Alzheimer's disease (Rocca *et al.*, 1986; Ritchie, 1997); it accounts for approximately 50 per cent of all cases of dementia (Fields, 1998). American studies show a 50 per cent incidence in people over 85 and 100 per cent incidence in one Dutch study of 19 centenarians – those over a hundred years old (Evans *et al.*, 1989; Hebert *et al.*, 1995; Blansjaar *et al.*, 2000). The percentage affected increases with age. Other studies suggest that some centenarians (around 30 per cent) are impervious to the disease (Andersen-Ranberg *et al.*, 2001; Silver *et al.*, 2001; Hagberg *et al.*, 2001). There is also evidence that patients over 65 years old who are later diagnosed with the disease show evidence of neuropsychological impairment at least three years before the diagnosis (Amieva *et al.*, 2005).

The disease was named after Alois Alzheimer at the beginning of the last century who reported the case of a 56-year-old female patient who exhibited cognitive impairment as a result of abnormal brain formations. These formations are the characteristics of Alzheimer's disease and include (1) neurofibrillary tangles, abnormal proteins which are found in various parts of the patient's brain, especially the temporal, parietal and frontal cortices (Foster *et al.*, 1997), and (2) senile plaques, abnormal nerve cell processes which surround the protein and are found in the cortex. These two features are illustrated in Figure 11.13. Animal models suggest that the specific protein which may contribute to the cognitive decline in Alzheimer's disease may be an assembly called AB*56 which is found outside cells (Lesne *et al.*, 2006). In the early, pre-clinical stage of the disease, plaques are seen in the parietal and medial prefrontal lobes (Mintun *et al.*, 2006).

Source: Beatty, J. (1995). *Principles of Behavioral Neuroscience*. New York: Brown and Benchmark/William C. Brown Communications Inc., 1995. Reprinted with permission.

There is significant neuron loss in Alzheimer's disease. The frontal and temporal gyri are thought to shrink by approximately 20 per cent and atrophy is found in the hippocampus, amygdala and other subcortical areas such as the raphe nuclei and nucleus basalis of Meynert. Figure 11.14 (a) and (b), and Figure 11.15 show how extensive this atrophy can be.

The disease can occur sporadically or in a genetic form called familial Alzheimer's disease. The familial form is thought to be autosomal-dominant with the gene carried on chromosome 21 and, possibly, chromosome 19. The gene expresses itself by producing the amyloid precursor protein from which the protein associated with the senile plaques is formed. Early-onset AD is associated

with this marker and also with mutations on chromosomes 1 and 14 (Bird, 1999). Evidence from Scandinavian studies suggests that the heritability of Alzheimer's disease is between 0.6 and 0.75 (Bergem *et al.*, 1997; Gatz *et al.*, 1997). The E4 allele of the apolipoprotein gene also appears to be a risk factor in Alzheimer's disease and for cognitive impairment (Farrer *et al.*, 1997; Slioter *et al.*, 1997).

Clinical features of DAT

The major cognitive impairment in AD is loss of memory. This impairment is gradual and occurs in the presence of a normal level of consciousness but in the absence of any other CNS disease that might account for the symptoms. Some of the more marked deficits in memory include:

- An inability to recall autobiographical information from long-term memory (information about people, events and conversations, for example) is the major characteristic of the disease and appears early on in the disorder's development (Greene and Hodges, 1996a; Fleischman and Gabrieli, 1999).
- Impaired recall of previously learned information and, sometimes, memory for conceptual or factual information.
- Rapid forgetting.
- Explicit memory impairment (implicit memory is relatively preserved).
- Short- and long-term memory impairment (Fleischman and Gabrieli, 1998).
- Tendency to show a lack of a primacy effect but to show a recency effect – patients will more correctly recall items from the end of a list than the beginning (Bayley *et al.*, 2000).
- Interference by previously learned information when new material is learned.
- Attention and working memory impairment.
- Semantic memory impairment – inability to recall over-learned information.
- Circumlocution and paraphrastic errors.
- Delayed-memory impairment – this appears to be best at discriminating DAT patients from controls (Zakzanis *et al.*, 1999).

One difficulty in diagnosing Alzheimer's disease is that senile plaques are seen with normal ageing (tangles tend not to be) whereas tangles are seen in other types of dementia (Ritchie, 1997). Although the effects of ageing and dementia may be distinguished by the fact that abnormalities in the elderly affect the superficial cortex, they go much deeper in Alzheimer's disease. There are also biochemical abnormalities seen in Alzheimer's disease.

In particular, there is significant loss of certain neurotransmitter pathways linking various brain structures, such as the cerebral cortex and the hippocampus, in Alzheimer's disease.

Memory decline in Alzheimer's disease

The major cognitive impairment in Alzheimer's disease is memory loss and episodic memory retrieval is thought to be one of the most seriously affected. A person's inability to recall autobiographical information from long-term memory (information about people and events, for example) is a major characteristic of the disease and appears early on in the disorder's development (Fleischman and Gabrieli, 1999). Figure 11.16 plots the decline in memory function in a patient with Alzheimer's disease and a matched control, across the lifespan. Figure 11.17 (a) and

(b) shows brain scans of patients with Alzheimer's disease who tried to retrieve episodic memory.

Explicit memory is more seriously affected than implicit memory and both short- and long-term memory are impaired (Fleischman and Gabrieli, 1998). Greene

and Hodges (1996a, b), for example, found that patients with Alzheimer's disease performed poorly at naming, identifying and recognising famous faces from the present and past but also found that memory for personally meaningful events declined less rapidly than did public memory (memory for events in public life).

The cognitive decline seen in Alzheimer's patients is much more severe than that seen in disease-free individuals during the course of normal ageing, and various cognitive deficits correlate with a reduction in the volume of the hippocampus, the temporal cortex and thalamus. It can sometimes be difficult to distinguish between the effects of DAT and symptoms of mild cognitive impairment (MCI). MCI seems to occupy a halfway house between the cognitive decline seen with normal ageing and dementia. Sixty-one per cent of MCI patients begin with memory impairments (Storandt, 2006) and it, too, has some of the hallmarks of Alzheimer's disease, such as the amyloid-B deposits (Goedert and Spillantini, 2006). In a study of people who had not manifested the symptoms of dementia – the sample is the famous Framingham Study which follows a large cohort of people through life (Elias *et al.*, 2000) – two tests were associated with the later development of dementia – verbal memory and the similarities test of the WAIS. Poor performance on these predicted later development of dementia. Other tests are thought to be good predictors, especially those which involve planning and sequencing (Storandt *et al.*, 2006).

Attentional problems

Some psychologists have suggested that attention deficit may also be an early cognitive characteristic (Perry and Hodges, 1999) and may explain the deficit in episodic memory (Balota and Faust, 2001). What is unclear, however, is whether this deficit in attention is a global and unitary one – where all types of attention are impaired – or whether different types of attention are affected differently (Baddeley *et al.*, 2001).

Baddeley *et al.* administered three tests of attention deficit to three groups of participants: a group of 41 patients diagnosed with probable Alzheimer's disease, a group of 36 age-matched controls and a group of 36 young controls. In the first attention test, participants performed simple and choice reaction time exercises which involved pressing a key whenever a stimulus appeared on a monitor (this was called a test of focal attention). The second test investigated the participants' ability to ignore distractors in a visual search task (for example, ignoring other letters when looking for the letter Z in an array of letters). The third test involved the ability to divide attention between two simultaneously

performed exercises. In each of the tests, there were two levels of difficulty. So, for the visual search task, for example, participants looked for the letter Z in an array of similar or dissimilar (difficult condition) letters. The researchers hypothesised that participants with Alzheimer's disease would perform significantly more poorly than the control group at the difficult versions of the tasks.

The experimenters found that whereas both groups were impaired at the normal and difficult versions of the choice reaction time task, there was no significant difference between the two groups, indicating that this type of attention may be relatively immune to the effects of Alzheimer's disease. The ability to ignore distractors in a visual search exercise, however, was significantly impaired in Alzheimer's disease (although both demented and old performed worse than the young). The greatest effect of the disease was found in the dual-task exercise: performance on this task was significantly worse in the Alzheimer group than the control group.

The results suggest that attention is not globally affected by Alzheimer's disease – providing evidence against the unitary hypothesis – but that there is selective impairment in attention, specifically divided attention.

As well as selective impairments in attention, people with Alzheimer's disease also experience other subtle and more pronounced difficulties. Memory impairments – such as disorientation over finding their homes, forgetting people's names and faces, and not being able to follow the flow of a conversation – are key features. The inability to comprehend sentences, however, is more subtle and some psychologists have suggested that this deficit stems not from some linguistic problem or decline but from a work-

The author Terry Pratchett, who has been diagnosed with dementia of the Alzheimer type.

ing memory impairment, similar to that seen when failing to follow conversation (Baddeley *et al.*, 1991). In 2003, the journalist and critic Adrian Gill wrote an article about his father, who suffers from Alzheimer's disease. Gill wrote:

Conversations with Daddy are like talking to someone who can travel through walls. In the middle of a sentence, he can be somewhere else. I have to open empirical, rational doors to follow him. He glides through time and subjects in a way that logic and language prevent me. It's a sort of itinerant freedom.

Dementia and the novelist: the case of Iris Murdoch

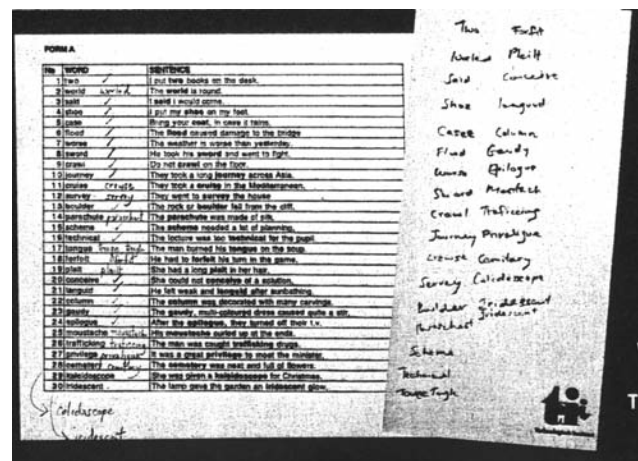

Fellow novelist A.S. Byatt spared no sensitivity when she reviewed Iris Murdoch's last novel, *Jackson's Dilemma*. The book, Byatt averred, was 'an Indian rope trick . . . in which all the people have no selves and therefore there is no story and no novel'. Murdoch, however, was no novelistic novice. In 1978, she won the Booker Prize for *The Sea, The Sea* and was made Dame Commander of the British Empire in 1987 in recognition of her contribution to literature. Published criticism is an occupational hazard in the novelist's world but Byatt's criticism may have unwittingly reflected an organic, rather than creative, decline. Murdoch was diagnosed with Alzheimer's disease at the age of 76, just after she had finished writing *Jackson's Dilemma*; a post-mortem three years later confirmed the diagnosis.

Following the diagnosis of suspected AD, Garrard *et al.* (2005) monitored structural changes in Murdoch's brain, as part of her neurological assessment. In 1997, there was evidence of global atrophy, especially in the hippocampus (bilaterally), as seen in Figure 11.18 (a). You can see examples of her neuropsychological performance in Figure 11.18 (b).

When *Jackson's Dilemma* was published in 1995, the author had suffered severe writer's block and had become unexpectedly inarticulate at a question and answer session with the public a year later. The following summer, she was only able to describe her surroundings by reference to a city name and was unable to subtract or spell backwards. Her picture naming became circumlocutory: a bus was described as 'something carried along'; and her spelling became regularised. She would spell cruise as 'crewse', for example. Her retrograde memory was profoundly impaired and her narrative speech was grammatical but lacked real content. For example: 'the girl is just holding a plate and various pieces of . . . well . . . something useful . . . standing at a window . . .

(a)

(b)

The effects of very early Alzheimer's disease on the characteristics of writing by a renowned author, in *Brain*, 2005, 128, pp. 250–60, by permission of Oxford University Press and Peter Garrard. (c) Bassouls Sophie/CORBIS Sygma.

whether the window is open is not quite clear to me. The thing where the water is running out. The girl doesn't bother. The window is open. Plate and two cups.'

Murdoch's disorder afforded Garrard *et al.* the opportunity to examine any relationship between the novelist's intellectual decline and the external manifestation of that decline – her final novel. The novelist regarded the work as being a true reflection of her output and requested no alterations be made to the text. Garrard *et al.* compared the vocabulary, syntax, grammatical class and lexical differences in this novel, in *Under the Net* (published in 1954) and in *The Sea, The Sea*.

The researchers found that her vocabulary was rich and innovative in the early work but was impoverished in the final novel. The number of words and class of words per sentence (ten sentences were taken from the first, middle and final chapters of each novel) was smallest in the last novel. There was no difference in word length between the novels but the final work contained more high frequency words, reflecting a decline in linguistic innovation. The use of high frequency words is, according to Garrard *et al.*, typical of temporal lobe pathology.

In a sense, of course, these data are correlational. The final novel exhibited the features described here and these features coincided with the development of the author's degenerative disease. Nonetheless, the data obtained from the analysis of the author's physical output reflects the behaviour observed by those closest to her.

Treatment for DAT

Is Alzheimer's disease reversible? The cost of caring for patients with DAT in the UK alone is estimated to be between £5 billion and £15 billion a year (Lowin *et al.*, 2001; McNamee *et al.*, 2001) but no treatment is able to halt the progress of the disease. Those treatments that have been attempted have focused on alleviating the memory impairments in DAT. The cholinergic hypothesis of Alzheimer's disease led to the development of drugs that specifically sought to redress the loss of cholinergic neurons and neurotransmitters (called cholinesterase inhibitors). Currently, five drugs have been approved for use by the US Drug and Food Administration (Robertson and Mucke, 2006). The mechanism of action for these drugs is the inhibition of the enzyme acetylcholinesterase, which divides the neurotransmitter at its receptors (Bullock, 2002). Three compounds currently used are donepezil, rivastigmine and galantamine.

Patients who have been given a course of either donepezil or rivastigmine have shown some improvement in memory performance (Cameron *et al.*, 2000; Evans *et al.*, 2000). Other drugs under review are anti-inflammatory drugs (because the incidence of Alzheimer's disease is

low in sufferers of rheumatoid arthritis who take these drugs) and antioxidants such as vitamin E. Neither, however, has been shown to demonstrate consistent efficacy (Bullock, 2002). Perhaps the most innovative treatment under investigation involves vaccinating the individual, thereby giving them an antibody to remove the amyloid protein that causes cell degeneration. Trials in mice have been effective in relieving symptoms of the disease and in preventing the development of plaques (Schenk *et al.*, 1999) but there is no such vaccine for humans, as yet.

Thinking

One of the most important components of cognition is thinking: categorising, reasoning and solving problems. When we think, we perceive, classify, manipulate, and combine information. When we are finished, we know something we did not know before (although our 'knowledge' may be incorrect).

The purpose of thinking is, in general, to solve problems. These problems may be simple classifications (What is that, a bird or a bat?); they may involve decisions about courses of actions (Should I buy a new car or pay to fix the old one?); or they may require the construction, testing and evaluation of complex plans of action (How am I going to manage to earn money to continue my education so that I can get out of this dead-end job, and still be able to enjoy life?). Much, but not all, of our thinking involves language. We certainly think to ourselves in words, but we also think in shapes and images. And some of the mental processes that affect our decisions and plans take place without our being conscious of them. Thus, we will have to consider non-verbal processes as well as verbal ones (Reber, 1992; Holyoak and Spellman, 1993).

Classifying

When we think, each object or event is not considered as a completely independent entity. Instead, we classify things – categorise them according to their characteristics. Then, when we have to solve a problem involving a particular object or situation, we can use information that we have already learned about similar objects or situations. To take a very simple example, when we enter someone's house for the first time, we recognise chairs, tables, sofas, lamps and other pieces of furniture even though we may never have seen these particular items before. Because we recognise these categories of objects, we know where to sit, how to increase the level of illumination, and so on.

Concepts are categories of objects, actions or states of being that share some attributes: cat, comet, team, destroying, playing, forgetting, happiness, truth, justice. Most thinking deals with the relations and interactions among concepts. For example, ‘the hawk caught the sparrow’ describes an interaction between two birds; ‘studying for an examination is fun’ describes an attribute of a particular action; and ‘youth is a carefree time of life’ describes an attribute of a state of being.

Concepts exist because the characteristics of objects have consequences for us. For example, angry dogs may hurt us, whereas friendly dogs may give us pleasure. Dangerous dogs tend to growl, bare their teeth and bite, whereas friendly dogs tend to prance around, wag their tails and solicit our attention. Thus, when we see a dog that growls and bares its teeth, we avoid it because it may bite us; but if we see one prancing around and wagging its tail, we may try to pat it. We have learned to avoid or approach dogs who display different sorts of behaviour through direct experience with dogs or through the vicarious experience of watching other people interact with them. The point is, we can learn the concepts of dangerous and friendly dogs from the behaviour of one set of dogs while we are young and respond appropriately to other dogs later in life. Our experiences with particular dogs generalise to others.

Formal and natural concepts

Formal concepts are defined by listing their essential characteristics, as a dictionary defini-

tion does. For example, dogs have four legs, a tail, fur and wet noses; are carnivores; can bark, growl, whine and howl; pant when they are hot; bear live young; and so on. Thus, a formal concept is a sort of category that has rules about membership and non-membership.

Psychologists have studied the nature of formally defined concepts, such as species of animals. Collins and Quillian (1969) suggested that such concepts are organised hierarchically in semantic memory. Each concept has associated with it a set of characteristics. Consider the hierarchy of concepts relating to animals shown in Figure 11.19. At the top is the concept ‘animal’, with which are associated the characteristics common to all animals, such as ‘has skin’, ‘can move around’, ‘eats’, ‘breathes’ and so on. Linked to the concept ‘animal’ are groups of animals, such as birds, fish and mammals, along with their characteristics. These hierarchies are illustrated by Figure 11.19.

Collins and Quillian assumed that the characteristics common to all members of a group of related concepts (such as all birds) were attached to the general concept (in this case bird) rather than to all the members. Such an arrangement would produce an efficient and economical organisation of memory. For example, all birds have wings. Thus, we need not remember that a canary, a jay, a robin and an ostrich all have wings; we need only remember that each of these concepts belong to the category of bird and that birds have wings.

Collins and Quillian tested the validity of their model by asking people questions about the characteristics of

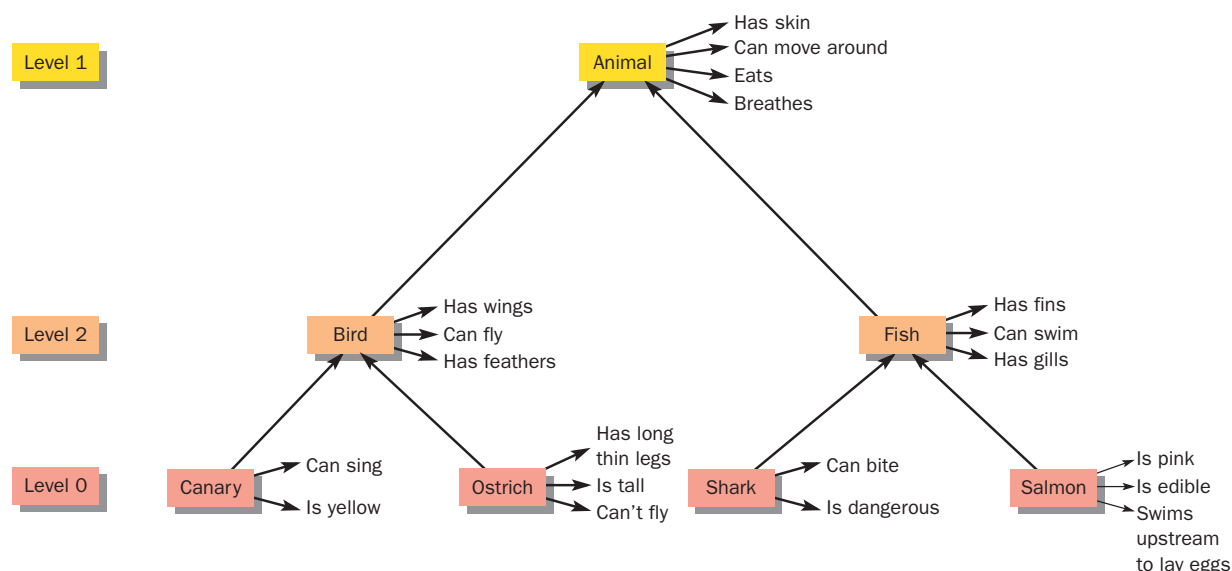

Figure 11.19 Collins and Quillian’s model of the hierarchical organisation of concepts in semantic memory.

Source: From Robert L. Solso, *Cognitive Psychology*, 2nd edn. Published by Allyn & Bacon, Boston, MA. Copyright © 1988 by Pearson Education. By permission of the publisher.

various concepts. Consider the concept ‘canary’. The investigators asked people to say true or false to statements such as, ‘A canary eats’. When the question dealt with characteristics that were specific to the concept (such as ‘can sing’, or ‘is yellow’), the subjects responded quickly. If the question dealt with a characteristic that was common to a more general concept (such as ‘has skin’ or ‘breathes’), the subjects took a longer time in answering. Presumably, when asked a question about a characteristic that applied to all birds or to all animals, the participants had to ‘travel up the tree’ from the entry for canary until they found the level that provided the answer. The further they had to go, the longer the process took.

The model above is attractive but it does not reflect realistically the way in which we classify concepts and their characteristics. For example, although people may conceive of objects in terms of a hierarchy, a particular person’s hierarchy of animals need not resemble that compiled by a zoologist. For example, Rips *et al.* (1973) found that people said yes to ‘A collie is an animal’ faster than they did to ‘A collie is a mammal’. According to Collins and Quillian’s model, animal comes above mammal in the hierarchy, so the results should have been just the opposite.

Although some organisation undoubtedly exists between categories and subcategories, it appears not to be perfectly logical and systematic. For example, Roth and Mervis (1983) found that people judged Chablis to be a better example of wine than of drink, but they judged champagne to be a better example of drink than of wine. This inconsistency clearly reflects people’s experience with the concepts. Chablis is obviously a wine: it is sold in bottles that resemble those used for other wines, it looks and tastes similar to other white wines, the word ‘wine’ is found on the label, and so on. By these standards, champagne appears to stand apart. A wine expert would categorise champagne as a particular type of wine. But the average person, not being particularly well acquainted with the fact that champagne is made of fermented grape juice, encounters champagne in the context of something to drink on a special occasion, something to launch ships with, and so on. Thus, its characteristics are perceived as being rather different from those of Chablis.

Rosch (1975; Mervis and Rosch, 1981) suggested that people do not look up the meanings of concepts in their heads in the way that they seek definitions in dictionaries. The concepts we use in everyday life are natural concepts, not formal ones discovered by experts who have examined characteristics we are not aware of. **Natural concepts** are based on our own perceptions and interactions with things in the world. For example, some things have wings, beaks and feathers, and they fly, build nests, lay eggs and make high-pitched noises. Other things are furry, have four legs and a tail, and run around on the

ground. Formal concepts consist of carefully defined sets of rules governing membership in a particular category; natural concepts are collections of memories of particular examples that share some similarities. Formal concepts are used primarily by experts (and by people studying to become experts), whereas natural concepts are used by ordinary people in their daily lives.

Rosch suggests that people’s natural concepts consist of collections of memories of particular examples, called **exemplars**, that share some similarities. The boundaries between formal concepts are precise, whereas those between natural concepts are fuzzy – the distinction between a member and a non-member is not always clear. Thus, to a non-expert, not all members of a concept are equally good examples of that concept. A robin is a good example of bird; a penguin or ostrich is a poor one. We may acknowledge that a penguin is a bird because we have been taught that it is, but we often qualify the category of membership by making statements such as ‘strictly speaking, a penguin is a bird’. Exemplars represent the important characteristics of a category – characteristics that we can easily perceive or that we encounter when we interact with its members.

According to Rosch *et al.* (1976), natural concepts vary in their level of precision and detail. They are arranged in a hierarchy from very detailed to very general. When we think about concepts and talk about them, we usually deal with **basic-level concepts** – those that make important distinctions between different categories – but do not waste time and effort with those that do not matter. For example, chair and apple are basic-level concepts. Concepts that refer to collections of basic-level concepts, such as furniture and fruit, are called **superordinate concepts**. Concepts that refer to types of items within a basic-level category, such as deckchair and Granny Smith’s, are called **subordinate concepts**. These can be seen in Figure 11.20.

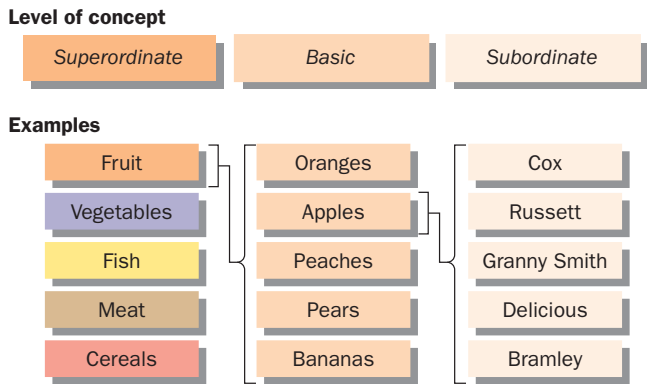

Figure 11.20 Examples of basic-level, subordinate and superordinate concepts.

The basic-level concept tends to be the one that people spontaneously name when they see a member of the category. That is, all types of chair tend to be called 'chair', unless there is a special reason to use a more precise label. People tend to use basic-level concepts for a very good reason: cognitive economy. The use of subordinate concepts wastes time and effort on meaningless distinctions, and the use of superordinate concepts loses important information. Rosch *et al.* (1976) presented people with various concepts and gave them 90 seconds to list as many attributes as they could for each of them. The subjects supplied few attributes for superordinate concepts but were able to think of many for basic-level concepts.

Subordinate concepts evoked no more responses than basic-level concepts did. Thus, because they deal with a large number of individual items and their characteristics, basic-level concepts represent the maximum information in the most efficient manner. When people think about basic-level concepts, they do not have to travel up or down a tree to find the attributes that belong to the concept. The attributes are directly attached to the exemplars that constitute each concept.

It is important to recognise that concepts can represent something more complex than simple exemplars or collections of attributes. Goldstone *et al.* (1991) showed participants groups of figures and asked them to indicate which were most similar to each other. When they showed the participants two triangles, two squares and two circles, the subjects said that the squares and triangles were most similar, presumably because both contained straight

lines and angles. However, when they added a square to each of the pairs, the participants said that the two most similar groups were the triangles plus square and the circles plus square. The task is illustrated by Figure 11.21.

The concept this time was 'two things and a square'. If the participants were simply counting attributes, then the addition of a square to the pairs should not have changed their decision. As this study shows very clearly, concepts can include relations among elements that cannot be described by counting attributes.

Concepts are the raw material of thinking; they are what we think about. But thinking itself involves the manipulation and combination of concepts. Such thinking can take several forms, but the most common forms are deductive reasoning and inductive reasoning.

Deductive reasoning

Deductive reasoning consists of inferring specific instances from general principles or rules. For example, the following two series of sentences express deductive reasoning:

John is taller than Phil
Sue is shorter than Phil
Therefore, John is taller than Sue
All mammals have fur
A bat is a mammal
Therefore, a bat has fur

Deductions consist of two or more statements from which a conclusion is drawn. The first group of sentences presented above involves the application of a simple mathematical principle. The second group presents a syllogism. The syllogism, a form of deductive logic invented by Aristotle, is often found in tests of intelligence. A syllogism is a logical construction that consists of a major premise (for example, 'all mammals have fur'), a minor premise ('a bat is a mammal'), and a conclusion ('a bat has fur'). The major and minor premises are assumed to be true. The problem is to decide whether the conclusion is true or false.

People differ widely in their ability to solve syllogisms. For example, many people would agree with the conclusion of the following syllogism:

All mammals have fur
A zilgid has fur
Therefore, a zilgid is a mammal

Figure 11.21 Concept formation. Participants were asked which of the groups of shapes were most similar. **(a)** Three pairs of geometrical shapes. **(b)** The same shapes with the addition of squares.

These people would be wrong; the conclusion is not warranted. The major premise says only that all mammals have fur. It leaves open the possibility that some animals that have fur are not mammals.

Mental models

Why are some people better than others at solving syllogisms? Johnson-Laird (1985) notes that syllogistic reasoning is much more highly correlated with spatial ability than with verbal ability. Spatial ability includes the ability to visualise shapes and to manipulate them mentally. Why should skill at logical reasoning be related to this ability? Johnson-Laird and his colleagues (Johnson-Laird and Byrne, 1991; Johnson-Laird *et al.*, 1992) suggest that people solve problems involving logical deduction by constructing **mental models**, mental constructions based on physical reality. When faced with a reasoning problem, people will generate a mental model of the puzzle and see

what conclusions they can draw from parts of the mental model. They search for alternative models that might contradict the conclusion reached from the initial model; but if this falsification is not forthcoming, the conclusion is accepted. If the alternative model does falsify the conclusion reached by previous reasoning, the search goes on for an alternative model which may help us to reach the correct conclusion. For example, if you consider the following problem:

A is less than C
B is greater than C
Is B greater than A?

in order to compare A with B, you must remember the order of the three elements. One kind of mental model is an imaginary line going from small to large in which you mentally place each item on the line as you encounter it.

Syllogistic reasoning – An international perspective

Several studies have suggested that illiterate, unschooled people in remote villages in various parts of the world are unable to solve syllogistic problems. Scribner (1977) visited two tribes of people in Liberia, West Africa – the Kpelle and the Vai – and found that tribespeople gave what Westerners would consider to be wrong answers. However, the people were not unable to reason logically but approached problems differently. For example, she presented the following problem to a Kpelle farmer. At first glance, the problem appears to be a reasonable one even for an illiterate, unschooled person because it refers to his own tribe and to an occupation he is familiar with.

All Kpelle men are rice farmers

Mr Smith is not a rice farmer

Is he a Kpelle man?

The man replied:

Participant: I don't know the man in person. I have not laid eyes on the man himself.

Experimenter: Just think about the statement.

Participant: If I know him in person, I can answer that question, but since I do not know him in person, I cannot answer that question.

Experimenter: Try and answer from your Kpelle sense.

Participant: If you know a person, *if a question comes up* about him you are able to answer. But if you do not know

the person, if a question comes up about him it's hard for you to answer.

Source: Scribner (1977), p. 490.

The farmer's response did not show that he was unable to solve a problem in deductive logic. Instead, it indicated that as far as he was concerned, the question was unreasonable. In fact, his response contained an example of logical reasoning: 'If you know a person . . . you are able to answer.'

Scribner found that illiterate people would sometimes reject the premises of her syllogism, replace them with what they knew to be true, and then solve the new problem, as they had defined it. For example, she presented the following problem to a Vai tribesperson.

All women who live in Monrovia are married

Kemu is not married

Does she live in Monrovia?

The answer was yes. The respondent said, 'Monrovia is not for any one kind of people, so Kemu came to live there.' The suggestion that only married women live in Monrovia was absurd, because the tribesperson knew otherwise. Thus, if Kemu wanted to live there, she could – and did.

Clearly, the intellectual ability of people in other cultures cannot be measured against Western standards. In the world of traditional tribal people, problems are solved by application of logical reasoning to facts gained through direct experience. Their deductive-reasoning ability is not necessarily inferior, it is simply different, pragmatic.

Then, with all three elements in a row, you can answer the question. Figure 11.22 illustrates this.

In fact, when we solve problems concerning comparisons of a series of items, we tend to think about our own mental model that represents the information rather than about the particular facts given to us (Potts, 1972). For example, consider this passage:

After reading this passage, people can more easily answer

Although the four craftsmen were brothers, they varied enormously in height. The electrician was the very tallest, and the plumber was shorter than him. The plumber was taller than the carpenter, who, in turn, was taller than the painter.

Source: Just and Carpenter (1987), p. 202.

questions about pairs of brothers who largely differ in height. For example, they are faster to answer the question, ‘Who is taller, the electrician or the painter?’ than the question, ‘Who is taller, the plumber or the carpenter?’ This finding is particularly important because the passage explicitly states that the plumber was taller than the carpenter, but one must infer that the electrician was taller than the painter. Just and Carpenter’s study shows that the result of an inference can be more readily available than information explicitly given. How can this be? The most plausible explanation is that when people read the passage, they construct a mental model that represents the four brothers arranged in order of height. The painter is clearly the shortest and the electrician is clearly the tallest. Thus, a comparison between the extremes can be made very quickly.

The type of syllogistic reasoning described in the previous section does not always lead to an alternative model being sought. Many reasoners rarely go beyond the initial model they construct (Evans *et al.*, 1999). Participants in Evans *et al.*’s experiment, for example, were more likely to accept conclusions that were consistent with their original model and reject conclusions that were inconsistent rather than construct a more accurate, reasonable model. This lack of ability to search for alternative models and accept conclusions that are inconsistent with the original mental models can have serious consequences for us, especially if people are making judgements about our character, demeanour and conduct. Nowhere is this more important than when judgements are made against a person accused of a crime in a court trial. In a later section, you will see how juries appear to make their decisions (and the factors that can affect the nature of this decision-making) and how biases in jurors’ reasoning can affect their verdict.

Figure 11.22 A mental model. Logical problems are often solved by imagining a physical representation of the facts.

Many creative scientists and engineers report that they use mental models to reason logically and solve practical and theoretical problems (Krueger, 1976). For example, the American physicist and Nobel laureate Richard Feynman said that he used rather bizarre mental models to keep track of characteristics of complex mathematical theorems to see whether they were logical and consistent. Here is how Feynman described his thought processes (1985, p. 70):

When I’m trying to understand . . . I keep making up examples. For instance, the mathematicians would come in with a . . . theorem. As they’re telling me the conditions of the theorem, I construct something that fits all the conditions. You know, you have a set [one ball] – disjoint [two balls]. Then the balls turn colours, grow hairs, or whatever, in my head as they [the mathematicians] put more conditions on. Finally, they state the theorem, which is some . . . thing about the ball which isn’t true for my hairy green ball thing, so I say ‘False!’

Such use of mental models by a talented and gifted scientist strengthens the conclusion that being able to convert abstract problems into tangible mental models is an important aspect of intelligent thinking.

There is some controversy in cognitive psychology at the moment regarding the spontaneity of people's search for alternative models.

Inductive reasoning

Deductive reasoning involves applying the rules of logic to infer specific instances from general principles or rules. This type of reasoning works well when general principles or rules have already been worked out. **Inductive reasoning** is the opposite of deductive reasoning; it consists of inferring general principles or rules from specific facts. In one well-known laboratory example of inductive reasoning, participants are shown cards that contain figures differing in several dimensions, such as shape, number and colour (Milner, 1964). On each trial, they are given two cards and asked to choose the one that represents a particular concept. After they choose a card, the experimenter indicates whether the decision is correct or not. The task is illustrated in Figure 11.23.

One trial is not enough to recognise the concept. If the first trial reveals that a card is correct, then the concept could be red, or four or triangle, or some combination of these, such as red triangle, four red shapes, or even four red triangles. Information gained from the second trial allows the subject to rule out some of these hypotheses – for example, shape does not matter, but colour and number do. The participant uses steps to solve the problem in much the same way as a scientist does: they form a hypothesis on the basis of the available evidence and test

that hypothesis on subsequent trials. If it is proved false, it is abandoned, a new hypothesis consistent with what went before is constructed and this new hypothesis is tested.

Logical errors in inductive reasoning

Psychologists have identified several tendencies that interfere with people's ability to reason inductively. These include the failure to select the information they need to test a hypothesis, the failure to seek information that would be provided by a comparison group, and the disinclination to seek evidence that would indicate whether a hypothesis is false.

Failure to select relevant information

When reasoning inductively, people often fail to select the information they need to test a hypothesis. For example, consider the following task, from an experiment by Wason and Johnson-Laird (1972):

Your job is to determine which of the hidden parts of these cards you need to see in order to answer the following question decisively:

For these cards is it true that if there is a vowel on one side there is an even number on the other side?

You have only one opportunity to make this decision; you must not assume that you can inspect the cards one at a time. Name those cards which it is absolutely essential to see.

Figure 11.23 A card sorting task. Participants are asked to sort cards according to a given criterion, such as colour or shape, that is unknown to them. After they have successfully determined this criterion, it is unexpectedly and unknowingly changed and the participant has to determine the new sorting criterion.

Source: From Pinel, P.J., *Biopsychology*, 3rd edn © 1997. Published by Allyn and Bacon, Boston, MA. Copyright © by Pearson Education. By permission of the publisher.

The participants were shown four cards like those in Figure 11.24. Most people say that they would need to see card (a), and they are correct. If there was not an even number on the back of card (a), then the rule is not correct. However, many participants failed to realise that card (d) must also be inspected. True, there is no even number on this card, but what if there is a vowel on the other side? If there is, then the rule is (again) proved

Figure 11.24 Cards used in a formal test of problem-solving.

wrong. Many participants also wanted to see card (c), but there is no need to do so. The hypothesis says nothing about whether an even number can be on one side of the card without there being a vowel on the other side.

People have to be taught the rules of logic; they do not automatically apply them when trying to solve a problem. But under certain circumstances, most people do reason logically. For example, Griggs and Cox (1982) presented a slightly different version of this test. They asked people to decide which cards should be checked to see whether the following statement was true: 'If a person is drinking beer, she must be over age 19.' The cards represented people; their age was on one side and their drink (beer or Coke) was on the other. Which card(s) would you check? (See Figure 11.25.)

Most participants correctly chose cards (a) and (d). They knew that if someone were drinking beer, she must be old enough. Similarly, if someone were 16 years old, we must check to see what she was drinking. The subjects readily recognised the fact that we do not need to know the age of someone drinking Coke, and someone 22 years old can drink whatever beverage she prefers. This study shows that experiments using puzzles designed to test people's reasoning ability do not always assess their ability to apply a logical rule to a practical situation.

In everyday life, people may commit biases in reasoning despite evidence showing that their reasoning is incorrect. The controversy in the UK concerning the possible role of the triple MMR (measles, mumps and rubella) vaccine in autism is an example of this. Some parents regard the multiple vaccination as potentially dangerous to their child and request single vaccines (one each for each of the infections). The reasoning is based on evidence from a study in which 12 children who received the MMR vaccine developed gut problems and symptoms of a developmental disorder called autism in which the child becomes withdrawn and does not engage in social and emotional communication. Other, larger, more sophisticated studies reporting no negative effect of the vaccine on child development did little to dispel the belief that MMR might cause autism.

Figure 11.25 Cards used in a more realistic version of the problem-solving test.

This real-life example mirrors findings from the laboratory. In fact, laboratory studies try to investigate why some people commit these biases in reasoning and decision-making. In one study, participants were presented with hypothetical social reforms that would benefit the majority of people but would leave a small minority less well off (Baron and Jurney, 1993). Although participants agreed that such social policy decisions would be beneficial to all people, they voted against the proposals because some people might be worse off. This type of reasoning may explain why politicians behave in the way that they do.

Failure to utilise a comparison group

Another tendency that interferes with people's ability to reason inductively is their failure to consider a comparison group. Imagine that you learn that 79 per cent of the people with a particular disease get well within a month after taking a new, experimental drug (Stich, 1990). Is the drug effective? The correct answer to this question is: we cannot conclude anything – we need more information. What we need to know is what happens to people with the disease if they do not take the drug. If we find that only 22 per cent of these people recover within a month, then we would conclude that the drug is effective; 79 per cent is much greater than 22 per cent. On the other hand, if we find that 98 per cent recover without taking the drug, then we would conclude that the drug is worse than useless – it actually interferes with recovery. In other words, we need a control group. But most people are perfectly willing to conclude that, because 79 per cent seems like a high figure, the drug must work. Seeing the necessity for a control group does not come naturally; unless people are deliberately taught about control groups, they will not realise the need for them.

Failure to seek or use information that would be provided by a control group has been called ignoring base rate information. As several researchers have suggested, the problem here may be that we engage in two types of reasoning (Reber, 1992; Evans *et al.*, 1996; Stanovich, 1999). One type of reasoning is deliberate and conscious and involves explicit memories of roles that we can describe verbally. The other type of reasoning is unconscious and uses information we have learned implicitly. Because the explicit and implicit memory systems involve at least some different brain mechanisms, information from one system cannot easily interact with information from the other system. One of the most serious consequences of this reasoning error can be seen in so-called pseudo-diagnosticity tasks (Doherty *et al.*, 1979). This task involves making a medical diagnosis and is presented in the following way:

A patient shows symptom A which is present in 95 per cent of patients suffering from disease B.

Does this give grounds to suspect that the patient is suffering from disease B?

This decision can only be made by considering whether symptom A is also present in other illnesses; that is, the person must be aware of the base rate likelihood of disease B occurring relative to other diseases. If symptom A is present in other diseases, the data presented above do not give good grounds for an exclusive diagnosis of disease B. People who are untrained reasoners usually fail to consider this possibility: they are not sensitive to base rate information (Evans *et al.*, 2002).

If people are allowed to observe actual occurrences of certain events (that is, acquire the information about the base rate of occurrence automatically and implicitly), however, they can consider information about event frequency (Holyoak and Spellman, 1993). Furthermore, if people are given explicit instructions to consider alternative hypotheses, they will make decisions that take these alternative hypotheses into account (Klayman and Brown, 1993; Evans *et al.*, 2002).

Confirmation bias

Individuals may also show a disinclination to seek evidence that would indicate whether a hypothesis is false. Instead, people tend to seek evidence that might confirm their hypothesis; they exhibit the **confirmation bias**. For example, Wason (1968) presented people with the series of numbers '2, 4, 6' and asked them to try to figure out the rule to which they conformed. The participant was to test their hypothesis by making up series of numbers and saying them to the experimenter, who would reply yes or no. Then, whenever the participant decided that enough information had been gathered, they could say what the hypothesis was. If the answer was correct, the problem was solved. If it was not, the participant was to think of a new hypothesis and test that one.

Several rules could explain the series '2, 4, 6'. The rule could be 'even numbers', or 'each number is two more than the preceding one', or 'the middle number is the mean of the first and third number'. When people tested their hypotheses, they almost always did so by presenting several sets of numbers, all of which were consistent with their hypotheses. For example, if they thought that each number was two more than the preceding one, they might say '10, 12, 14' or '61, 63, 65'. Very few participants tried to test their hypotheses by choosing a set of numbers that did not conform to the rules, such as '12, 15, 22'. In fact,

the series '12, 15, 22' does conform to the rule. The rule was so simple that few participants figured it out: each number must be larger than the preceding one.

The confirmation bias is very strong. Unless people are taught to do so, they tend not to think of possible non-examples of their hypotheses and to see whether they might be true – the way that scientists do. But, in fact, evidence that disconfirms a hypothesis is conclusive, whereas evidence that confirms it is not.

The confirmation bias in inductive reasoning has a counterpart in deductive reasoning. For example, consider the following sentences (Johnson-Laird, 1985):

All the pilots are artists

All the skiers are artists

True or false: All the pilots are skiers

Many people say 'true'. They test the truth of the conclusion by imagining a person who is a pilot and an artist and a skier – and that person complies with the rules. Therefore, they decide that the conclusion is true. But if they would try to disconfirm the conclusion – to look for an example that would fit the first two sentences but not the conclusion – they would easily find one. Could a person be a pilot but not a skier? Of course; the first two sentences say nothing to rule out that possibility. There are artist-pilots and there are artist-skiers, but nothing says that there must be artist-pilot-skiers.

The tendency to seek (and to pay more attention to) events that might confirm our beliefs is demonstrated by the way we have distorted the original meaning of the saying, 'the exception proves the rule'. Most people take this to mean that we can still consider a rule to be valid even if we encounter some exceptions. But that conclusion is illogical: if there is an exception, the rule is wrong. In fact, the original meaning of the phrase was, 'the exception tests the rule', which it does. The word 'prove' comes from the Latin *probare*, 'to test'.

Sure-thing principle

The sure thing principle states that if you believe that you prefer A to B in all states of the world, then you should prefer A to B in any state of the world (Hardman and Harries, 2002). Usually, when people commit violations of the principle, it indicates an inability to think through a problem or situation. For example, Shafir *et al.* (1993) asked students to imagine they were waiting for exam results and to plan for two outcomes: making a deposit for a holiday and deferring a decision on whether to go on holiday until after the exam results are published, or booking a cheap holiday immediately. Students who were told their

Cutting edge – Who believes in spoon bending?

‘Would any one in the audience who believes in telepathy, please put my hand up’, asked Emo Phillips in one of his stand-up routines. This chapter, as well as Chapter 15, shows that people can make very poor reasoners and can make ineffective use of evidence to make judgements or inform decisions. Our decisions are affected by our own biases, personal beliefs and convictions. A recent review has highlighted some of these elementary reasoning errors in people who are convinced of their belief in something a little strange: psychic ability (Wiseman and Watt, 2006).

The two commonest types of psychic ability are extra-sensory perception (ESP) and psychokinesis. ESP is the ‘apparent ability to receive information via a channel of communication not presently recognised by mainstream science and includes alleged clairvoyance, telepathy and precognition (in which the information related to a future event)’. Psychokinesis is the ‘apparent ability to influence physical objects and biological systems using unknown means, and encompasses a wide range of alleged phenomena, including causing objects to levitate, dice to roll at above chance levels and paranormal healing’. Is there something defective or unusual about the reasoning of the people who believe in such things?

Some psychologists have argued that believers in the paranormal have poor cognitive ability because they misattribute

psychic causes to normal or natural phenomena – they cannot see a simple relationship between physical cause and effect (Alcock, 1981; Blackmore, 1992). There is some evidence of lower academic achievement in these individuals but the overall results are inconsistent.

People from the humanities are more likely to believe in psychic phenomena than are those with a science background but one study found that students of biology were greater believers than those from the humanities (Salter and Routledge, 1971). When asked to be critically evaluative of mock science papers, believers are less critical than non-believers (Gray and Mill, 1990). They are also poor at understanding probability. For example, if asked whether throwing 10 dice at the same time and getting 10 sixes is more or less likely than throwing one die 10 times and obtaining 10 sixes, believers underestimate the statistical likelihood (Musch and Ehrenberg, 2002). Believers are also more likely to see patterns in series of random dots (Blackmore and Moore, 1994) and to be prone to fantasy. ‘The more the individual possesses the ability to find connections between their experiences and actual events,’ writes Blackmore (1992), ‘the more likely they are to view their experiences as psychic.’

result booked a holiday, whether the result was a pass or a fail. Students who were not told, however, elected to pay a small deposit and decide whether to go when the results were published. The evidence showed that even if those who deferred their holiday knew they had failed or passed, they would have booked the holiday. If they booked the holiday whatever their results were, why did they defer the holiday when they did not know the results?

Probability heuristic

The probability heuristic is similar to the confirmation bias in the sense that it shows how people can draw conclusions based on what they believe rather than on available evidence. The difference between them is that the probability heuristic shows how people can draw erroneous conclusions by not taking into account the probability of an outcome (Kahneman *et al.*, 1982; Tversky and Kahneman, 1983). The example in Table 11.6 illustrates the concept. Read through the example now and then come back to the text to see how you did.

In what position in life did you place Linda? If you responded like those participants in the original experiment, you would be significantly less likely to indicate that Linda was a bank teller than a bank teller and a feminist.

For some reason, people were not likely to consider bank tellers to be active feminists (or vice versa), thereby ignoring the principles of probability. This type of error, called a

Table 11.6 The Linda problem

Linda is 31 years old, single, outspoken and very bright. She majored in philosophy. As a student, she was deeply concerned with issues of discrimination and social justice, and also participated in anti-nuclear demonstrations.

Please rank the following by their probability, using 1 for the most probable and 8 for the least probable.

- A Linda is a teacher in primary school
- B Linda works in a bookstore and takes yoga classes
- C Linda is an attractive feminist
- D Linda is a psychiatric social worker
- E Linda is a member of Woman Against Rape
- F Linda is a bank teller
- G Linda is an insurance salesperson
- H Linda is a bank teller and is an active feminist

Source: Tversky, A. and Kahneman, D., Extensional versus intuitive reasoning: Conjunction fallacy in probability judgement. *Psychological Review*, 1983, 90, 293–315, © 1983 by the American Psychological Association, reprinted with permission.

conjunction error, is reduced when the initial description of the person is followed by text stating that 100 people fit the description they have read and the reader is asked how many of them are bank tellers and bank tellers and active feminists. When led in this way, people do not commit errors in reasoning that take little account of probability; without such guidance, these errors are committed.

An example of real-life decision-making is seen every time a juror reaches a verdict in a trial. Jurors' decisions carry great weight and in some cases can determine whether a person lives or dies. The Psychology in Action box describes some of the factors that can influence a juror's decision-making and tries to explain how jurors reach their decisions.

Cutting edge – How eBay works

Ever wondered why you missed out on that item you bid for on eBay? Why you were outbid, maybe at the last minute? Reasoning can often be tossed overboard in auctions because people's desire for an item, coupled with competition for that item, means that people will pay much more than the item is intrinsically worth. Researchers at the London Business School and Northwestern University in the USA sought to see what determines winning bids on internet auctions sites, like eBay, and whether the behaviour of bidders followed economic and logical rules (Ku *et al.*, 2006).

In a series of experiments, they used data collected from actual auctions (for shirts, rugs and cameras) run by sellers on eBay. They found that the greatest determinant of a high winning bid was a low starting price. So, for example, an item with

a starting bid of \$1 would attract more 'traffic' (i.e. bids) and a higher final price than would one with a starting price of \$20. Despite the fact that bidders ought to reduce the maximum amount of their bid as the number of bids for an item increases, they failed to.

Of course, if you saw a holiday advertised at \$1, this might ring alarm bells. Apart from the authenticity of the offer, you might question the value of the product or item. And this is what the researchers found. A low starting price affected the perception of the item's value, but because the amount of traffic attracted to the low price increased, the increase in bids means that the price was pushed up. This increase led to a re-evaluation of the item as valued.

Psychology in action – Jury decision-making

Trial by jury itself, instead of being a security to persons who are accused, will be a delusion, a mockery and a snare. Source: Lord Denman, Lord Chief Justice.

The outcomes of many famous trials by jury in Europe and the USA in recent years may give some credence to Denman's thoughts. The verdict in the O.J. Simpson case in the USA and the acquittal of the Maxwell brothers of fraud in the UK have led to calls for a review of the jury system (Doran and Jackson, 1997). The UK government is considering the abolition of juries for some offences. Jury systems exist in many countries. In England and Wales, for example, juries are considered part of the justice delivery system, but only 2 per cent of criminal cases go to trial by jury. In the UK, jurors are usually laypersons with no especial expertise in law or the subject of the trial; numbers vary between 12 (England and Wales) and 15 (Scotland). The lay nature of juries has made some question the verdicts of fraud trials, for example, where it is felt that the detailed evidence of fraud presented by the prosecution

cannot be fully appreciated by a lay juror. In other countries, a jury may comprise a mixture of lay and expert jurors, called an 'escabinato jury'.

In Western societies, the jury symbolises all that is democratic, fair and just in a society. Jury decisions can call into question core values, and can have dramatic social consequences. For example, the 1992 Los Angeles riots, which left 50 dead and 2,300 injured, were sparked by the perception that an all-white jury had delivered an unjust verdict of 'not guilty' in the trial of white police officers accused of beating a black motorist. Several factors affect jury decision-making including the decision-making process itself, the number of people on a jury, jurors' prior beliefs, features specific to the case such as the sex, employment record and criminal history of the defendant, whether the crime involved the use of a weapon, and the availability of eyewitness testimony (Howitt, 2002).

Much of the research relies on experiments in which trials are simulated and mock juries hear (often genuine) court evidence, and draw their conclusions. The invented nature of

Psychology in action – Continued

much of these experiments obviously encourages us to be cautious when interpreting their results. However, many studies make their protocol as realistic as possible and encourage their participants to behave as if they were making real-life jury decisions.

Factors influencing juries' verdicts

The results make interesting reading. Allowing jurors to take notes or to ask questions leads to no significant change in the verdict reached or in the perception of the prosecution or defence (Penrod and Heuer, 1997), but makes the processing of complex evidence easier. The publicity given to a case (Otto *et al.*, 1994), the attractiveness of the victim (Kerr, 1978) and the order of evidence (Kassin *et al.*, 1990; Kerstholt and Jackson, 1998) have all been found to influence eventual verdicts. People who are anti-police are more likely to acquit than are those who do not hold anti-police views (Vidmar *et al.*, 1997), and people are more persuaded by an expert witness when the evidence is complex (Cooper *et al.*, 1996).

Jury size is important. In the case of *Williams v. Florida*, the US Supreme Court ruled that six jurors were as effective as twelve. Juries usually require unanimity: in the UK this may be required at first but if this is not forthcoming a 10/12 majority is required. In Spain, on the other hand, there is what is called qualified majority voting. To reach a verdict of not guilty, a majority of 5/9 must be reached; for a verdict of guilty, 7/9 is required.

Large juries tend to result in hung verdicts (Zeisel, 1971; Saks and Marti, 1997) and spend longer deliberating on the verdict, engage in more irrelevant deliberations, make more assertions, regard trial evidence less meaningfully and are more intransigent than their unanimous-verdict counterparts (Arce *et al.*, 1998). Large juries are also likely to reach more guilty verdicts (Saks and Marti, 1997). Striking a note of caution, however, Saks and Marti found that although large mock juries reached more hung judgments, only 1 per cent of real juries were hung. When agreement between jurors is made compulsory, however, members do spend more time deliberating evidence in detail (Arce *et al.*, 1998).

In a study of 1,000 defendants on felony charges, Myers (1979) found that there were some specific features of the case that influenced verdicts. These included whether: a weapon was recovered, a large number of witnesses gave testimony or were prepared to, the defendant had previous convictions and was employed, whether the defendant was young or old; and the seriousness of the crime was also a factor. Factors not associated with the final verdict were the eyewitness testimony of the defendant, the testimony of experts and the defendant's relation to the victim.

How do jurors reach a verdict?

Psychologists have suggested two models which might account for this type of decision-making (Honest and Charman, 2002). The story model argues that jurors evaluate evidence/information in a step-by-step manner and construct a meaningful narrative using the evidence they hear. During the course of the trial, the juror begins to form a story and evaluates subsequent evidence in light of this (Pennington and Hastie, 1986, 1992). The second model is the dual-process model. This model argues that the juror engages in two types of processing during decision-making. The first type, systematic processing, involves paying close attention to case detail and engaging in close scrutiny of information. The second type, heuristic processing, involves paying less attention to detail but paying more attention to the social, emotional, subjective aspects of the case such as the persuasiveness of expert evidence, and the belief that there is 'no smoke without fire' (Eagly and Chaiken, 1993).

Current evidence suggests that the story model best accounts for jury decision-making (Carlson and Russo, 2001). The model also suggests that because all jurors have access to evidence, their construction of stories will depend on the juror's own beliefs, predispositions and personal experiences.

The personal and subjective nature of story construction was recently addressed by Carlson and Russo (2001). They argued that if a juror adopts a specific position at the beginning of the trial, then subsequent evidence will be interpreted in the context of this position. However, Carlson and Russo were not interested in the prior beliefs of the jurors but in the judgement they reached or beliefs they held about guilt or innocence in the early stages of a trial. Jurors interpret evidence according to the judgement predominating at the time (Russo *et al.*, 1996). Failure to ignore a judge's instructions or to dismiss evidence deemed inadmissible is thought to contribute to this bias in reasoning. Inadmissible evidence would still be evaluated, partially, according to the judgement the juror has already reached about the culpability of the defendant. Carlson and Russo call this 'predecisional distortion' because evidence is interpreted in a partial way before a verdict is reached.

'Predecisional distortion'/bias

Carlson and Russo found that predecisional bias was greater in prospective mock jurors than it was in a group of students. These jurors distorted evidence twice as much, held stronger prior beliefs and were more confident in their judgements than were the student juror group, possibly because the prospective jurors were older than the students or because the students were more analytical and reflective. This is a reasonable hypothesis given that the prospective group held strong prior beliefs that were not particularly susceptible to change.

Psychology in action – Continued

If this bias is inherent in the system – because jurors are thinking individuals with differences in belief, thinking style and intellect – how can it be avoided? For a juror to reach a verdict before all the evidence is presented, and to interpret evidence in a way that is consistent with that verdict, is clearly problematic (Constantini and King, 1980). There is some evidence, however, that if people are given instructions not to develop biased thinking (either pro- or anti- an individual), then these biases can be removed. In mock jury settings, giving juries instructions before evidence is presented is more effective than instructing them after all the evidence has been heard (Bourgeois *et al.*, 1995).

There are some biases, however, that people would find very difficult to avoid. Pre-trial publicity is a good example of

information presented prior to trial that could influence a juror's view of the evidence. Some judges in the UK consider such publicity could prejudice a defendant's case, as happened in 2001 when a judge ordered a retrial of two professional footballers accused of assaulting a man in Leeds city centre. A retrial was ordered after a national newspaper published an interview with the father of the assaulted man. The judge ruled that the defendants would not receive a fair trial. Although it seems intuitively reasonable, there is no systematic evidence to support the idea that pre-trial information could cause juror bias. More realistically, however, as Studebaker and Penrod (1997) note, there is no trial anywhere in the world where a juror would not be aware of some aspects of the crime.

Problem-solving

The ultimate function of thinking is to solve problems. We are faced with an enormous variety of them in our daily lives: fixing a television set, planning a picnic, choosing a spouse, navigating across the ocean, solving a maths problem, tracking some game, designing a bridge, finding a job. The ability to solve problems is related to academic success, vocational success, and overall success in life, so trying to understand how we do so is an important undertaking.

The spatial metaphor

According to Holyoak (1990), a problem is a state of affairs in which we have a goal but do not have a clear understanding of how it can be attained. As he notes, when we talk about problems, we often use spatial metaphors to describe them (Lakoff and Turner, 1989). We think of the solving of a problem as finding a path to the solution. We may have to get around roadblocks that we encounter or backtrack when we hit a dead end. If we get lost, we may try to approach the problem from a different angle. If we have experience with particular types of problem, we may know some short cuts.

In fact, Newell and Simon (1972) have used the spatial metaphor to characterise the problem-solving process. At the beginning of a person's attempt to solve a problem, the initial state is different from the goal state – if it were not, there would be no problem. The person solving the problem has a number of operators available. Operators are actions that can be taken to change the current state of the problem; metaphorically, operators move the current state from

one position to another. Not all people will be aware of the operators that are available. Knowledge of operators depends on education and experience. In addition, there may be various costs associated with different operators; some may be more difficult, expensive or time-consuming than others. The problem space consists of all the possible states that can be achieved if all the possible operators are applied. A solution is a sequence of operators (a 'path') that moves from the initial state to the goal state.

Algorithms and heuristics

Some kinds of problem can be solved by following a sequence of operators known as an algorithm. **Algorithms** are procedures that consist of series of steps that, if followed in the correct sequence, will provide a solution. If you apply properly the steps of an algorithm (such as long division) to divide one number by another, you will obtain the correct answer. But many problems are not as straightforward as this. When there is no algorithm to follow, we must follow a heuristic to guide our search for a path to the solution. Heuristics (from the Greek *heuriskein*, 'to discover') are general rules that are useful in guiding our search for a path to the solution of a problem. Heuristics tell us what to pay attention to, what to ignore and what strategy to take.

Heuristic methods can be very specific, or they can be quite general, applying to large categories of problems. For example, management courses try to teach students problem-solving methods they can use in a wide variety of contexts. Newell and Simon (1972) suggest a general heuristic method that can be used to solve any problem: means–ends analysis. The principle behind **means–ends analysis** is that a person should look for differences

between the current state and the goal state and seek ways to reduce these differences. The steps of this method are as follows (Holyoak, 1990, p. 121):

- 1 Compare the current state to the goal state and identify differences between the two. If there are none, the problem is solved; otherwise, proceed.
- 2 Select an operator that would reduce one of the differences.
- 3 If the operator can be applied, do so; if not, set a new subgoal of reaching a state at which the operator could be applied. Means–ends analysis is then applied to this new subgoal until the operator can be applied or the attempt to use it is abandoned.
- 4 Return to step 1.

At all times, the person's activity is oriented towards reducing the distance between the current state and the goal state. If problems are encountered along the way (that is, if operators cannot be applied), then subgoals are created and means–ends analysis is applied to solving that problem, and so on until the goal is reached.

Of course, there may be more than one solution to a particular problem, and some solutions may be better than others. A good solution is one that uses the smallest number of actions while minimising the associated costs. The relative importance of cost and speed determines which solution is best. Intelligent problem-solving involves more than trying out various actions (applying various operators) to see whether they bring you closer to the goal. It also involves planning. When we plan, we act vicariously, 'trying out' various actions in our heads. Obviously, planning requires that we know something about the consequences of the actions we are considering. Experts are better at planning than are novices. If we do not know the consequences of particular actions, we will be obliged to try each action (apply each operator) and see what happens. Planning is especially important when many possible operators are present, when they are costly or time-consuming, or when they are irreversible. If we take an irreversible action that brings us to a dead end, we have failed to solve the problem.

Where in the brain does decision-making occur?

For most of our complex, intelligent behaviour, a region in the front of the brain appears to be essential. Damage to the frontal lobes is associated with deficits in planning, putting stimuli in the correct order, behaving spontaneously and inhibiting incorrect responses (Adolphs *et al.*, 1996).

Damasio and colleagues' studies of patients with frontal lobe damage show that these individuals have

great difficulty in making correct decisions (Damasio, 1995; Bechara *et al.*, 1996, 1997). Damasio suggests that the ability to make decisions leading to positive or potentially harmful consequences depends on the activation of somatic (that is, bodily) states. Damasio calls this the **somatic marker hypothesis** because such decisions involve automatic, endocrine and musculoskeletal routes. These routes mark events as important, but appear to be impaired in certain frontal lobe patients. When the decision can have a positive or negative outcome, the degree of physiological activity, such as heart rate and galvanic skin response (see Chapter 4) that is normally seen in healthy individuals is absent in these patients (Bechara *et al.*, 1997).

In a typical experiment, patients were taught to play a card game (the Iowa Gambling Task) where they were told to make as much money as possible (Bechara *et al.*, 1997). There are four decks of cards and some have a high probability of delivering a large immediate monetary reward or a large delayed monetary loss or a low immediate monetary reward or a low delayed monetary loss. No participant was told which deck contained the greatest probability of obtaining these outcomes and, therefore, had to learn from experience, turning over cards and remembering the outcomes. They had hunches. When a decision involved a high degree of risk, for example, a healthy individual would show a characteristic increase in physiological arousal; the frontal lobe patient, however, would not. Neuroimaging studies of the same task are associated with increases in blood flow to the ventromedial region of the frontal cortex (Elliott *et al.*, 1997; Grant *et al.*, 2000).

Bechara *et al.* found that the VM-damaged patients opted for the disadvantageous decks and failed to be sensitive to future consequences. Instead, they seemed to be guided by immediate reward. The researchers called this 'myopia for the future'. Even when the future consequences of behaving in a particular way were undesirable, these patients continued to behave in an inappropriate way. The group followed this up with a study showing that substance abusers performed within the same range as people with damage to the ventromedial cortex (Bechara *et al.*, 2001).

Manes *et al.* (2002) found that dorsolateral lesions were associated with working memory, set shifting and Iowa Gambling Task impairments; dorsomedial lesions were associated with planning and Iowa Gambling Task impairments, and orbitofrontal lesions were associated with performance at control level but showed prolonged deliberation on the Tower of London Task, a task that required forward planning (see Chapter 13 for an example of this task). However, the group with large frontal lesions showed great impairment and was the only group to show risky decision-making. According to Manes *et al.*'s criteria, patients in the Bechara studies would be classified as having large frontal lesions.

Reasoning and the brain

In healthy individuals, blood flow tends to increase in the frontal and parietal lobes during reasoning tasks (Goel *et al.*, 1997, 1998). According to theories of deduction, our ability to reason is either based on understanding the linguistic rules that underpin logic or based on whether visuospatial relations are involved in the reasoning (Goel, 2007). These two different interpretations probably explain why the results from neuroimaging have been inconsistent. Different types of reasoning tasks recruit different regions. For example, early studies, such as the PET studies of Goel – cited above – asked people to follow syllogisms such as:

Some officers are generals
No privates are generals
Some officers are not privates

and found increased activation in the left frontal and temporal lobes.

Later studies, using fMRI, found increases in both sides of the prefrontal cortex, the left temporal lobe and both sides of the parietal lobe (Goel *et al.*, 2000; Goel, 2003).

Differences in activation are seen depending on whether the reasoning task involves conditional reasoning (participants have to follow if – then relations), complex conditional reasoning (such as the card sorting task described earlier), and transitive inferences (e.g. understanding that the relationship between A and B or B and C can be transferred to A and C). Left prefrontal activation is seen during the first, bilateral occipital, parietal and frontal activation during the second and frontal and parietal activation in the last. Goel and Dolan (2001), for example, using the third type, asked people to reason problems such as:

Graham is taller than Mike
Mike is taller than Lynn
Graham is taller than Lynn

Knauff *et al.* (2003) extended this to action sentences:

A dog is cleaner than a cat
An ape is dirtier than a cat
A dog is cleaner than an ape

and found similar activation.

According to Goel (2007), these studies suggest that the frontal-temporal pathway provides us with a heuristic system for reasoning – it helps us process conceptually coherent material – whereas the parietal lobe underpins a more formal system based on universal reasoning rules – it is involved in processing non-conceptual, incoherent material.

There is an exception to this model, however. Take a look at the following statements:

- 1 Mary is cleverer than John; John is cleverer than George; Mary is cleverer than George
- 2 Mary is cleverer than John; John is cleverer than George; George is cleverer than Mary
- 3 Mary is cleverer than John; Mary is cleverer than George; John is cleverer than George

Patients with damage to the left prefrontal cortex cannot process the first two types; patients with damage to the right are poor at processing the last, suggesting that there may be a degree of reasoning-related asymmetry in the brain.

In general, however, a small network of regions is involved in reasoning and, whatever the task, the prefrontal cortex is involved.

Brain activation in the very intelligent

Would more or less activation in the frontal lobes be apparent in very bright individuals? An early PET study indicated that individuals with high IQ had lower metabolic rates than those with low IQ during problem-solving (Haier *et al.*, 1988). When high and low IQ individuals were trained on a computer game, both groups' brain activity declined but the decline in the high IQ group was more rapid, suggesting that the highly intellectually able may need to use less of their neural machinery to think (Haier *et al.*, 1992).

A study by Chinese researchers, however, has found that intelligence is not simply related to activity in the frontal lobe but to connections between this region and other brain areas (Song *et al.*, 2008). They used fMRI to study 59 healthy adults and correlated intelligence scores with the strength of connections between the dorsolateral prefrontal cortex and other brain regions. They found that the greater the intelligence score, the greater the strength between the prefrontal cortex and the regions within it, and with the parietal, limbic and occipital cortices. The results suggest that intelligence can be correlated with increased brain activation, even when the brain is at rest.

Creative thinking

Creativity has almost as many definitions as intelligence. We recognise that the writing of

a novel, the design of a sculpture and the construction of a painting are creative products but what does it mean to be creative? Feldhusen and Goh (1995) define creativity as a 'complex mix of motivational conditions, personality

factors, environmental conditions, chance factors and end products'. Vernon (1989) suggests that creativity is a person's capacity to produce ideas, inventions, artistic objects, insight and products evaluated highly by experts. Torrance (1975) defines creativity as a set of abilities, skills, motivations and states linked to dealing with problems. Others define the components of creative thinking as involving a realisation that a problem exists, formulation of questions to clarify the problem, determining the causes of the problem, clarifying the

desired goal or solution and selecting a way to achieve this goal (Feldhusen, 1993). Still others have suggested that creativity involves producing a recognised, important end-product, not rubbish.

All of these definitions seem to have a common feature – that creativity involves some form of end-product. However, this end-product need not be material. Albert (1990), for example, has suggested that creativity is expressed through decisions not products. There do, however, seem to be different degrees of creativity. The production of a novel, painting or sculpture is undoubtedly creative, but solving inductive and deductive problems also involves a degree of creative thinking. However, artistic production seems to require creativity plus talent. These are high-level creative behaviours as opposed to the basic creative behaviour involved in solving deductive reasoning puzzles.

Given that psychologists cannot measure high-level creativity directly in the laboratory – they cannot ask individuals to come into the laboratory and write full-length novels, for example – they have devised other tests which tap the capacity to engage in creative thinking. The Torrance Tests of Creativity, for example, measure performance on a series of verbal and figural tasks such as naming as many objects as possible beginning with a specific letter or creating as many designs as possible using the same basic design (for example a circle). Torrance (1975) reports that performance on these tests predicts creative achievement, occupation and creative writing. Other tests include those by Wallach and Kogan (1965). These tests are verbal and measure verbal fluency – the ability to devise many uses for objects and the ability to detect similarities between stimuli. There is little evidence that performance on tests such as the Wallach and Kogan and the Torrance Tests – called tests of divergent thinking – predicts creativity (Brown, 1989).

Are there any features of the creative individual's personality that can predict creativity? Dacey (1989) has listed nine personality factors predictive of creativity and includes in this list flexibility, risk-taking and tolerance of ambiguity. Other factors suggested by other psychologists include: cognitive complexity, perceptual openness, field independence, autonomy and self-esteem (Woodman and Schoenfeldt, 1989), and fluency, flexibility, curiosity and humour (Treffinger *et al.*, 1990). Other personality factors that have recently attracted a great deal of interest are psychopathological or psychotic personality characteristics. Are creative people more prone to mental disorder? Does the mental disorder predispose the individual to creative thinking? These questions are discussed in the Controversies in Psychological Science box below.

In Greek mythology, Prometheus stole fire from the gods for mankind's use. Humans were thus able to use their own creativity and not rely on divine creation. The gods became displeased and released Pandora's Box on mankind – a casket of evil.

Cutting edge – Creativity and romance

‘In order to create,’ said the great Russian violinist Igor Stravinsky, ‘there must be a dynamic force – and what force is more potent than love?’ Researchers at Arizona State University examined the relationship between romantic motives and creativity in a series of experiments (Griskevicius *et al.*, 2006).

Men and women looked at photographs of attractive people of the opposite sex, or imagined being in a romantic scenario, and then completed subjective (writing a short story) and objective (the Remote Associates Test) creativity tests. The Remote Associates Test asks people to come up with one word that links three others in 15 seconds. For example, ‘sun’ would correctly bring together ‘dress’, ‘dial’ and ‘flower’.

For men, thinking about an attractive woman as a potential romantic partner increased creativity. Women’s creativity only

increased when the man was perceived as trustworthy and committed. Men’s increased creativity was therefore associated with attraction to a short-term mate, whereas women’s was associated with attraction to a long-term mate. Women did not show increased creativity when thinking about a short-term or long-term mate who could not demonstrate good long-term viability as a partner. Although both sexes reported increased positive mood and arousal after appraising a person who might become a short-term partner, mood was unrelated to creativity.

The next step would be to examine not only the relationship between creativity and actual courtship, but also the relationship between the quality of the relationship and creativity.

Case studies in creativity

Mozart thought out symphonies, etc., entirely in his head . . . and then transcribed them, in completeness, onto paper. Beethoven wrote fragments of themes in notebooks, working on and developing them over years. The Mozartian type of genius is able to plumb the greatest depths of his own experience by the tremendous effort of a moment; the Beethovenian must dig deeper and deeper into his consciousness, layer by layer . . .

Source: ‘Making of a Poem’, Stephen Spender, *Partisan Review* (1946).

According to the theory of creativity proposed by Sternberg and Lubart (1991), there are three features of creativity that highly creative individuals possess. These features are: (1) domain-relevant skills – abilities the individual has in their domain and their knowledge of the domain; (2) creativity-relevant processes – the personality, cognitive style or other individual differences which promote creativity; and (3) intrinsic task motivation – the internal drive which motivates the individual and which can be influenced by the individual’s environment. Domains for creative individuals such as John Irving, Charles Darwin and Claude Monet, for example, would be fiction, science and art, respectively.

In a special issue of *American Psychologist* on creativity for the new millennium, introduced by Sternberg and Dess (2001), case studies of these and other creative individuals are presented and assessed for the features that make such individuals especially creative. Creative people are thought to produce products that are high in quality and novelty; intelligent, but not particularly creative, people can produce products of high quality but these may not be novel (Sternberg, 2001). The novel nature of creativity also suggests that its products ‘defy the crowd’

(Sternberg and Lubart, 1995): creative individuals produce unusual (sometimes) counter-intuitive products (ideas, as well as physical items), and some individuals, like Darwin, attempt to persuade the crowd with their ideas. Creatives also analyse the many ideas they have or may redefine problems or make unexpected connections between two things.

Sternberg and Lubart (1991) also suggest that the creative individual is a little like a successful market trader: they buy low and sell high. That is, they identify a problem needing a solution or find/pose an important question, and are then the first to provide the solution, leaving others to elaborate on these solutions and refine them. Some creatives may not be well known because they try to pose too many questions or attempt solutions to too many problems. Martindale (2001) describes one such case: the British polymath, Thomas Young.

Young (1773–1829) was a physician and Fellow of the Royal Society (at the age of 21) whose legacy to science is phenomenal. He suggested an explanation for colour-blindness, proposed the trichromatic theory of colour vision (described in Chapter 5), founded the modern wave theory of light in physics, explained Newton’s rings (why colours are seen on thin films of soap bubbles), was the first to measure the diameter of the molecule, provided the first modern classification of disease, proposed a theory of tide movement that improved on Newton’s and decoded the meaning of the Egyptian hieroglyphics on the Rosetta Stone. Despite all of this, he produced only 80 publications (which might suggest that the quality of the publications was more important than the quantity).

Martindale suggests that Young’s behaviour supports Eysenck’s (1995) theory of creativity. According to Eysenck, creative individuals possess characteristics designed to promote creativity. These features combine so

that the absence of one can lead to a lack of creativity. Creative individuals think in analogical ways, are highly intelligent, love hard work and novelty, dislike the traditional, and have very high self-confidence. Young seems to possess all of these characteristics. Why, then, is he not as well known as other scientists? One reason, Martindale suggests, is that science became too specialised. Scientists in specific disciplines rarely step outside their own territory. Perhaps if he had focused on one discipline and worked within it, he may have made an even greater mark on science.

One of Young's most salient characteristics was his curiosity. This is a trait which, according to some psychologists, marks out the creative from the non-creative (Kashdan and Fincham, 2002). But is there a more fundamental characteristic of creativity which psychology's current questionnaires and measures do not tap? According to Sternberg (2002), there is. It is

the decision to be creative. People who create decide that they will forge their own path and follow it, for better or for worse. The path is a difficult one because people who defy convention often are not rewarded. Hence, at times, their self-esteem may be high, at other times, low. At times, they may work in groups, at other times individually. At times, they may feel curious, at other times, less so. But if psychologists are to understand and facilitate creativity, I suggest they must start, not with a kind of skill, not with a personality trait, not with a motivational set, and not with an emotional state, but rather, simply, with a decision . . . for creativity to occur, it must be preceded by a personal decision to think and act creatively, with all the risks attendant on doing so.

Controversies in Psychological Science – Are creativity and psychopathology related?

The issue

According to Dryden, 'Great wits are sure to madness near allied, and thin partitions do their bounds divide.' As if providing direct evidence for Dryden's poetic analysis, Lady Caroline Lamb once famously described Lord Byron as mad, bad and dangerous to know. Although the link between badness, danger and creativity has not been the source of much research in psychology, the link between creativity and madness (or psychopathology) has. (Chapter 18 provides more detail on the various types of mental illness that fall under the category of psychopathology.) Anecdotal evidence suggests that two types of mental illness, manic depression (alternating periods of elation and chronic sadness) and clinical depression exist preponderantly in novelists, poets, artists and performers. But what empirical evidence is there to link psychopathology and creativity? If there is a relationship, does creativity cause psychopathology or does psychopathology cause creativity? Is it possible to determine this?

The evidence

Kraepelin (1921) had originally described a disorder called manic-depressive insanity in which the manic aspect of the disorder would produce changes in thought that would increase creativity and thinking. A number of authors report that increases in creativity are common during the manic episodes of bipolar disorder (Jamison, 1989; Sutherland, 1987; Goodwin and Jamison, 1990). Jamison (1989), for

example, found that creative individuals, especially poets, reported states of mania during creation although she did not specify the direction of the change in behaviour (whether the poetry caused the mania or vice versa). There was also a high incidence of suicide in poets. Weisberg (1994), in studying the quantity and quality of the work of the composer Franz Schubert, who suffered what we would today call a bipolar disorder, found that although the quantity of the composer's work increased during manic episodes, the quality was not significantly improved.

In a famous study of the relationship between creativity and psychopathology, Ludwig (1994) compared 59 women writers from a Women Writers' Conference at the University of Kentucky and 59 women from a housewives' association, medical centre and university women's club. Ludwig found that the writers were more likely to suffer from mood disorders, drug abuse, panic attacks, general anxiety and eating disorders. The results of this study complement those of writers attending an Iowa writers' workshop, 90 per cent of whom were men (Andreasen, 1987). The study found a greater incidence of mood disorder in this group than in the general population (80 per cent v. 30 per cent) and a greater incidence of bipolar disorder. Shapiro and Weisberg (1999) sought to determine if the same relationship held for non-eminent samples. They gave a creativity and creativity personality questionnaire to 20 undergraduates (from a sample of 70) who met strict criteria for bipolar disorder. The presence of hypomanic or euphoric symptoms was found to be signifi-

cantly associated with creativity, although depressive symptoms were not. The authors speculated that the depressed effect may be a part of the creative individual's behaviour because the inability to be creative (because of pressures in other areas of life) makes the individual depressed.

In two studies of creativity, Post (1994, 1996) analysed extensively the biographies of 291 world-famous creative men (visual artists, composers, creative writers, scientists, scholars and statesmen). He found that 90 per cent of the writers in his sample exhibited some traits which would be classified as a personality disorder according to mental disorder diagnostic manuals; only one scientist showed this profile (Henry Babbage, inventor of the first computer). In addition, 73.4 per cent of scientists exhibited unremarkable sexual behaviour whereas only 39 per cent of writers did. Depressive episodes occurred in 72 per cent of the writers. These data suggested to Post that, although the study was retrospective, a 'causal nexus' existed between creativity and psychopathology. In a subsequent study of 100 American and British writers (Post, 1996), there was a high prevalence of mood disorder, as seen in Table 11.7. Poets showed the greatest degree of bipolar disorder, although the incidence of depression, marital/sexual problems and alcoholism in poets was low. Recently the degree of cognitive distortions found in the work of 36 eminent depressed and 36 non-depressed authors was analysed (Thomas and Duke, 2007). There were more distortions in the depressed writers, and poets exhibited more than did novelists.

A study of 40 innovative American jazz musicians from the 1940s, 1950s and 1960s found that about 50 per cent were addicted to heroin, and 27 per cent became dependent on alcohol (Wills, 2003). Only one of the sample (Bud Powell) was schizophrenic but 28 per cent had 'probable' depression. This study, according to the author, 'adds weight to the finding that outstanding workers in the arts can suffer from above-average levels of mental health problems but manage to produce exceptional work despite this'.

Table 11.7 Mood disorders found in a sample of 100 writers

	N	Bipolar psychoses	Unipolar psychoses	Severely disabling depressions	Milder depressions	Brief reactions only	Depressive traits only	Cyclothymic traits only	Totals
Poets	35	2	1	4	11	4	5	1	28
Poets/novelists	41	2	1	8	13	2	7	0	33
Playwrights	24	1	0	4	8	4	3	1	21
Totals	100	5	2	16	32	10	15	2	82

Controversies in Psychological Science – *Continued*

If creativity and psychopathology are related, what creates this link? One personality trait which has been linked with creativity is psychoticism (Eysenck, 1995). **Psychoticism** refers to a cold, manipulative and indifferent personality style. A number of studies has shown that creative individuals score highly on tests of psychoticism (Fodor, 1994; Stavridou and Furnham, 1996). According to Kris (1952), creative people are able to shift between two modes of thinking called primary and secondary thinking. Primary thinking is artistic, free associative, analogical and relies on concrete rather than abstract concepts; secondary thinking is abstract and reality-oriented. There seems to be no link between psychoticism and primary thinking, however (Martindale and Dailey, 1996). Similarly, Aguilar-Alonso (1996) found no difference between high and low psychoticism on a measure of verbal and drawing creativity. Rawlings (1985) has suggested that individuals high in psychoticism show the same impulsive, non-conforming

processes that underlie creative thinking ability. Perhaps what underlies creativity and psychoticism is disinhibition, the ability not to inhibit behaviour and thought.

Conclusion

Retrospective evidence suggests that there is a strong link between mental disorder and creativity. The problem with retrospective studies, however, is that we cannot empirically examine the personalities of creative individuals who are dead: we have to rely on books, anecdotes, personal reminiscences of creative individuals' relatives, friends or lovers. The findings of some recent empirical studies have been inconsistent. Modern studies employ creativity tests thought to tap specific forms of thinking but these may be far removed from the creativity seen in a visual artist, a poet or a novelist. While we may still be able to describe creative individuals as bad or dangerous, their madness is still open to question.

Cutting edge – The key to creativity – shut up!

Evidence suggests that thinking aloud, surprisingly, impairs people's ability to be creative. A study from Tilburg and Amsterdam universities has shown that this is especially so when people are sensitive to what others think of them (de Vet and de Dreu, 2007).

In one experiment, they asked people to complete a standard test of creativity – specifically, to think of unusual uses for a tin can – while either thinking aloud as they did so or to keep quiet. Those in the quiet condition produced the same number of uses for the tin can but their efforts were judged to

be more original. When participants' sensitivity to what others thought of them was measured in a second experiment, the researchers found that the most sensitive produced less original ideas in the thinking-aloud condition.

The researchers argue that thinking aloud requires more in the way of cognitive resources than does keeping quiet, resources that could be used for thinking creatively and originally. Speech is also slower than thought and so it could be that speaking out loud prevents other, quicker, possibly more original and immediate thoughts from being generated.

Chapter review

Theories of intelligence

- Although intelligence is often represented by a single score – the IQ – modern investigators do acknowledge the existence of specific abilities. What is controversial is whether a general factor also exists.
- Factor analysis is a data reduction technique that attempts to explain a large amount of data with reference to one or two factors.
- Spearman argued that a general intelligence factor existed (which he called *g*) and demonstrated that people's scores on a variety of specific tests of ability were correlated. He also believed that specific factors (*s* factors) also existed.
- Thurstone performed a factor analysis on 56 individual tests that revealed the existence of seven factors, not a single *g* factor.
- Cattell's factor analysis on such data obtained two factors. The nature of the tests that loaded heavily on these two factors

suggested the names fluid intelligence (g_f) and crystallised intelligence (g_c), with the former representing a person's native ability and the latter representing what a person learns.

- Sternberg's triarchic theory of intelligence attempts to integrate laboratory research using the information processing approach and an analysis of intelligent behaviour in the natural environment.
- According to Sternberg, we use componential intelligence to plan and execute tasks. We use experiential intelligence to apply past strategies to new problems. Finally, we use contextual intelligence to adapt to, select, or shape our environment.
- Gardner's multiple intelligences theory is based primarily on the types of skill that can be selectively lost through brain damage. His definition of intelligence includes many abilities that are commonly regarded as skills or talents.
- Like Sternberg's theory, Gardner's theory emphasises the significance of behaviours to the culture in which they occur.
- The most consistent sex difference in cognition is for mental rotation – men are better at it than are females.
- Men overestimate their own IQ but both sexes rate their fathers and male children as having higher IQs than their mothers or female children.

Intelligence testing

- Although the earliest known instance of ability testing was carried out by the ancient Chinese, modern intelligence testing dates from the efforts of Galton to measure individual differences.
- Galton made an important contribution to the field of measurement, but his tests of simple perceptual abilities were abandoned in favour of tests that attempt to assess more complex abilities, such as memory, logical reasoning and vocabulary.
- Binet developed a test that was designed to assess students' intellectual abilities in order to identify children with special educational needs.
- Although the test that superseded his, the Stanford–Binet Scale, provided for calculation of IQ, Binet believed that 'intelligence' was actually a composite of several specific abilities. For him, the concept of mental age was a convenience, not a biological reality.
- Wechsler's two intelligence tests, the WAIS-III for adults (and its variants) and the WISC-R for children, are the most widely used tests of intelligence.
- The reliability of modern intelligence tests is excellent, but assessing their validity is still difficult. Because no single criterion measure of intelligence exists, intelligence tests are validated by comparing the scores with measures of achievement, such as scholastic success.
- Tests also need to be intelligible and quick to complete.
- Intelligence tests can have both good and bad effects on the people who take them. The principal benefit is derived by identifying children with special needs (or special talents) who will profit from special programmes.

The roles of heredity and environment

- Variability in all physical traits is determined by a certain amount of genetic variability, environmental variability, and an interaction between genetic and environmental factors.
- The degree to which genetic variability is responsible for the observed variability of a particular trait in a particular population is called heritability or h .
- Heritability is not an indication of the degree to which the trait is determined by biological factors; rather, it reflects the relative proportions of genetic and environmental variability found in a particular population.
- Intellectual development is affected by many factors, both prenatal and post-natal. Potential intelligence can be permanently reduced during prenatal or post-natal development by injury, toxic chemicals, poor nutrition or disease.
- Twin studies and studies comparing biological and adoptive relatives indicate that both genetic and environmental factors affect intellectual ability, which is probably not surprising. These studies also point out that not all of a person's environment is shared by other members of the family; each person is an individual and is exposed to different environmental variables.
- The evidence suggests that biological children who are adopted are intellectually more like their biological parents; this finding applies across all age ranges.
- Although there are differences between races in terms of IQ score, it is unclear whether this is due to heredity. There are also problems in defining race.

Thinking

- Formal concepts are defined as lists of essential characteristics of objects and events. In everyday life, we use natural concepts – collections of memories of particular examples, called exemplars.
- Concepts exist at the basic, subordinate and superordinate levels. We do most of our thinking about concepts at the basic level.
- Deductive reasoning consists of inferring specific instances from general principles.
- One of the most important skills in deductive reasoning is the ability to construct mental models that represent problems.
- Inductive reasoning involves inferring general principles from particular facts. This form of thinking involves generating and testing hypotheses.
- Without special training (such as learning the rules of the scientific method), people often ignore relevant information, ignore the necessity of control groups or show a confirmation bias – the tendency to look only for evidence that confirms one's hypothesis.
- Jury decision-making is one important real-life example of reasoning, and jurors can reach decisions that do not follow logic and that are influenced by factors other than trial

evidence (such as jury size, pre-existing beliefs, aspects of the trial and so on).

- Current evidence suggests that jurors evaluate evidence in a step-by-step manner and construct a meaningful narrative using the evidence they hear.
- Problem-solving is best represented spatially: we follow a path in the problem space from the initial state to the goal state, using operators to get to each intermediate state. Sometimes a problem fits a particular mould and can be solved with an algorithm – a cut-and-dried set of operations.
- However, in most cases, a problem must be attacked by following a heuristic – a general rule that helps guide our search for a path to the solution of a problem. The most general heuristic is means–ends analysis, which involves taking steps

that reduce the distance from the current state to the goal. If obstacles are encountered, subgoals are created and attempts are made to reach them.

- The regions of the brain recruited most consistently during reasoning and decision-making are the prefrontal cortex and parietal lobe.
- Creativity has been defined in many ways but most psychologists agree that it describes a person's capacity to produce novel ideas, inventions, objects or products and to engage in successful problem-solving.
- Studies suggest a link between psychopathology (such as manic depression and depression) and creativity, but whether the link is causal is open to question.

This chapter includes activities on: Experiencing the visual cliff • Sexual identity development • Kohlberg's stage of moral reasoning • What makes a bully? • Check your understanding and prepare for your exams using the multiple choice, short answer and essay practice tests also available.

Police refute Bridgend suicides link

Nico Hines

A total of 17 people aged between 15 and 27 and living in and around Bridgend have hanged themselves since January 2007. Local police, who have dismissed fears of a suicide cult, continue to deny any connection between the deaths.

At least ten of the victims seem to have been known to each other, however, with several having friendship links on Bebo, a social networking site. After their deaths, the profiles of many of the victims have quickly been transformed into virtual shrines with condolences.

Some commentators have suggested that the website allows the glorification of the deaths, promoting copycat suicides.

WHAT YOU SHOULD BE ABLE TO DO AFTER READING CHAPTER 12

- Describe the major stages of psychological development from birth.
- Outline the nature of foetal development and learning.
- Describe how infant perception, memory and cognition develop.
- Describe the emotional and social development of the child from infancy to adolescence and attempt to explain how this occurs.
- Describe the psychological changes that occur during adolescence, adulthood and old age and attempt to explain why these changes occur.

QUESTIONS TO THINK ABOUT

- Can a foetus learn?
- How does a child learn to think and perceive?
- Does a child's cognitive development progress in discernible stages?
- Is an infant's ability to perceive certain stimuli, such as faces, innate?
- What is the relationship between brain development and cognitive development?
- What are a child's most important psychological functions?
- How valid are categories such as 'adolescence' and 'infancy'?
- How does the child interpret the perceptual world?
- When and how do children develop a sense of morality?
- What causes disorders of cognition and emotion in infants?
- How important is the nature of peer interaction to the social development of adolescents?
- Is adulthood marked by similar psychological milestones to those in infancy?
- How does social and cognitive behaviour change as people get older?
- Is cognitive decline in old age preventable?
- Are some cognitive abilities better preserved (or even improved) as we enter old age?

Developmental psychology

Apart from conception, development is probably the most astonishing thing we do. From birth to around late adolescence, we develop from a fairly unsophisticated bundle of reflexes and crude cognition to a fantastically efficient organism that can use language, perceive depth, colour, shape and motion, walk, run and jump, drive a car, or parachute from a plane, become a novelist, mathematician or physicist. There is an impressively rapid development of sensory, perceptual, social and cognitive ability during infancy and childhood and this, together with the further development of these abilities in adolescence and adulthood, is the subject matter of **developmental psychology**.

Developmental psychologists study both the similarities and the differences among people as they develop and change over the course of their life. Because of the longitudinal nature of this study, the area is sometimes described as lifespan developmental psychology, which acknowledges the fact that development does not end when adolescence ends.

The major developmental periods across the lifespan are the prenatal period, infancy and childhood, adolescence, adulthood, middle and late adulthood, and old age. This chapter considers the main developments that characterise each stage.

Prenatal development

The nine months between conception and birth is called the **prenatal period** and the length of a normal human pregnancy is 266 days, or 38 weeks. The prenatal period involves three developmental stages: the zygote, the embryo and the foetal stages.

Stages of prenatal development

Zygote stage

Conception, or the union of the ovum (egg) and sperm, is the starting point for prenatal development. During the **zygote stage**, which lasts about two weeks, the zygote, or the cell that is formed at conception, divides many times and the internal organs begin to form. By the end of the first week, the zygote consists of about 100 cells. Many of the cells are arranged in two layers, one for the skin, hair, nervous system and sensory organs, and the other for the digestive and respiratory systems and glands. Near

the end of this stage, a third layer of cells appears, those that will eventually develop into the circulatory and excretory systems and muscles.

Embryo stage

The second stage of prenatal development, the **embryo stage**, begins at about two weeks and ends about eight weeks after conception (see Figure 12.1).

During this stage, the zygote is transformed into an embryo and development occurs at a rapid pace. Within a month after conception, a heart has begun to beat, a tiny brain has started to function, and most of the major body structures are beginning to form. By the end of this stage, the major features that define the human body – the arms, hands, fingers, legs, toes, shoulders, head and eyes – are discernible. Behaviourally, the embryo can react reflexively to stimulation. For example, if the mouth is stimulated, the embryo moves its upper body and neck. This stage is also noteworthy because it is here that the embryo is most susceptible to chemicals that can cause birth defects. These chemicals include drugs such as alcohol or toxins produced by diseases such as German measles, and are called **teratogens** (from the Greek *teras*, meaning ‘monster’).

Sexual development begins during the embryo stage. The determining factor for sex is the Y chromosome, which is contributed by the male parent at conception. If it is present, the embryo will become a male (XY); if it is not, it will become a female (XX). Early in prenatal development, the embryo develops a pair of gonads that will become either ovaries or testes (the word ‘gonad’ comes from the Greek *gonos*, meaning ‘procreation’). If a Y chromosome is present, a gene located on it causes the production of a chemical signal that makes the gonads develop into testes. Otherwise, the gonads become ovaries.

The development of the other sex organs is determined by the presence or absence of testes. If testes are present, they begin secreting a class of sex hormones known as **androgens** (*andros* in Greek means ‘man’; *gennan* means ‘to produce’) which bring about the development of the male internal sex organs, the penis and the scrotum. Thus, these hormones are absolutely necessary for the development of a male. The most important androgen is testosterone and in Chapter 13 we will see how this hormone is involved in other behaviours such as dominance and aggression.

In contrast, the development of female sex organs (uterus, vagina and labia) occurs naturally, it does not need to be stimulated by a hormone. If the gonads completely fail to develop, the foetus becomes female, with normal female sex organs. Of course, lacking ovaries, such a person cannot produce ova. See Figure 12.2.

Figure 12.1 As this photograph of a six-week-old foetus illustrates, most of the major features that define the human body are present near the end of the embryonic stage of development (which starts at about two weeks and ends about eight weeks after conception).

Source: Neil Harding/Getty Images.

Foetal stage

The final stage of prenatal development is the **foetal stage**, which lasts about seven months. It officially begins with the appearance of bone cells and ends with birth. At the end of the second month of pregnancy, the foetus is about 3 cm long and weighs about 28 g. By the end of the third month, the development of major organs is completed and the bones and muscles are beginning to develop. The foetus is now 7–8 cm long and weighs about 90 g. The foetus may show some movement, especially kicking.

By the end of the fourth month, the foetus is about 18 cm long and weighs about 180 g. It is also now sleeping and waking regularly. Foetal movements also become strong enough to be felt by the mother, and the heartbeat is strong enough to be heard through a stethoscope. During the sixth month, the foetus grows to over 33 cm long and weighs almost 1 kg. The seventh month is a critical month because if the foetus is born prematurely at this point, it has a fair chance of surviving. However, foetuses mature at different rates, and some 7-month-old foetuses may be mature enough to survive whereas others may not.

During the last two months of prenatal development, the foetus gains weight at the rate of about 0.2 kg per week. On average, the foetus is about 50 cm long and weighs about 2.8 kg at the end of this period. The foetus is now ready to be born. Figure 12.3 shows how the body's shape changes from the embryo stage to adulthood.

Figure 12.2 Differentiation and development of the sex organs.

Threats to normal prenatal development

Under normal conditions, the prenatal environment provides just the right supply of nutrients to the foetus. Probably the single most important factor in the foetus's development is the mother's diet: the food she eats is the foetus's only source of nutrition. If the mother is extremely malnourished, the foetus's nervous system develops abnormally, and it may be born mentally retarded (Brown and Pollitt, 1996).

Teratogens can also cause birth defects. Psychologists who study birth defects are very interested in how drugs affect the foetus because taking drugs is a behaviour that is directly under the control of the mother. Certain antibiotics, especially when taken in large quantities over long periods, can produce foetal defects. For example, tetracycline, a common antibiotic, can cause irregularities in the bones and discoloration of the teeth. Certain tranquillisers may produce a cleft palate. Heroin and cocaine produce more dramatic effects. If a pregnant woman is addicted to heroin, her baby is likely to be born addicted. The baby will show withdrawal symptoms, such as hyperactivity, irritability and tremors. The symptoms make the baby harder to care for, which, in turn, makes attachment between mother and baby difficult.

Dennis *et al.* (2006) examined the effect of prenatal exposure to another pharmacological substance – cocaine – on a child's later adjustment. They studied 174 largely Afro-Caribbean 4½ year-olds in a longitudinal investigation. Sixty-five had been exposed to cocaine during pregnancy. The researchers studied the time taken by chil-

dren to solve a frustrating problem, the children's degree of frustration with finding a solution, and the children's disruptive behaviour. The problem involved trying to obtain a toy from a basket that was held by a rope tied to a hook on a wall. To obtain the toy, the children had to learn to undo the knot which would release the rope and lower the basket.

Children exposed to cocaine took longer to solve problems and the boys were significantly poorer than were the girls. Boys were also more disruptive and were quicker to become frustrated. The researchers leave open the question of whether those children exposed to cocaine were less able to perform the problem-solving task or were less engaged with it but the results implicate prenatal cocaine exposure with impaired cognitive performance.

A pregnant woman's cigarette smoking and alcohol use are other behaviours that can affect the foetus. The carbon monoxide contained in cigarette smoke reduces the supply of oxygen to the foetus. Reduced oxygen levels are particularly harmful to the foetus during the last half of pregnancy when the foetus is developing most rapidly and its demand for oxygen is greatest. The main effects of mothers' smoking are increased rate of miscarriages, low birthweight babies and increased chance of premature birth.

Alcohol use during pregnancy has been associated with both pre-and post-natal growth deficits, deformations of the eyes and mouth, brain and central nervous system abnormalities, and heart deformation. Collectively, these symptoms are called **foetal alcohol syndrome (FAS)**. The likelihood of stunted growth is doubled if a woman drinks alcohol. Drinking as little as two ounces of alcohol a day

early in pregnancy can produce some symptoms of FAS (Astley *et al.*, 1992). Even if children with FAS are reared in healthy environments with regular, nutritious meals, their physical and intellectual development still falls short of that of normal children (Hanson *et al.*, 1976).

Physical and perceptual development in infancy and childhood

Babies are called infants until 2 years of age. A newborn human infant is a helpless creature, absolutely dependent

on adult care. But recent research has shown that newborns interact proactively, not simply passively, with their carers. They quickly develop skills that shape the behaviour of the adults with whom they interact. As John Betjeman remarked in his poem, *Summoned by Bells*, 'Childhood is measured out by sounds and smells/ And sights before the dark of reason grows.' This section reviews the development of some of the infant's most important skills and some of the physical milestones of an infant's development. It begins with a brief review of brain development.

Controversies in Psychological Science – Does foetal learning exist?

The issue

We assume that most development (cognitive, social and emotional) occurs from birth onwards. However, some research suggests that learning could occur before then, in the womb, a phenomenon called **foetal learning**. The foetus is active and can respond to its external environment. The important question, however, is whether this activity represents meaningful behaviour characteristic of learning or means nothing more sophisticated than a few automatic, involuntary motor or sensory responses.

The evidence

One of the earliest studies of foetal behaviour was published in 1925. Using a very simple paradigm, Pieper reported that when a hand was placed on the pregnant woman's abdomen and a car horn was sounded, the foetus would move about 25–30 per cent of the time. The finding suggested that the foetus might be more sensitive to external sensory stimulation than had previously been assumed.

Modern studies use foetal heart rate (FHR) as a measure of the foetus's responsiveness. The rationale is that if the foetus responds to external stimulation, there will be a change in FHR that is not seen when the foetus is not exposed to such stimulation. The movement of the foetus is also used as a measure

of responsiveness. Using these measures, researchers have found that 37–42-week-old foetuses respond to noises (Schmidt *et al.*, 1985), and FHR responses can be recorded in foetuses as young as 29 weeks (Kisilevsky, 1995; Kisilevsky and Low, 1998). Movement has also been reported in 24–26-week-old foetuses about 1–5 seconds after the onset of a stimulus (Shahidullah and Hepper, 1993).

Is the foetus responding to the acoustic stimuli because it is stimulated by the noise or is it simply showing a reflex action resulting, perhaps, from the vibration caused by the noise? One source of evidence for a foetus's ability to discriminate between stimuli (and, therefore, some demonstrated form of elementary cognition) comes from studies of heart deceleration (or reduction). Deceleration of heart rate is thought to be a good measure of attention because a stimulus which impinges on the foetus's attentional radar is usually accompanied by a reduction in heart rate (Lecanuet *et al.*, 1992). Foetuses have shown evidence of deceleration when they are exposed to different sounds. For example, Lecanuet *et al.* (1989) found that a foetus's heart rate decelerated when the stimulus changed from the word 'babi' to 'biba', suggesting that it was capable of discriminating between phonetic stimuli, at least as measured by heart rate.

Another measure of foetal learning is dishabituation – the renewed responding to a stimulus after the initial response has declined (Hepper, 1994). Habituation and dishabituation involve a degree of sensory discrimination because some stimuli will activate a response and others will not. While this can be measured in the foetus – by separating testing sessions – psychologists have also been interested in the foetus's post-natal response to the stimuli they were exposed to in the womb. For example, if a foetus responded to a stimulus in the womb would they show evidence of learning by preferring that stimulus once it is born? How would we measure this learning?

One way is by studying 'non-nutritive sucking' – the degree of sucking a baby makes when it is exposed to an experimental

Infants can be quick learners and responders to sound, but there is evidence that foetuses also show evidence of learning.

Source: Getty Images/AFP

Controversies in Psychological Science – *Continued*

and control stimulus. Greater sucking is meant to indicate greater interest or attention. Newborns show greater evidence of sucking when they hear their mother's voice or when they are presented with melodies or stories they were exposed to in the womb (DeCasper and Fifer, 1980; DeCasper *et al.*, 1994).

Another aspect of discriminatory learning that appears to occur prenatally is olfactory learning. Newborns are more attracted to the odour of amniotic fluid than other, unfamiliar odours (Schaal *et al.*, 1995), and given a choice between a breast covered in amniotic fluid and one covered with an unfamiliar fluid, they choose to suckle on the nipple coated with amniotic fluid (Winberg and Porter, 1998). Even the mother's eating pattern can influence this 'learning'. Mothers who were garlic eaters gave birth to infants who 'recognised' the odour of garlic (Hepper, 1995). A group of French researchers exposed 3–4-day-old infants to a novel odour (camomile) placed on the mother's nipple and measured whether they preferred this odour to the odour of breast milk or a new odour when tested later (Delaunay-El Allam *et al.*, 2006). Preference was measured via head orientation in a paired odour choice paradigm in which the babies were presented with two odours. (Infants orient, or move, towards the stimuli they prefer.)

Those exposed to the novel odour preferred that odour to a new odour (those not exposed did not show this preference).

When the infants were presented with maternal milk and camomile odours, those exposed to camomile found both equally attractive; those not exposed to camomile preferred the breast milk. The results show that even 4-day-old infants can learn to express preferences for odours to which they have been previously exposed.

Conclusion

Does all of this evidence suggest that the foetus is capable of cognition? This depends on what we mean by cognition. If this means the ability to discriminate between stimuli, then neonates do demonstrate cognitive ability. They may be able to distinguish between the phonetic patterns in two stories, one of which was read to them when they were in the womb, but they clearly did not learn anything about the content or meaning of the story. Their learning was at a basic, perhaps even reflex, level. The auditory system may have sensed the phonetic nature of the story, but the neonate may not have been consciously aware of this sensation. The evidence suggests that the foetus is not simply an inactive, non-behaving organism, but a responsive and potentially discriminating human being.

Brain development

The brain allows the infant to process information around it, to assimilate this material and to act on it. As you saw in Chapter 10, during childhood the brain exhibits a degree of considerable 'plasticity'. A child can quite quickly recover from localised brain injury or damage, to a significantly greater extent than can adults. If damage occurs between infancy and 6 or 7 years old, the function undertaken by the damaged region can recover speedily as long as adequate rehabilitation and support from family and friends are present (as you saw in Chapters 4 and 10). The case of Nico, the child who had half of his brain removed to prevent epileptic fits, exemplified this relatively sophisticated recovery.

Another important feature of brain development is myelination – the process whereby nerve fibres (the axons) are covered in a milky sheath (myelin) which assists the propagation of nerve impulses sent down these fibres. The most dramatic, and the fastest, changes in myelination occur between birth and 6 months; there is slightly slower change between the age of 12 and 24 months and then a period of stable myelination that progresses until early adulthood (Hermoye *et al.*, 2006; Miller *et al.*, 2003).

Reflecting the functions that the infant relies on first, myelination is fastest in regions of the brain responsible for basic motor behaviour, the pons and cerebellum. Figure 12.4 shows myelination's milestones through childhood.

A number of factors influence the rate at which our brain grows and can impair this growth in the critical early stages when the cells of the brain are beginning to develop and make connections with other neurons. A lack of stimulation at a very early age can lead to a significant dysfunction in the nervous system. The failure to stimulate the visual system in animals, for example, leads to long-term disruption of this system's functioning (Blakemore and Mitchell, 1973). Malnutrition, discussed earlier, can have serious consequences for brain development and intellectual functioning.

Until recently, much of what we knew about the development of the brain and its function came from post-mortem studies, studies of acquired brain damage or rare case studies of children deprived of stimulation such as Genie or the Wild Boy of Aveyron, as you saw in Chapter 10. Even then, these rare studies did not tell us precisely what occurred during brain development. The techniques described in Chapter 4, however, such as functional magnetic resonance imaging (fMRI) and MRI have

Figure 12.4 How myelination develops as the brain grows.

enabled researchers to compare stages of development across the lifespan both within a sample (that is, longitudinally) and between samples (cross-sectionally).

Giedd *et al.* (1999) compared the development of the brains of participants tested from age 4 to 20 years, at two-year intervals using MRI. They found that white matter increased steadily over time but the development of grey matter was slightly more irregular. Recall from Chapter 4 that grey matter is made up of blood vessels and neurons whereas white matter is made up of nerve fibres. The development of grey matter peaked just before adolescence and occurred in specific regions of the brain. Frontal and parietal lobe development peaked at 12 and 16 years, respectively, but occipital lobe development continued to 20 years. Although the initial sample was large ($N=145$), the number of individuals who underwent more than three scans was only 33, which suggests caution in interpreting the results. Nevertheless, the results suggest that development in some form continues past adolescence to adulthood.

Recently, an ambitious study mapped cortical development in 4–21-year-olds (Gogtay *et al.*, 2004). This study imaged grey matter changes every two years for 8–10 years and the findings can be seen in Figure 12.5. One of the principal observations is that higher order association cortices mature after lower order somatosensory and visual cortices. The regions of the brain considered to be the oldest were those which matured earliest (e.g. the entorhinal cortex, piriform cortex). Regions within the temporal lobe were the last to show grey matter maturity. An animated version of the development of these regions can be found at www.Pnas.org/cgi/content/full/0402680101/DC1.

Does the environment affect brain development?

The nature–nurture controversy is one of the oldest in psychology. Normally, this controversy revolves around the origins of a particular behaviour, talent or personality trait. People ask, ‘Is it caused by biological or social factors?’, ‘Is it innate or learned?’, ‘Is it a result of hereditary or cultural influences?’, ‘Should we look for an explanation in the brain or in the environment?’ Almost always, biology, innateness, heredity and the brain are placed on the ‘nature’ side of the equation. Society, learning, culture and the environment are placed on the ‘nurture’ side. Rarely does anyone question whether these groups of items form a true dichotomy.

Studies using humans and laboratory animals show that interactions between hereditary and environmental factors – between nature and nurture – begin very early in life. Rosenzweig and his colleagues examined the effects of environmental stimulation on the development of the brain (see Rosenzweig, 1984, for a review) by dividing litters of rats and placing the animals into two kinds of environment: enriched and impoverished. The enriched environment contained items such as running wheels, ladders, slides and ‘toys’ that the animals could explore and manipulate. The experimenters changed these objects every day to maximise the animals’ experiences and to ensure that they would learn as much as possible. The impoverished environments were plain cages in a dimly illuminated, quiet room.

The researchers found that the brains of rats raised in the enriched environment had a thicker cerebral cortex, a better blood supply, more protein content and more acetylcholine, a transmitter substance that appears to play an important role in learning.

What is the evidence from humans that environment is important for proper neuronal development? A group of researchers from Canada, Japan and Germany measured the electrical activity of the brains of twelve 4–6-year-olds as the participants listened to the tone of a violin or a

Figure 12.5 Scans showing the degree of brain development from 5 years old to 20 years old.

burst of noise (Fujioka *et al.*, 2006). Over the course of a year, half of the children received music lessons; the other half did not. MEG was used to record brain activity at four points during the year.

The researchers found that a brain electrical potential recorded from the left hemisphere appearing 250 ms after the onset of the violin sound was larger, and appeared earlier, in those children who had received musical training. As you might expect, musical discrimination was better in the trained group, but so was non-musical working memory. The study suggests that musical training can influence the brain's ability to produce electrical potentials elicited by music, but not non-music, sounds.

In a natural experiment, Skeels (1966) had reported that children removed from orphanages and placed in mental institutions developed normal intelligence whereas those that stayed in orphanages did not. These marked effects of environment on cognitive development have been seen in a very real context. According to UNICEF, 1.5 million children in Central and Eastern Europe are in orphanages, as a result of war. An estimated 10–20 per 1,000 children between 0 and 18 years of age in Bulgaria, Russia and Romania and 5–10 per 1,000 in Poland, Hungary, Moldova, Lithuania, Latvia and Estonia are institutionalised (Brown *et al.*, 2004). In 2004, 23,000 international adoptions were made in the US, and most of

the children came from Eastern Europe, Russia and China (Nelson, 2007).

Many of the institutions may not encourage or nurture a child's intellectual ability. There is one caregiver per 15 children and there is little training for these caregivers. Sensory stimulation is basic – there is little patterned light, for example, and walls are usually painted white. Infants are left in cribs, rarely held, and strict dress codes are usually applied, as are eating times (Nelson, 2007). As the early Skeels study showed, institutionalisation's effects are not positive and these effects are seen in current institutions (Maclean, 2003). These negative effects include poor health, physical impairment, impaired brain development, delay in speech and language, inattention, hyperactivity, impaired cognition and behavioural problems (Johnson, 1997; 2000; Albers *et al.*, 1997; Rutter *et al.*, 1999).

Can the decline be reversed? Sir Michael Rutter and his colleagues from the Institute of Psychiatry, London, examined the extent of 'developmental catch-up' in a group of 111 Romanian orphans adopted into English families within 24 months of being born (Rutter and English and Romanian Adoptees Study Team, 1998). Compared with a control group of 52 English adopted children, the orphans showed poorer attainment of the typical developmental milestones. At 4 years of age, however, the orphans had 'caught up' with their English counterparts. The reason for

such catching up is thought to be the brain's plasticity. According to Nelson (1999), neural plasticity 'can best be thought of as the subtle dance that occurs between the brain and the environment; specifically, it is the ability of the brain to be shaped by experience and, in turn, for this newly remolded brain to facilitate the embrace of new experiences'. It reflects the capacity of the brain to be flexibly organised and reorganised during the early years and seems to explain why brain injury in early childhood is more beneficial to cognitive development and speech than is injury sustained during adolescence or adulthood.

Two longitudinal studies of Romanian adoptees have found that lower IQ and higher degrees of behavioural and attachment problems are seen in children who spent eight months or more in an institution (Macleay, 2003). A comparison of Romanian adoptees and children adopted within the UK found that problems correlated with the length of institutionalisation (O'Connor and Rutter, 2000). The Bucharest Early Intervention Project has found similarly negative effects (Zeanah *et al.*, 2003). Children removed from institutions and fostered, however, appeared to show some improvement.

In terms of brain development, institutionalisation appears to be harmful. Eight-year-old Romanian children who had been institutionalised for an average of 38 months (and had been placed at the institution by the age of 18 months) showed reduced brain metabolism in the frontal lobes and were impulsive and had attention deficits, compared to a group of 10-year-old children with epilepsy (Chugani *et al.*, 2001). Institutionalised children also show reduced EEG activity (Marshall *et al.*, 2004).

Several factors can influence these outcomes – the time at which a child was placed in an institution, the length of stay and the quality of the institutional environment. But the problem with institutionalised children in Eastern Europe looks set to extend to elsewhere. Nelson (2007), for example, notes that Wasil Noor, Deputy Minister of Social Welfare in Afghanistan; has indicated that there are 1.6 million orphans in Afghanistan; 10,000 of these are living in institutions. If there ever was a case for using psychological research to improve the lot of a human being, it would be this.

Motor development

At birth, the infant's most important movements are reflexes – automatic movements in response to specific stimuli. The most important reflexes are the rooting, sucking and swallowing responses. If a baby's cheek is lightly touched, they will turn their head towards the direction of the touch (the rooting response). If the object makes contact with the baby's lips, the baby will open its mouth and begin sucking. When milk or any other liquid enters the mouth, the baby will automatically make

swallowing movements. These reflexes are important for the baby's survival and for an infant's social development.

Normal motor development follows a distinct pattern, which appears to be dictated by maturation of the muscles and the nervous system. **Maturation** refers to any relatively stable change in thought, behaviour or physical growth that is due to the ageing process and not to experience. Although individual children progress at different rates, their development follows the same basic maturational pattern. Development of motor skills requires two ingredients: maturation of the child's nervous system and practice. Development of the nervous system is not complete at birth; considerable growth occurs during the first several months. In fact, some changes are still taking place in early adulthood.

Particular kinds of movement must await the development of the necessary neuromuscular systems. But motor development is not merely a matter of using these systems once they develop. Instead, physical development of the nervous system depends, to a large extent, on the baby's own movements while interacting with the environment. In turn, more complex movements depend on further development of the nervous system (Thelen, 1995). There is evidence that increased locomotion at 9 months is associated with more flexible memory. Crawlers, for example, are better able to imitate a set of actions when the original context in which these actions occurred is changed (Herbert *et al.*, 2007).

Perceptual development

If we want to study how older children or adults perceive the world, we can simply ask them about their experiences. We can determine how large an object must be for them to see it or how loud a sound must be for them to hear it. But we cannot talk to infants and expect to get any answers; we must use their non-verbal behaviour as an indicator of what they can perceive. Newborn infants indicate their taste preferences by facial expression and by choosing to swallow or not to swallow different liquids. When an infant is given a sweet liquid, the face relaxes in an expression rather like a smile; but when it is given a sour or bitter liquid, the face indicates displeasure. Newborn infants can even learn to recognise particular odours. Sullivan *et al.* (1991) presented 1-day-old infants with a citrus odour and then gently stroked them. The next day, these infants (but not control infants) turned towards a cotton swab containing the odour that had been paired with the stroking.

Most investigations of the perceptual abilities of newborn infants have taken advantage of the fact that babies have good control of movements of their head, eyes and mouth. We will look at the results of some of these studies next.

Perception of patterns

The visual perceptual abilities of infants can be studied by observing their eye movements as visual stimuli are shown to them. A harmless spot of infrared light, invisible to humans, is directed onto the baby's eyes. A special television camera, sensitive to infrared light, records the spot and superimposes it on an image of the display that the baby is looking at. The technique is precise enough to determine which parts of a stimulus the baby is scanning. For example, Salapatek (1975) reported that a 1-month-old infant tends not to look at the inside of a figure. Instead, the baby's gaze seems to be 'trapped' by the edges.

By the age of 2 months, the baby scans across the border to investigate the interior of a figure. Before the age of 2 months, infants seem to be more concerned with the contours of visual stimuli and rarely attend to internal features. This is called the **externality effect** (Bushnell, 1979). One reason for the externality effect could be that the infant's visual system is developing and does not possess the acuity or contrast sensitivity (the ability to discriminate between degrees of shade) necessary to perceive complex stimuli. Figure 12.6 shows how babies in the early weeks of life prefer to examine the periphery of a stimulus and stare at areas of high contrast (such as hairline or the chin of the face). At around 2 months, the child inspects the internal features of the stimulus, such as the features of the face (Bronson, 1991).

At around 3 weeks of age, newborns will prefer to look at chequerboards made up of large squares rather than smaller ones; at around 8 to 14 weeks, the preference shifts to the small squares (Brennan *et al.*, 1966). See Figure 12.7 for an example of the stimuli the newborns prefer at different ages.

One reason for this difference in preference may be due to the development of contrast sensitivity. A chequerboard with large squares, for example, will show great contrast because the white and the black blocks are big and, therefore, contrast with each other clearly. Small squares on a chequerboard allow little opportunity for contrast and the newborn may perceive these as a blur.

The work by Salapatek and his colleagues suggests that at the age of 1 or 2 months, babies are probably not perceiving complete shapes; their scanning strategy is limited to fixations on a few parts of the object at which they are looking. Their ability to focus on stimuli, and their visual acuity (the ability to discriminate elements within a stimulus) is relatively poor.

Infants can see objects at 6 metres that adults can at 200 (Courage and Adams, 1990). However, by 3 months, babies show clear signs of pattern recognition and the visual system develops quite rapidly. At 3 months, the babies' ability to focus is as good as adults'. Newborns show evidence of colour preference – they prefer to look at coloured stimuli rather than grey ones – but their ability to discriminate between individual colours is poor. The ability to discriminate between colours, however, is seen by 2 months (Brown, 1990) and this improves over the next three months.

Face perception at birth

Perhaps one of the most salient perceptual features of infant development is the gradual shift in preference from simple stimuli to patterned ones. For example, newborns prefer to look at stimuli that resemble the human face than at stimuli that do not (Rosser, 1994), and they prefer to look at scrambled faces than at a black and white oval stimulus (Fantz, 1961).

As Chapter 6 showed, perceiving and recognising faces seems to rely on different perceptual mechanisms from those that allow us to recognise and perceive objects. At 2 years of age, infants show a preference for natural face arrangements rather than face arrangements that have disorganised features, which suggests that they show evidence of familiarity with the human face (Fantz, 1961). There are two hypotheses regarding the way in which young infants perceive faces and other visual stimuli. The first, the sensory hypothesis, suggests that visual perception occurs in two stages (Kleiner, 1993). The first involves the infant

comparing stimuli for contrast. If these stimuli are similar, then a second stage – the analysis of structure – takes place. This theory, therefore, suggests that if sensory characteristics are similar or identical, then preference for a stimulus will depend on the comparison of structure.

A competing hypothesis, the structural hypothesis, suggests that infants show a preference for face-like arrangements over non-face arrangements not because of the differences in the sensory properties of these stimuli but because infants have a specific device that contains information about the structural features of people's faces (Johnson and Morton, 1991). Johnson and Morton referred to this device which allows children to orient towards face-like stimuli as 'conspic'. Conspic is involved in perceiving the spatial relations between features of a face. For example, this device is responsible for perceiving that a cartoon face has elements in the right place to represent the mouth and eyes. Because conspic is a visual/perceptual device, it has a neural basis (in a subcortical structure called the superior colliculus, which guides the infant's attention to visual patterns). Another process allows the infant to learn about faces because they are guided towards paying attention to them – this is called 'conlearn'. Conlearn is thought to be a cortical function because it involves more sophisticated processing of information.

Current evidence is inconsistent regarding which hypothesis is correct, although the structural hypothesis has been successfully tested (Valenza *et al.*, 1996). Umiltà and his colleagues, for example, presented healthy newborns with a variety of different face stimuli in a series of experiments. The aim of the experiments was to discover whether the sensory properties of faces accounted for babies' orienting response or whether the arrangement of features in faces was the most important determinant of orienting (Umiltà *et al.*, 1996; Simion *et al.*, 1998). In one experiment, newborns were presented with two stimuli: one with facial features in correct arrangement, the other in a different order. The babies preferred to look at the correctly arranged stimulus (Umiltà *et al.*, 1996). When face-like patterns were presented which differed only in their degree of sensory salience – the 'eyes' and 'nose' were either blobs or the outline of blobs – babies preferred to look at the outlined blobs.

In a further experiment, the researchers found that the babies also preferred stimuli whose sensory properties were pronounced. The researchers presented newborns with a face-like stimulus and a non-face-like stimulus that had optimal sensory properties but had features arranged in a different way. The structural hypothesis states that babies would prefer the correctly structured face to that which is incorrectly structured but visually more stimulating. In this experiment, newborns preferred to look at the face-like stimulus, thus providing evidence for the structural explanation of babies' preference for faces.

Young infants' visual acuity is poor. The figure on the right is how the figure on the left would be perceived by a newborn.

It was once thought that, up to the age of 10, children processed faces analytically – they looked at the individual features of a face when trying to recognise it. After this age, they began processing faces configurally – looking at the relations between features on a face in order to recognise it (Carey and Diamond, 1977). Research suggests that this is not the case and that both adults and children process faces configurally (Flin, 1985; Baenninger, 1994).

There is an improvement in face recognition with age, however (Itier and Taylor, 2004). The N170 **event-related potential (ERP)**, for example, appears to be associated with face recognition rather than general object recognition. It also appears to be larger, or delayed, when recognising inverted rather than upright faces (the former is difficult and is thought to be processed featurally rather than configurally). (The N170 is an evoked potential – described in Chapter 4 – that is seen approximately 170 milliseconds after the onset of a stimulus.)

Earlier ERP waves, such as the P100, which reflect sensory processing, were elicited in even very young children when viewing faces. However, the appearance of the N170 elicited by inverted faces started from mid-childhood (mid-teens), suggesting that the ERP data reflect maturational development in the neural systems that allows us to recognise faces.

The ability to see faces as wholes can be disrupted by visual deprivation during childhood (LeGrand *et al.*, 2004). A group of 12 right-handed children who had been treated for bilateral congenital cataracts (they had been deprived of sight in early childhood but had recovered the sense) was asked to say whether the top halves of two faces were the same when the bottom halves were different. In a second condition, the top and bottom halves were misaligned so that the bottom half appeared to have been moved half way along the page. Normal individuals had difficulty in making this decision, but improved when the top and bottom halves were misaligned, suggesting that they processed the face holistically, as a whole. Children who had been deprived of sight, however, showed no evidence of holistic processing and performed better than controls when the top and bottom halves were aligned – they were 20 per cent more accurate and 175 ms faster. This suggests that holistic face processing can be disrupted by visual deprivation that can last for as little as three months.

Perception of space

The ability to perceive three-dimensional space and ability to judge the distance of objects from each other (depth perception) comes at an early age. Gibson and Walk (1960) placed 6-month-old babies on what they called a visual cliff – a platform containing a chequerboard pattern (see Figure 12.8). The platform adjoined a glass shelf mounted several feet over a floor that was also covered

by the chequerboard pattern. Most babies who could crawl would not venture out onto the glass shelf. The infants acted as if they were afraid of falling.

You saw in Chapter 6 that several different types of cue in the environment contribute to depth perception. One cue arises from the fact that each eye gets a slightly different view of the world (Poggio and Poggio, 1984). The ability to perceive the world using information from both eyes – binocular depth cues – emerges at around 2–3 months of age and improves rapidly thereafter. Both eyes need to be properly aligned in order for depth perception to occur properly. If one eye is out of alignment, a condition called strabismus arises (cross-eyedness). However, the infant usually never develops stereoscopic vision, even if the eye movements are later corrected by surgery on the eye muscles. Banks *et al.* (1975) studied infants whose eye movement deficits were later corrected surgically. If surgery occurred before 3 years of age, stereoscopic vision developed; if the surgery occurred later, it did not. This suggests that there is a critical period for the development of aspects of the visual system: if the aspect is developing, it can be modified; if it is complete, modification is not possible.

Other cues, such as kinetic depth cues and pictorial depth cues (such as those used by artists to draw in three dimensions and which allow us to view a receding rail-track as receding), also improve with age. For example, at the age of 3–4 weeks, babies will blink if an object looms towards them (Nanez, 1987).

The development of depth perception appears to be closely allied with motor development because the child's movement (especially of the head) helps the child to locate objects and helps them navigate their way around the environment. Babies who have considerable experience of crawling are more anxious about crossing the visual cliff than are those with little crawling experience (Bertenthal *et al.*, 1984). These experienced crawlers are also better able to remember the location of objects and to find hidden objects (Bai and Bertenthal, 1992).

Figure 12.8 A visual cliff. The child does not cross the glass bridge.

Cognitive development in infancy and childhood

As children grow, their nervous systems mature and they undergo new experiences. Perceptual and motor skills become more complex and children become more competent at executing them. Children learn to recognise particular faces and voices, begin to talk and respond to the speech of others, and learn how to solve problems. Infants as young as 13 months are even able to form memories of specific events they experience (Bauer, 1997). In Chapter 10, you saw how psychologists and linguists have studied the development of language, written and spoken, from infancy onwards. This section considers our current understanding of the development of two other major aspects of cognitive development: memory and thinking.

Development of memory

Memory development in infancy

Memory is a difficult process to study in infants because they have yet to develop language and cannot give the sophisticated linguistic responses that older children can.

It has been suggested that we have difficulty in retrieving memories from this period of our lives (before the age of 4 years) because our verbal ability and our memory structures are not yet sufficiently functional for us to be able to transfer material into long-term memory (Rubin, 1982; Eacott and Crawley, 1998). One-year-old infants, in particular, show rapid forgetting of material. The ‘loss’ of memory for events that occurs in infancy is called childhood or **infantile amnesia**.

Measures of memory in infancy

Because infants do not have sophisticated language, psychologists have had to devise other methods of studying the way in which their memory works.

Usually when presented with two stimuli, one of which is familiar and the other novel, infants who are older than 8–10 weeks will look longer at the novel stimulus. This suggests that the infant is capable of being distracted by stimuli which it perceives as new. The perception of a stimulus as new implies that there is a memory of the old stimulus which is used as a comparison.

A version of this task, the paired-comparison task, involves exposing the infant to a stimulus and then, after a short while, presenting it with the pre-exposed stimulus and a novel one. Memory is measured by monitoring the length of time the infant gazes at the stimuli (Fantz, 1958). For successful recognition, the length between the initial presentation and the subsequent recognition task depends on the infant’s age. Nine-month-old infants can recognise a stimulus successfully after a delay of between 90 and 160 seconds, whereas 6-month-old infants require a much shorter interval.

Habituation paradigms involve the presentation of stimuli to infants repeatedly until they cease to make an orienting response to it, that is, they begin to ignore it because it does not seem to interest them. Attention tends to be paid to stimuli that are different from those that have been repeatedly presented. The longer the delay between the habituated stimulus and a novel stimulus, the more likely it is that the infant will produce a response to the habituated stimulus.

Operant conditioning makes use of the child’s manipulation of mobiles. The child learns that if it moves its foot, which is attached to the mobile, the mobile moves and, therefore, catches its attention. The more vigorous the kicking, the greater the movement of the mobile (Rovee and Rovee, 1969). Technically, this paradigm is called the **mobile conjugate reinforcement paradigm**. A version of this paradigm involves a period of not being able to move the mobile, then a period of being able to move the mobile (via a ribbon attached to the child’s foot) followed by a period of not being able to move the mobile again (Sullivan *et al.*, 1979). This indicates whether the child has learned the association between moving its foot and the resulting effect on the mobile (see Figure 12.9).

	First condition	Later condition
Group A	Head turning causes mobile to move. <i>Babies learn to move head.</i>	Head turning causes mobile to move. <i>Babies continue to move head.</i>
Group B	Mobile remains stationary.	Head turning causes mobile to move. <i>Babies do not learn to move head.</i>
Group C	Mobile intermittently moves on its own.	Head turning causes mobile to move. <i>Babies do not learn to move head.</i>

Figure 12.9 The importance of a responsive environment.

Source: Based on Watson, J.S. and Ramey, C.T., Reactions to responsive contingent stimulation in early infancy. *Merrill-Palmer Quarterly*, 1972, 18, 219–227.

Using this technique, researchers have found that young infants' recognition memory is relatively poor. Young infants of 2–3 months, although able to detect small changes in the mobile, are unable to recognise the mobile one day after training if the mobile has more than one element that has been changed, as measured by their reluctance to move the mobile (Rovee-Collier and Hayne, 1987). As the infant becomes older, however, the delay that can occur between presentations can become longer. For example, a 6-month-old infant can discriminate between a novel and a familiar stimulus after a delay of two weeks; an infant of 3 months can discriminate after a delay of only three days (Borovsky and Rovee-Collier, 1989).

The **deferred imitation paradigm** involves exposing the child to an adult who is performing some actions with a set of novel stimuli. After a delay, the 9–18-month-old infant is allowed to manipulate the objects used by the adult. Learning and memory is measured by the infant's ability to model its behaviour on the adult's (Meltzoff, 1988, 1995). If the toddler can understand instructions, it is given structured tasks, removed from the laboratory, returned again and asked to re-enact the activities it performed earlier. Memory performance for recently acquired actions (making a rattle) and familiar actions (putting a teddy to bed) is quite accurate (Bauer and Mandler, 1992; Mandler and McDonough, 1995).

Over the course of development from 1 to 2 years, the number of sequences of actions that the child can remember increases. At 20 months, for example, the child is able to remember three sequences (Bauer and Dow, 1994); at 24 months, the child can act out five (Bauer and Travis, 1993); at 30 months, the number of actions in the sequence can increase to eight. The finding that children can recall successively increasing series of steps with increasing age suggests that their memory capacity is increasing (or perhaps that their means of encoding is becoming more sophisticated and organised).

As age increases, so the delay between the initial learning period and recall sessions can also increase without any detriment to performance. By 14 months, for example, children have been found to be able to demonstrate the use of a series of observed props after a delay of one week (Meltzoff, 1988). The interesting question that arises from these findings is whether the child is engaging in imitation or in real reasoning. A recent study suggests that the child may be actually capable of reasoning, rather than imitating. Meltzoff's (1988) famous study of imitation learning in infants showed that when 14-month-old children watched an adult turn on a light box by touching the top of the box with the top of the head, two-thirds of the children attempted to switch on the light in this way a week later. None of the control group attempted to switch the light on in this way.

Gergely *et al.* (2002) repeated Meltzoff's study but instead of having the adult turn the light on with their head with hands free, they had adults either do the same as those in the Meltzoff study or had them occupy both hands. In the experiment, the hands-occupied condition was achieved by having adults wrap their arms and torso in a blanket. Twenty-seven infants viewed either the 'hands-free' or 'hands-occupied' adult switching on the light.

When the adult's hands were free, 69 per cent of infants used their heads to switch on the light; when the adult's hands were occupied, only 21 per cent of infants used their heads. The study suggests that infants may be capable of greater rationality than that implied in Meltzoff's seminal study. 'The early imitation of goal-directed actions', the authors conclude, 'is a selective, inferential process that involves evaluation of the rationality of the means in relation to the constraints of the situation.'

By around 3 months of age, the infant shows awareness of changes in its environment; by 6 months, it is able to remember temporal order of stimuli. At 8 months, it is able to recognise words spoken in a story that it heard a while before. For example, Jusczyk and Hohne (1997) exposed fifteen 8-month-old infants to three children's stories for ten days. After two weeks, infants heard words that either occurred frequently in the stories or did not occur frequently. The infants listened significantly longer to the words that had been part of the stories.

The findings of this study suggest that because a delay of two weeks had passed between exposure and recognition, the infant is already beginning to form long-term memories for words occurring in speech. This, of course, has implications for language development (as we saw in Chapter 10).

Memory in early childhood

Between the ages of 1 and 3 years, the child develops the rudimentary language that allows them to communicate and to express an awareness of memory (Bauer, 1997). This awareness of events experienced in the past is quite considerable. For example, a child of 3 years can recall a visit to McDonald's or report an event that occurred when they were 2 or younger (Nelson, 1986; Fivush *et al.*, 1987). When the child is prompted by an adult, the memory performance is even more impressive (Fivush, 1984; Bauer *et al.*, 1995). If the child is asked to act out the event, as opposed to providing a verbal report of it, they are able to recall twice as much information.

At this age, children's memory can be tested in more sophisticated ways than those used for very young infants. For example, two of the most commonly used measures of memory in young children involve object hiding and retrieval and the acting out of observed events. In the hidden object task, the child sees an object

being hidden by an adult and after a delay is asked to retrieve it (DeLoache, 1984). In the observed actions task, the child is exposed to an adult performing a series of actions with props; either immediately after this, or after a delay (and, in both cases, without practice), the child is asked to act out this demonstration.

Children are able to perform such tasks, even at 1–2 years of age. Bauer and Dow (1994), for example, required 16- and 20-month-old infants to demonstrate a series of seen actions after a delay of one week. At the time of the initial exposure, the action was putting a child's toy character to bed; at the retrieval session (one week later), the props had changed to a small dog and a plastic crib. Although the props were changed, the performance of the demonstration after a week's delay was not significantly different.

Knowing where things are – spatial development at 2 years old

Toddlers are quite adept at demonstrating their knowledge of where an object is: very young children can use information about distance and geometry to determine the location of an object. However, this ability is tempered, especially in younger toddlers. This suggests that the neural mechanism that allows such location finding may be developing at this age. For example, when 16–36-month-old toddlers watch a toy being placed in a box and are then moved to the opposite side of the box and asked to find the toy, 22-month-old children are able to use landmarks in the room to guide their object location but younger children fail to do so (Newcombe *et al.*, 1998). Two-year-old children forget more, after a delay between encoding and retrieval, than older infants, even when the effects of learning are kept constant (Bauer, 2006). This type of 'place learning' is thought to depend on the integrity of the hippocampus. When the context is changed or when a memory cue alters, infants remembering is impaired, perhaps because they interpret or perceive the cue and context as being a unitary representation, rather than considering both relatively and separately (Jones and Herbert, 2006). This ability to see relations between objects is thought to be attributable to the function of the hippocampus and this is not mature in infants.

Sluzenski *et al.* (2004) had 18–42-month-old infants complete tasks in which they had to remember multiple locations, learn the relations between objects and recall a learned location after a delay. For example, the two-location task involved the children observing two objects being hidden simultaneously in a box filled with sand. Whereas the performance of 18- and 24-month-old infants did not differ significantly when attempting to find the first toy, the 24-month-olds were better at finding

the second object. In another task, children were taught the spatial relation between two objects and were asked to search for one of these when another was revealed. Performance was poor in most of the children. In a retention task, children were asked to find an object after a delay between observing the object being hidden and retrieving it. The 18-month-olds performed more poorly than the other groups, especially the older ones.

The data suggest that specific changes in the ability to learn spatial relations occurs between 18 months and 24 months and beyond. While the authors were unable to measure hippocampal development and relate this to the changes they observe, they also note that the improvement they saw may be related to the development of structures surrounding the hippocampus.

Why does the child's memory improve dramatically from 1 to 4 years of age?

Three factors seem to account for the child's ability to recall information better with age: the formation of memory-related structures, the development of language and the development of metamemory, i.e. the realisation that using memory strategies will help the child to think and behave. The relative contribution of each is unclear but we know that the brain develops until the age of adolescence (and some parts become mature after this). Myelination, for example – the process whereby the axons of the brain become insulated and which allows them to transmit information to neurons more efficiently continues to adolescence – is correlated with speed of processing in children (Travis, 1998).

The development of language means that a child has the capability to encode material verbally instead of via some other representation such as visual representation. By the age of 3 years, for example, the child begins initiating conversation (Fivush *et al.*, 1987). Interestingly, it has been suggested that it is not the verbal encoding of material per se that causes improvement in memory but the verbal expression of memory. That is, if a memory is verbally expressed, then this memory will be retained longer than if it had not been expressed (Nelson, 1993; Bauer and Wewerka, 1995).

It has also been suggested that the types of memory recalled from early and later infancy are dependent on whether the child is employing a narrative technique to give structure and meaning to events. Autobiographical memory develops later in infancy and this form of memory relies on the structuring and organisation of events to make them meaningful. Perhaps one reason why we can remember events as adults from the age of 4 years onwards but not before then is because we did not have a narrative structure in place before the age of 4 to give material meaning and depth (Nelson, 1993). This is quite a controversial idea.

The development of cognition: Jean Piaget

The most influential student of child development has been Jean Piaget (1896–1980), a Swiss psychologist, who viewed cognitive development as a maturational process. Piaget formulated the most comprehensive description of the process of cognitive development that we have. His conclusions were based on his observations of the behaviour of children – first, of his own children at home and, later, of other children at his Centre of Genetic Epistemology in Geneva. He noticed that children of similar age tend to engage in similar behaviours and to make the same kinds of mistakes in problem-solving. He concluded that these similarities are the result of a sequence of development that all normal children follow. Completion of each period, with its corresponding abilities, is the prerequisite for entering the next period.

According to Piaget, as children develop they acquire **cognitive structures** – mental representations or rules that are used for understanding and dealing with the world and for thinking about and solving problems. The two principal types of cognitive structure are schemata and concepts. **Schemata** (‘schema’ is the singular form) are mental representations or sets of rules that define a particular category of behaviour – how the behaviour is executed and under what conditions. A child is said to have a ‘grasping schema’ when they are able to grasp a rattle in their hand. Once they have learned how to grasp a rattle, they can then use the same schema to grasp other objects. A child has acquired a ‘picking up schema’ when they are able to lift the rattle from a surface.

Piaget suggested that as a child acquires knowledge of the environment, they develop mental structures called concepts – rules that describe properties of environmental events and their relations to other concepts. For example, concepts about the existence of various objects include what the objects do, how they relate to other objects, and what happens when they are touched or manipulated. Thus, an infant’s cognitive structure includes concepts of such things as rattles, balls, crib slats, hands and other people.

Infants acquire schemata and concepts by interacting with their environment. According to Piaget, two processes

help a child to adapt to its environment: assimilation and accommodation. **Assimilation** is the process by which new information is modified to fit existing schemata. For example, when a child moves a wooden block along a surface while making the rumbling sound of an engine, they have assimilated the wooden block into their schema of a car. **Accommodation** is the process by which old schemata are changed by new experiences. Accommodation produces either new schemata or changes in existing ones. For example, suppose that a young girl’s concept of animal has three categories: doggies, kitties and teddies. If she sees a picture of a deer and calls it a kitty, she has assimilated the new information into an existing concept. However, if she decides that a deer is a new kind of animal, she will accommodate her animal concept to include the new category. Now this concept consists of doggies, kitties, teddies and deer.

Assimilation and accommodation are closely linked in that they both work together but there are periods in the child’s life when it will assimilate more than it will accommodate (and vice versa). Piaget referred to this state as cognitive ‘equilibrium’. When the child undergoes periods of quick and radical change, however, there is disequilibrium – new information does not match what the child knows and so the child has to accommodate the new information, rather than assimilate it. Once accommodation has taken place, the child returns to assimilation.

Piaget’s four periods of cognitive development

Although development is a continuous process, the cognitive structures of children vary from age to age. We can make inferences about the rules that children of certain ages use to understand their environment and control their behaviour. Piaget divided cognitive development into four periods: sensorimotor, preoperational, concrete operational and formal operational. What a child learns in one period enables them to progress to the next period. This conception of stages was viewed as invariant – they always appeared in this order – and universal – they emerge in this way in all children. See Table 12.1 for a summary of Piaget’s stages.

Table 12.1 The four periods of Piaget’s theory of cognitive development

Period	Approximate age (years)	Major features
Sensorimotor	0–2	Object permanence; deferred imitation; rudimentary symbolic thinking
Preoperational	2–6 or 7	Increased ability to think symbolically and logically; egocentric; cannot yet master conservation problems
Concrete operational	6 or 7–11	Child can master conservation problems, can understand categorisation; cannot think abstractly
Formal operational	11 upwards	Child can think abstractly and hypothetically

The sensorimotor period

The **sensorimotor period**, which lasts for approximately the first two years of life, is the first stage in Piaget's theory of cognitive development. It is marked by an orderly progression of increasingly complex cognitive development ranging from reflexes to symbolic thinking. During this period, cognition is closely tied to external stimulation. An important feature of the sensorimotor period is the development of **object permanence**, the idea that objects do not disappear when they are out of sight. Until about 5 months of age, children appear to lose all interest in an object that disappears from sight – the saying 'out of sight, out of mind' seems particularly appropriate. In addition, cognition consists entirely in behaviour: thinking is doing.

At first, infants do not appear to have a concept for objects. They can look at visual stimuli and will turn their heads and eyes towards the source of a sound, but hiding an object elicits no particular response. At around 3 months, they become able to follow moving objects with their eyes. If an object disappears behind a barrier, infants will continue to stare at the place where the object has disappeared but will not search for it.

At around 5 months, infants can grasp and hold objects and gain experience with manipulating and observing them. They can also anticipate the future position of a moving object. If a moving object passes behind a screen, infants turn their eyes towards the far side of the screen, seeming to anticipate the reappearance of the object on the other side.

During the last half of their first year, infants develop much more complex concepts concerning the nature of physical objects. They grasp objects, turn them over and investigate their properties. By looking at an object from various angles, they learn that the object can change its visual shape and still be the same object. In addition, if an object is hidden, infants will actively search for it; their object concept now contains the rule of object permanence. For infants at this stage of development, a hidden object still exists. 'Out of sight' is no longer 'out of mind'.

By early in their second year, object permanence is well enough developed that infants will search for a hidden object in the last place they saw it hidden. However, at this stage infants can only keep track of changes in the hiding place that they can see. For example, if an adult picks up an object, puts it under a cloth, drops the object while their hand is hidden, closes the hand again and removes it from the cloth, infants will look for the object in the adult's hand. When they do not find the object there, they look puzzled or upset and do not search for the object under the cloth (see Figure 12.10).

Near the end of the sensorimotor period, two other interesting developments occur. First, children develop the ability to imitate actions that they have seen others per-

form, a behaviour that Piaget called **deferred imitation**. This behaviour is due to their increasing ability to form mental representations of actions that they have observed. These representations may then be recalled at a later time to direct particular imitative actions and symbolic play, such as pretending to feed a doll or taking a stuffed animal for a walk. Secondly, as having an imagination shows, 2-year-old children begin to think symbolically. They can use words to represent objects such as balls and animals. This is a critical developmental step because this skill is crucial to language development.

The preoperational period

Piaget's second period of cognitive development, the **preoperational period**, lasts from approximately age 2 to age 7 and involves the ability to think logically as well as symbolically. This period is characterised by rapid development of language ability and of the ability to represent

Figure 12.10 Object permanence. An infant will not realise that the object has been left under the cloth.

things symbolically. The child arranges toys in new ways to represent other objects (for example, a row of blocks can represent a train), begins to classify and categorise objects, and starts learning to count and to manipulate numbers. By the age of $2\frac{1}{2}$ years, children have been shown to be able to treat objects such as kitchen utensils, bathroom items, animals, plants and so on as distinct categories of object (Bauer and Mandler, 1989).

Piaget asserted that development of symbolism actually begins during the sensorimotor period, when a child starts imitating events in his or her environment. For example, a child might represent a horse by making galloping movements with the feet or a bicycle by making steering movements with the hands. Symbolic representations like these are called signifiers: the motor act represents (signifies) the concept because it resembles either the movements that the object makes or the movements the child makes when interacting with the object.

Concepts can also be represented by words, which are symbols that have no physical resemblance to the concept; Piaget referred to such abstract symbols as signs. Signifiers are personal, derived from the child's own interactions with objects. Therefore, only the child and perhaps members of the immediate family will understand a child's signifiers. In contrast, signs are social conventions. They are understood by all members of a culture. A child who is able to use words to think about reality has made an important step in cognitive development.

Piaget's work demonstrated quite clearly that a child's representation of the world is different from that of an adult. For example, most adults realise that a volume of

water remains constant when poured into a taller, narrower container, even though its level is now higher. However, early in the preoperational period, children will fail to recognise this fact; they will say that the taller container contains more water. The ability to realise that an object retains mass, number or volume when it undergoes various transformations is called **conservation**; the transformed object conserves its original properties.

Piaget concluded that the abilities to perceive the conservation of number, mass, weight and volume are attributes of increasing cognitive development. His studies showed number to be conserved by age 6, whereas conservation of volume did not occur until age 11. Presumably, conservation of number comes first because children can verify the stability of number once they learn to count, although conservation skill is seen in children who are not proficient counters (see Figure 12.11). This is an example of what Piaget called 'horizontal decalage' – the development of a skill within a period.

Another important characteristic of the preoperational period is **egocentrism**, or a child's belief that others see the world in precisely the way that they do. For example, a 3-year-old child may run to a corner, turn his back to you and cover his eyes in an attempt to hide during a game of hide and seek, not realising that he is still in full view. In a typical 'egocentric thinking' task, the child may be presented with models of three mountains which differ according to colour and features: some may have a cross on or snow or a house. A doll is placed at one end of the mountains and the child at the other. The child is then asked what they think the doll can see.

Figure 12.11 Various tests of conservation.

Source: Lefrancois, G.R., *Of Children: An introduction to child development*, Wadsworth (Lefrancois, G.R. 1983) with permission of Guy Lefrancois

Because giving a verbal response is difficult for the child, the child either selects the doll's view from ten images or is given models of the mountains and has to arrange them in such a way to represent the doll's viewpoint. Children aged 8–9 years perform poorly at this task, usually selecting the image that represents their, rather than the doll's, point of view. According to Piaget, the child was unable to 'decentre'. He concluded that the children 'really imagine that the doll's perspective is the same as their own' (p. 220; cited in Donaldson, 1978).

However, there have been challenges to Piaget's view of the child's cognitive development during this period. A significant series of studies, for example, has demonstrated that the child's egocentric thinking may not be as egocentric as Piaget suggested. If children are given familiar objects in the three mountains' task, for example, or are given alternative methods of giving a response – rather than choosing one of ten pictures which is difficult even for older children – even very young children show evidence that they can see viewpoints from another's perspective (Newcombe and Huttenlocher, 1992). If the difficulty and the unfamiliarity of a task are eliminated, therefore, children during this period do better than Piaget's conception would predict.

Young children also show evidence that they can engage in non-egocentric thinking: they change their language, depending on the context in which they find themselves. For example, 2-year-olds use shorter sentences when talking to their peers than when talking to adults suggesting that they are responsive to those interacting with them and possibly modify their own linguistic output accordingly (Gelman and Shatz, 1978).

Simplification of the tasks Piaget used has also shown that children in this period are capable of conservation. If the number of conserved items is reduced from six or seven to three, even 3-year-old children can perform the task correctly (Gelman, 1972). In one example of a conservation task, sugar is dissolved in water and the child is asked whether the sugar still exists. Although Piaget's studies suggested that children incorrectly responded that the sugar did not exist, recent research suggests that 3–5-year-olds are capable of responding that the sugar exists and can be tasted but that its particles are too small to be visible (Au *et al.*, 1993).

Children also seem to be more capable of understanding transformations than Piaget's theory suggests. For example, in an experiment where a dry cup becomes a wet cup or a wet cup becomes a dry one, 3-year-old children have difficulty in picking out the object that caused the cup to change its appearance (from water, cloth, feather), but 4-year-olds could perform the task correctly (McCabe and Peterson, 1988).

The period of concrete operations

Piaget's third stage of cognitive development, the **period of concrete operations**, spans approximately ages 7 to 11 and involves children's developing understanding of the conservation principle and other concepts such as categorisation. Its end marks the transition from childhood to adolescence. This period is characterised by the emergence of the ability to perform logical analysis, by an increased ability to empathise with the feelings and attitudes of others, and by an understanding of more complex cause-and-effect relations. The child becomes much more skilled at the use of symbolic thought. For example, even before the period of concrete operations, children can arrange a series of objects in order of size and can compare any two objects and say which is larger. However, if they are shown that stick A is larger than stick B and that stick B is larger than stick C, they cannot infer that stick A is larger than stick C.

During the early part of this period, children become capable of making such inferences. However, although they can reason with respect to concrete objects, such as sticks that they have seen, they cannot do so with hypothetical objects. For example, they cannot solve the following problem: Judy is taller than Frank and Frank is taller than Carl. Who is taller, Judy or Carl? The ability to solve such problems awaits the next period of cognitive development.

The period of formal operations

During the **period of formal operations**, which begins at about age 11, children become capable of abstract reasoning. They can now think and reason about hypothetical objects and events. They also begin to understand that under different conditions their behaviour can have different consequences. Formal operational thinking is not 'culture free' – it is influenced by cultural variables, especially formal schooling (Piaget, 1972; Rogoff and Chavajay, 1995). Without exposure to the principles of scientific thinking, such as those taught at school, people do not develop formal operational thinking.

The period is also critical in another way. At around age 11 the child is beginning the journey into adolescence where physical, bodily changes are significant and where a type of formal operational egocentrism, the ability to imagine what others think about them and the belief that their views of others are shared by others, develops (Inhelder and Piaget, 1955). Teenagers seem to have two distinct views of themselves and others, believing that they are constantly on stage, performing to an imaginary audience and being the focus of attention (Elkind and Bowen, 1979), and believing that others are always talking or thinking about them. They feel they are special. These two views peak during this period and decline steadily throughout the adolescent years.

Although Piaget held that there are four periods of cognitive development, not all people reach the formal operational period, even as physically mature adults. In some tribal cultures, formal operations do not emerge at all, probably because there is a lack of opportunity to engage in hypothetico-deductive reasoning (Gellatly, 1987). In some cases, adults show formal operational thought only in their areas of expertise. Thus, a mechanic may be able to think abstractly while repairing an engine but not while solving maths or physics problems. A physicist may be able to reason abstractly when solving physics problems but not while reading poetry. However, once an individual reaches that level of thinking, they will always, except in the case of brain disease or injury, perform intellectually at that level.

However, a child does not necessarily reach this stage during the adolescent years. Some are capable of abstract reasoning at a much earlier age (6 years old) if the variables that are thought about are not many. The difficulty in the early years appears to revolve around understanding contradictory information. For example, Moshman and Franks (1986) found that if children younger than 10 years were presented with a reasoning problem that was unusual, for example:

Dogs are bigger than elephants
Elephants are bigger than mice
Therefore, dogs are bigger than mice

they regarded the reasoning as illogical, probably because their knowledge of concrete objects (dogs, elephants, mice) interfered with general formal reasoning which required an understanding of the reasoning process rather than the objects referred to in the problem.

Play and its role in social and cognitive development

Play is often regarded as a social behaviour – children interact with each other or with objects in the environment in an enjoyable and positive way – but it is also a cognitive one in which children learn about these objects and the objects' relationship to the environment. Babies as young as 1 year begin to play with objects, although in an unsophisticated way. For example, objects may be picked up, sucked and thrown, but little more than this. However, as the infant grows older, it begins to play with objects in a more symbolic way. Through play, it appears to show evidence of developing cognition.

At 12–18 months, infants begin to play with objects symbolically – they pretend that the object is something else. For example, an object (a pencil) used for one purpose (writing), is used to carry out another behaviour (combing

the hair) (Belsky and Most, 1981). About half of the infants who reach 14 months can pretend that they are sleeping by putting their head on a pillow, but it takes a further six months before they are able to use a doll to signify sleeping by putting the doll to bed (Watson and Fischer, 1977). At the age of 4 years, children use play to find out more about their environment and the social values of the environment around them as well as its customs and traditions.

According to Piaget, play is the opposite of imitation. When children imitate, accommodation predominates over assimilation; when children play, the opposite occurs. According to Vygotsky (1976/1933), the meaning of an object in children's play completely usurps its actual physical meaning. In the comb and pencil example, the pencil had become the comb – it combed hair; it did not write messages on paper. This creativity in the child's use of objects increases in the presence of a parent but only if the parent joins in (Slade, 1987), which indicates that the parent's involvement in the child's developing imagination and exploration of objects is an important one.

Because of the complex nature of the activity, Piaget (1945/1951) saw play as a cognitive activity rather than a social one. He gave it the name **symbolic play** because infants used objects to symbolise other objects or used them to symbolise other activities (e.g. the pencil symbolised a comb). The transition from play to symbolic or pretend play occurred in two stages, according to Piaget.

The first stage occurs when the infant is between 0 and 4 years and, in typically Piagetian fashion, this stage is further subdivided into three substages. In substage 1, the child develops an idea of what an object is and preserves its unique characteristics; this enables it to project these characteristics onto other objects. The infants might observe a behaviour in those around them, develop a schema of those objects they observe and translate this schema into a different type of behaviour. For example, a child may observe an adult cleaning with one object but use another to carry out the same activity.

In substage 2, the child shows evidence of independence from the prop/object they use. That is, the knowledge of an object precedes the use of the object. A brush placed above the head is symbolically treated as an umbrella. The child not only has an awareness of what umbrellas do but is also able to use another object to signify the use of an umbrella. Another example is where the child plays hide and seek but plays the part of the person doing the hiding.

In substage 3, various actions are combined together to form an ensemble of meaning. This example comes from Piaget's study of one of his daughters: a shoe box is used as a bath, and a blade of grass is used as a thermometer. The child dips the blade into the shoe box and declares it too hot; a short while later, she repeats the action and declares that it is just right. This degree of imagination appears to occur at the same time as the creation of imag-

inary characters in the child's world. At this stage, this type of symbolic play becomes more organised.

How would you go about developing a test for determining which of Piaget's periods of cognitive development a child is in? What kinds of activity would you include in such a test and how would the child's behaviour with respect to those activities indicate the child's stage of development?

Evaluation of Piaget's contributions

Piaget's theory has had an enormous impact on research in developmental psychology (Beilin, 1990; Halford, 1990). However, not all of Piaget's conclusions have been accepted uncritically. One criticism levelled at Piaget is that he did not always define his terms operationally. Consequently, it is difficult for others to interpret the significance of his generalisations. Many of his studies lack the proper controls. Thus, much of his work is not experimental, which means that cause-and-effect relations among variables cannot be identified with certainty. Perhaps the greatest criticism of Piaget has been reserved for his periods of cognitive development. Attempts to verify the timetable of Piaget's periods of cognitive development have met with little success (Flavell, 1992). Children can be trained to perform Piaget's tasks correctly so that a child who should be operating at a level occurring in an early period might correctly attempt cognitive tasks that characterise a later developmental period (Beilin, 1978). This illustrates a problem with Piaget's theorising: there are not many abilities that are completely absent in one specific period and present in another. One view suggests that the child has the capacity for all of these abilities but they are present at different levels in different children, which would account for variations in children's cognitive performance.

Subsequent research has suggested that a child's ability to conserve various physical attributes occurs earlier than Piaget had supposed. Piaget also appears to have underestimated the ability of young children to understand another person's point of view, as you saw in the section on the pre-operational period. For example, Flavell *et al.* (1981) found that even a 3-year-old child realises that a person looking at the opposite side of a card to that which the child is examining will not see the same thing. Clearly, the child recognises the other person's point of view. Flavell and colleagues also showed that even very young children can tell the difference between appearance and reality. They presented a series of disguised items and asked children what the objects really were (Flavell *et al.*, 1989).

Piaget's prediction would be that children would identify the disguise, rather than the object underneath. However, Flavell *et al.* found that 3-year-old children were capable of correctly identifying the disguised object. They were also able to distinguish between the way an object

felt and how it actually was. For example, although an ice cube held by a rubber glove was not perceived as cold, children were able to understand that the cube still maintained the property of coldness. Therefore, the children showed evidence of logical thinking before they reached the concrete operations period.

Piaget also largely discounted experience in his theory of development; periods would develop naturally and in order and did not depend on experience. However, culture does seem to have a significant effect on cognitive skills such as conservation. The children of the Hausa tribe in Nigeria, for example, do not go to school and do not understand conservation principles until they are around 11 years old (Fahrmeier, 1978), suggesting that some degree of daily activity involving conservation may be necessary before this concept is mastered.

Finally, it is interesting to discover that around 40–60 per cent of students fail Piaget's formal operations problems (Keating, 1979). Again, this may be because people are better able to reason abstractly with information that is familiar to them than with unfamiliar Piagetian information. Despite the fact that Piaget's method of observation led him to underestimate some important abilities, his meticulous and detailed observations of child behaviour have been extremely important in the field of child development and have had a great influence on educational practice. With Vygotsky (see below), Piaget has made probably the greatest contribution to our understanding of child development.

Vygotsky's sociocultural theory of cognitive development

Piaget's theory of cognitive development focuses on children's interactions with the physical world – children form internal representations of the world based on their experiences with physical objects. Another theorist, the Russian psychologist Lev Vygotsky, agreed that experience with physical objects is an important factor in cognitive development, but he disagreed that this is the whole story. Instead, he argued that the culture in which one lives also plays a significant role in cognitive development: the child's cognitive development was promoted by the interaction between the child and its social environment (Vygotsky, 1987). Although Vygotsky's work was conducted during the 1920s and early 1930s (he died of tuberculosis in 1934, aged 37), his writings have had a major impact on more recent conceptualisations of cognitive development during childhood (Smith *et al.*, 1997).

Vygotsky argued that children do not learn to think about the physical world in a vacuum. The cultural context – what they hear others say about the world and how they see others interact with physical aspects of the

world – matters. Thus parents, teachers, friends and many others help children to acquire ideas about how the world works. We would expect, then, that the development of children raised in non-stimulating environments devoid of stimulating interactions with others, with books, and even television, would lag behind that of children raised in more stimulating environments. And this is exactly what has been found.

Vygotsky further believed that children's use of speech also influences their cognitive development. Piaget had argued that the private speech that children engage in was egocentric – children were unable to imagine others' points of view – and that this conversation would be rattled off as if in a stream of consciousness. As the child interacts with peers and as the child grows older and interacts with adults, this private speech is eliminated and the child engages in social speech – they listen to others talking and respond appropriately. Children up to about age 7 can often be observed talking to themselves. While drawing in a colouring book, a child may say, 'I'll colour her arms and face green and her trousers black.' Piaget would interpret such talk as being egocentric and non-social because it is directed at the self, because it may not make sense to a listener, and because its purpose is not to communicate information.

Vygotsky's (1934/1962) interpretation was different. He argued that the child's talk reflected the formulation of a plan that would serve as a guide to subsequent behaviour. According to Vygotsky, language is the basis for cognitive development, including the ability to remember, solve problems, make decisions and formulate plans. As children became better at tasks that involved attention, memorisation, planning and so on, then their private vocal speech would disappear and would be internalised instead. Studies have shown that children engage more in private speech if a task is challenging, if it makes them make mistakes or results in confusion about what to do next (Berk, 1992, 1994). The children who use such speech when faced with challenging tasks are more attentive and show better improvement in cognitive performance than are those who are less talkative (Behrend *et al.*, 1992).

After about the age of 7 children stop vocalising their thoughts and instead carry on what Vygotsky labelled 'inner speech'. **Inner speech** represents the internalisation of words and the mental manipulation of them as symbols for objects in the environment. As children socially interact with their parents, teachers and peers, they learn new words to represent new objects. As the 'expertise' of the people they interact with increases, so does the children's cognitive skills. For example, Rogoff (1990) has shown that children become better problem solvers if they practise solving problems with their parents or with more experienced children than if they practise the problems alone or with children of similar cognitive ability. Vygotsky explained this process by referring to the **zone of proximal (or potential) development**. This describes a

range of tasks or skills that a child is unable to master alone but can with the assistance of adults or their peers. The greater the interaction with adults, then the more adult the child's language becomes. But what aspect of the interaction is important for the change in development?

There are two possible candidates. One is a process whereby two people begin with a different understanding and by mutual discussion reach a common understanding. This has been called intersubjectivity (Newson and Newson, 1975) because one member of the dyad adjusts their point of view according to the behaviour of the other. The other possibility is that the interaction acts as a form of 'scaffolding' – peers and adults provide social support in the learning environment but this support can be adjusted (Bruner, 1983). Mothers who provide good social support while their child learns – and are, therefore, good scaffolders – produce children that generate more private speech and who are more successful than children with less social support when completing puzzles alone (Behrend *et al.*, 1992).

Thus, while Piaget argued for a purely maturational view of children's cognitive development – skills developed within periods defined by cognitive characteristics as well as age – Vygotsky placed greater importance of sociocultural influences such as language and interactions with other people. As we have seen, research partially supports both theorists' ideas. However, Vygotsky's work has gone beyond Piaget's theory in explaining how cultural variables, especially language, influence cognitive development.

Developmental models of information processing in cognitive development

Both Piaget and Vygotsky saw cognitive development as a process of forming internal representations of the external world. Piaget focused on the development of schemata, the processes of assimilation and accommodation, and abstract reasoning. Vygotsky focused on the role of language in the development of problem-solving skills, decision-making, and formulating plans. An alternative approach is to view cognitive development in terms of information processing, which involves the storage, encoding and retrieval of information. Figure 12.12 shows you how cognitive performance, in terms of processing speed, improves from the age of 8 years onwards and then tails off in early adulthood. Two developmental models of information processing have emerged in recent years: Case's M-space model and Fischer's skill model.

Case's M-space model

According to Case (1985, 1992), cognitive development is a matter of a child becoming more efficient in using mental strategies. The heart of Case's model is **mental space (M-space)**, a hypothetical construct, similar to short-term or

working memory, whose chief function is the processing of information from the external world. Expansion of M-space, or increases in a child's information processing capacity, is caused by a combination of three variables.

Figure 12.12 How the ability to engage in visual search, to rotate three-dimensional images mentally and to perform mental addition becomes faster from the age of 8 years onwards.

First, as the brain matures, so does its capacity to process greater amounts of information. Maturation of the brain, specifically the increasing number of networks of neural connections and increasing myelination of neurons, also enhances more efficient processing of information. Secondly, as children become more practised at using schemata, less demand is placed on cognitive resources, which can now be devoted to other, more complex cognitive tasks. For example, when children first learn to ride a bicycle, they must focus entirely on keeping their balance and steering the bike in a straight line. After they have acquired these skills, they no longer have to devote so much attention to steering the bike and not falling off. Now they can look around, talk to other bike riders and so on. Thirdly, schemata for different objects and events become integrated so that children now think in novel ways about these objects and events. The net result of such integration is the acquisition of central conceptual structures – networks of schemata that allow children to understand the relationships among the objects and events represented by schemata. As increasingly complex central conceptual structures are formed, children advance to higher levels of cognitive development, as represented in Piaget's stages. Each of the milestones in Piaget's theory, such as deferred imitation and conservation, requires increasing amounts of M-space.

Fischer's skill model

In Fischer's skill model, cognitive development involves the learning of skills, or the acquisition of competencies on particular tasks, such as those found in each of Piaget's developmental periods. Fischer emphasises the child's **optimal level of skill performance**, or the brain's maximal capacity for information processing. According to Fischer, as the brain matures, the child advances through stages of cognitive growth that parallel Piaget's periods of cognitive development (Fischer and Farrar, 1987; Fischer and Pipp, 1984). During each stage, the child's capacity to process information increases, as does the level of skill required for mastery of specific cognitive tasks, such as conservation tasks. As the child encounters different problems, new skills are acquired, practised and perfected. These skills become integrated, leading to increases in the child's ability to reason and think abstractly.

A child cannot progress from one Piagetian period to another until their brain has matured sufficiently to permit acquisition of the cognitive skills necessary to master tasks representative of the next period. For example, a preoperational child is not able to solve conservation tasks until their brain has matured sufficiently to permit acquisition of the necessary skills. Even if a parent explains the task, the child's brain will not be able to encode, store and later retrieve those instructions. When faced with the

conservation problem later, the child will still be unable to solve it.

Both Case's M-space model and Fischer's skill model rely on brain maturation as the primary explanation for children's increasing ability to think logically and abstractly. And both models in essence rephrase Piaget's theory of cognitive development in information-processing terms. The purpose of these models has not been to discredit Piaget's theory. On the contrary, one important function of these models has been to reinterpret the theory in the language of modern cognitive psychology. Perhaps by conceptualising children's thought processes in terms of the interplay of Piaget's theory, brain maturation processes, and the acquisition of novel and more complex information processing abilities, further advances in understanding cognitive development will emerge.

Social and emotional development in infancy and childhood

Normally, the first adults with whom infants interact are their parents. In most cases, one parent serves as the primary carer. As many studies have shown, a close relationship called attachment is important for infants' social development. **Attachment** is a social and emotional bond between infant and carer that spans both time and space. It involves both the warm feelings that the parent and child have for each other and the comfort and support they provide for each other, which becomes especially important during times of fear or stress. This interaction must work both ways, with each participant fulfilling certain needs of the other.

Formation of a strong and durable bond depends on the behaviour of both people in the relationship. According to theorist John Bowlby (1969), attachment is a part of many organisms' native endowment. He and Mary Ainsworth have developed an approach that has succeeded in discovering some of the variables that influence attachment in humans (Ainsworth and Bowlby, 1991).

Infant attachment

Newborn infants rely completely on their parents (or other carers) to supply them with nourishment, keep them warm and clean, and protect them from harm. To most parents, the role of primary carer is much more than a duty; it is a source of joy and satisfaction. Nearly all parents anticipate the birth of their children with the expectation that they will love and cherish them. And when a child is born, most of them do exactly that. As time goes on, and as parent and child interact, they become strongly attached to each other.

What factors cause this attachment to occur? Evidence suggests that human infants are innately able to produce special behaviours that shape and control the behaviour of their carers. As Bowlby (1969) noted, the most important of these behaviours are sucking, cuddling, looking, smiling and crying.

Sucking

A baby must be able to suck in order to obtain milk. But not all sucking is related to nourishment. Piaget (1952) noted that infants often suck on objects even when they are not hungry. Non-nutritive sucking appears to be an innate behavioural tendency in infants that serves to inhibit a baby's distress. In modern society, most mothers cover their breasts between feedings or feed with a bottle, so a baby's non-nutritive sucking must involve inanimate objects or the baby's own thumb. But in Uganda, mothers were observed to give their babies access to a breast when they were fussy, just as mothers in other cultures would give them a dummy (Ainsworth, 1967).

Cuddling

Infants of all species of primates have special reflexes that encourage front-to-front contact with their mothers. For example, a baby monkey clings to its mother's chest shortly after birth. This clinging leaves the mother free to use her hands and feet. Human infants are carried by their parents and do not hold on by themselves. However, infants do adjust their posture to mould themselves to the contours of the parent's body. This cuddling response plays an important role in reinforcing the behaviour of the carer. Some infants, perhaps because of hereditary factors or slight brain damage, do not make the cuddling response and remain rigid in the adult's arms. Adults who hold such infants tend to refer to them as being not very lovable.

Harry Harlow (1974) conducted a series of experiments on infant monkeys and showed that clinging to a soft, cuddly form appears to be an innate response. Harlow and his colleagues isolated baby monkeys from their mothers immediately after birth and raised them alone in cages containing two mechanical surrogate mothers. One surrogate mother was made of bare wire mesh but contained a bottle that provided milk. The other surrogate was padded and covered with terry cloth but provided no nourishment.

The babies preferred to cling to the cuddly surrogate and went to the wire model only to eat. If they were frightened, they would rush to the cloth-covered model for comfort. These results suggest that close physical contact with a cuddly object is a biological need for a baby monkey, just as food and drink are. A baby monkey clings to and cuddles with its mother because the contact is innately reinforcing, not simply because she provides it with food.

Undoubtedly, physical contact with soft objects is also inherently reinforcing for human infants. The term 'security blanket' suggests that these objects are comforting during times of distress. Indeed, children are most likely to ask for their special blankets or stuffed animals before going to bed, when they are ill, or when they are in an unfamiliar situation.

Looking

For infants, looking serves as a signal to parents: even a very young infant seeks eye-to-eye contact with its parents. If a parent does not respond when eye contact is made, the baby usually shows signs of distress. Tronick *et al.* (1978) observed face-to-face interactions between mothers and their infants. When the mothers approached their babies, they typically smiled and began talking in a gentle, high-pitched voice. In return, infants smiled and stretched their arms and legs. The mothers poked and gently jiggled their babies, making faces at them. The babies responded with facial expressions, wiggles and noises of their own.

To determine whether the interaction was really two-sided, the experimenters had each mother approach her baby while keeping her face expressionless or mask-like. At first, the infant made the usual greetings, but when the mother did not respond, the infant turned away. From time to time, the infant looked at her again, giving a brief smile, but again turned away when the mother continued to stare without changing her expression. These interactions were recorded on videotape and were scored by raters who did not know the purpose of the experiment, so the results were not biased by the experimenters' expectations.

Each mother found it difficult to resist her baby's invitation to interact. In fact, some of the mothers broke down and smiled back. Most of the mothers who managed to hold out (for three minutes) later apologised to their babies, saying something like, 'I am real again. It's all right. You can trust me again. Come back to me' (Tronick *et al.*, 1978, p. 110). This study clearly shows that the looking behaviour of an infant is an invitation for the mother to respond.

Smiling

By the time an infant is 5 weeks old, visual stimuli begin to dominate as elicitors for smiling. A face (especially a moving one) is a more reliable elicitor of a smile than a voice is; even a moving mask will cause an infant to smile. At approximately 3 months of age, specific faces – those of people to whom the infant has become attached – will elicit smiles. In particular, the infant will engage in more generic smiling when gazing at its mother's face than when gazing elsewhere (Van Beek *et al.*, 1994). The infant also smiles when the mother smiles (Kaye and

Fogel, 1980). Are these smiles indicative of genuine joy/positive emotion or are they reflective of some other process, such as imitation? When infants play, for example, they often smile with their mouths open. When 10–18-month-old children engage in social games, this is the facial response that dominates and one which makes the mother laugh (Jones *et al.*, 1990).

However, Fogel and colleagues have noted that infants engage in other forms of smiling such as that involving the raising of the cheeks. They found that while cheek-raising was characteristic of the early stages of tickling, open-mouth and cheek-raising smiling became more dominant as the tickling game progressed (Fogel *et al.*, 2000). When Fogel *et al.* examined the type of smiling elicited in a group of thirteen 1–6-month-old infants who interacted with their mother, they found that the infants generated distinct patterns of smiling depending on what the mother did. Cheek-raising smiles were associated with responding to the mother's positive affect; open-mouthed smiling was associated with visually engaging with the mother; and both of these facial movements were associated with a combination of visual engagement and response to the mother's positive affect (Messinger *et al.*, 2001).

Crying

For almost any adult, the sound of an infant's crying is intensely distressing or irritating. An infant usually cries only when it is hungry, cold or in pain (Wolff, 1969). In these situations, only the intervention of an adult can bring relief. The event that most effectively terminates crying is being picked up and cuddled, although unless the baby is fed and made more comfortable it will soon begin crying again. Because picking up the baby stops the crying, the parent learns through negative reinforcement to pick up the infant when it cries. Thus, crying serves as a useful means for a cold, hungry or wet child to obtain assistance.

Wolff (1969) suggested that babies have different patterns of crying. Konner (1972), who was studying a hunter-gatherer tribe in Africa, found that a pain cry caused all the people in earshot to turn towards the infant and induced several of them to run towards the child. However, only the child's carers responded to a hunger cry. More recent evidence suggests that babies' cries do not fall into need-specific categories – there is no 'hunger cry', no different cry for pain, and so on. Instead, cries simply vary in intensity, according to the level of the infant's distress. However, the onset of crying provides important information. If a baby suddenly begins crying intensely, mothers are more likely to assume that the baby is afraid or in pain. If the cry begins more gradually, mothers suspect hunger, sleepiness or a need for a nappy change (Gustafson and Harris, 1990).

The nature and quality of attachment

For an infant, the world can be a frightening place. The presence of a primary caregiver provides a baby with considerable reassurance when they first become able to explore the environment. Although the unfamiliar environment produces fear, the caregiver provides a secure base that the infant can leave from time to time to see what the world is like.

Stranger anxiety and separation anxiety

Babies are born prepared to become attached to their primary caregiver, who in most cases is their mother. Attachment appears to be a behaviour pattern that is necessary for normal development (Ainsworth, 1973; Bowlby, 1973). However, although attachment appears to be an inherited disposition, infants do not have a natural inclination to become attached to any one specific adult. Rather, the person to whom the baby becomes attached is determined through learning; the individual who serves as the infant's primary caregiver (or, in Bowlby's terms, 'attachment figure') is usually the object of the attachment.

Attachment partially reveals itself in two specific forms of infant behaviour: stranger anxiety and separation anxiety. **Stranger anxiety**, which usually appears in infants between the ages of 6 and 12 months, consists of wariness and sometimes fearful responses, such as crying and clinging to their carers, that infants exhibit in the presence of strangers. Male strangers generate the most anxiety in infants. Child strangers generate the least anxiety, while female strangers generate an intermediate amount of anxiety (Skarin, 1977). Stranger anxiety can be reduced and even eliminated under certain conditions. For example, if the infant is in familiar surroundings with its mother, and the mother acts in a friendly manner towards the stranger, the infant is likely to be less anxious in the presence of the stranger than it would if the surroundings were unfamiliar or if the mother was unfriendly towards the stranger (Rheingold and Eckerman, 1973).

Separation anxiety is a set of fearful responses, such as crying, arousal and clinging to the carer, that an infant exhibits when the carer attempts to leave the infant. Separation anxiety differs from stranger anxiety in two ways: time of emergence and the conditions under which the fear responses occur. It first appears in infants when they are about 6 months old and generally peaks at about 15 months – a finding consistent among many cultures (Kagan *et al.*, 1978). Like stranger anxiety, separation anxiety can occur under different conditions with different degrees of intensity. For example, if an infant is used to being left in a certain environment, say a daycare centre, it may show little or no separation anxiety

(Maccoby, 1980). The same holds true for situations in which the infant is left with a sibling or other familiar person (Bowlby, 1969).

However, if the same infant is left in an unfamiliar setting, it will show signs of distress. Some infants show 'disorganised' attachment behaviour, that is, they show conflicting behaviour towards the carer. They may rush to the sound of an opening door when hearing the carer about to enter a room and then run away when the carer enters; they may also adopt a 'frozen' or still posture when the carer is in the room (Main and Solomon, 1990). A longitudinal study of disorganised attachment behaviour in 157 children (studied from 24 months to 19 years), found that disorganised behaviour was correlated with insensitive caring, living alone with the infant, neglect, physical and psychological neglect and an intrusive caring style (Carlson, 1998).

Ainsworth's Strange Situation

One measure of separation anxiety was devised by Ainsworth and her colleagues (Ainsworth *et al.*, 1978). They developed a test of attachment called the **Strange Situation** that consists of a series of eight episodes, during which the baby is exposed to various events that might cause some distress. The episodes involve the experimenter introducing the infant and the parent to a playroom and then leaving, the parent leaving and being reunited with the infant, or a stranger entering the playroom with and without the parent present. Each episode lasts for approximately three minutes. The Strange Situation test is based on the idea that if the attachment process has been successful, an infant should use its mother as a secure base from which to explore an unfamiliar environment. By noting the infant's reactions to the strange situation, researchers can evaluate the nature of the attachment. The characteristics of the different types of attachment are summarised in Table 12.2.

The use of the Strange Situation test led Ainsworth and her colleagues to identify three patterns of attachment. **Secure attachment** is the ideal pattern: infants show a distinct preference for their mothers over the stranger. Infants may cry when their carers leave, but they stop as soon as they return. Babies may also form two types of insecure attachment. Babies with **resistant attachment** show tension in their relations with their carers. Infants stay close to their mother before the mother leaves but show both approach and avoidance behaviours when the mother returns. Infants continue to cry for a while after their mother returns and may even push her away. Infants who display **avoidant attachment** generally do not cry when they are left alone. When their mother returns, the infants are likely to avoid or ignore them. These infants tend not to cling or cuddle when they are picked up.

Table 12.2 Episodes in the Strange Situation

Episode	Events	Attachment behaviour observed
1	Experimenter introduces parent and baby to playroom and then leaves	
2	Parent is seated while baby plays with toys	Parent as a secure base
3	Stranger enters, is seated, and talks to parent	Reaction to unfamiliar adult
4	Parent leaves room. Stranger responds to baby and offers comfort if baby is upset	Separation anxiety
5	Parent returns, greets baby, and offers comfort if necessary. Stranger leaves the room	Reaction to reunion
6	Parent leaves room	Separation anxiety
7	Stranger leaves room and offers comfort	Ability to be soothed by stranger
8	Stranger returns, greets baby, offers comfort if necessary, and tries to reinterest baby in toys	Reaction to reunion

Note: Episode 1 lasts about 30 seconds; each of the remaining episodes lasts about 3 minutes. Separation episodes are cut short if the baby becomes very upset. Reunion episodes are extended if the baby needs more time to calm down and return to play.

Although infants' personalities certainly affect the nature of their interactions with their carers and hence the nature of their attachment, mothers' behaviour appears to be the most important factor in establishing a secure or insecure attachment (Ainsworth *et al.*, 1978; Isabella and Belsky, 1991). Mothers of securely attached infants tend to be those who respond promptly to their crying and who are adept at handling them and responding to their needs. The babies apparently learn that their mothers can be trusted to react sensitively and appropriately. Mothers who do not modulate their responses according to their infants' own behaviour – who appear insensitive to their infants' changing needs – are most likely to foster avoidant attachment. Mothers who are impatient with their infants and who seem more interested in their own activities than in interacting with their offspring tend to foster resistant attachment.

The nature of the attachment between infants and carers appears to be related to children's later social behaviour. For example, Waters *et al.* (1979) found that children who were securely attached at 15 months were among the most popular and the most sociable children in their nursery schools at 3½ years of age. In contrast, insecurely attached infants had difficulties with social adjustment later in childhood; they had poor social skills and tended to be hostile, impulsive and withdrawn (Erickson *et al.*, 1985).

While these attachment behaviours are seen cross-culturally, there are cultural differences. German babies, for example, appear to show more avoidant attachment than do American ones, possibly because German parents

encourage their children to be independent from an early age (Grossman *et al.*, 1985). Japanese babies are thought to exhibit more resistant attachment, possibly because Japanese mothers do not normally leave their charges in the care of others (Miyake *et al.*, 1985).

Predictors of secure attachment

Recall that Ainsworth and her colleagues found that the insecure attachment features just described were strongly related to attachment security. What is unclear from Ainsworth's study, however, is which aspects of the mother–child interaction, if any, are predictive of a secure attachment style. Are all the features listed above necessary for secure attachment or only one? Some researchers suggest that maternal sensitivity is the greatest predictor (Goldsmith and Alansky, 1987); others show different factors.

One problem with studies of attachment is the variation in methodology. Sometimes, conclusions are drawn from a single observation, others from multiple observations; the measures of attachment have ranged from asking parents about their attitudes to childcare to observing the frequency of physical contact (Frodi *et al.*, 1985; Benn, 1986; Kerns and Barth, 1995). As a result, the determinants of attachment are unclear because different studies adopt different research designs. In a meta-analysis of 66 attachment studies, De Wolff and van Ijzendoorn (1997) found that there was a moderately strong relationship between maternal sensitivity, defined as the ability to respond appropriately and promptly to the signals of the infant, and attachment.

Relationships with siblings

Along with parents and peers, siblings are the people with whom children share a close social and emotional relationship. Siblings may also cause resentment in older children because they attract most of the attention from parents and the older child may feel left out. Studies by Dunn and her colleagues, for example, have found that mothers are less warm towards their older children when their new baby is born (Dunn and Kendrick, 1982; Dunn, 1993). If the older child is over 2 years of age, they may also feel less secure and become more disruptive (Teti *et al.*, 1996). While this may draw attention to the child and maybe flag some underlying problem, the disruption can end up alienating the parent which itself may prolong the disruptive behaviour.

The elements of competition or jealousy between older and younger children is called sibling rivalry, but the degree of rivalry depends on a number of factors, including how secure the older child feels with its parents. Dunn and Kendrick (1982) found that if the first-born child already had a secure relationship with its parents, then its attitude towards the newborn was positive and the child adjusted reasonably well to the new arrival in the family. That said, there is often an element of tomfoolery in the siblings' relationships: one study found that disagreements and fights among siblings were as frequent as 56 an hour (Dunn, 1993). The disagreements, however, peter out by adolescence and the older sibling frequently takes the dominant role, initiating positive behaviours when engaging with the younger sibling. As siblings get older, there is a greater sense of equality between them and they eventually spend less time with each other and more time with their peers, as you will see in a later section on adolescence.

The relationship between parents is an important predictor of the security of sibling relationships. If parents get on, so do siblings. Similarly, if both parents are sensitive to the needs of all of their children, and are not selectively sensitive to one, there is less conflict between siblings (Brody, 1998). Parents' ability to stamp on skirmishes between siblings also predicts later conflict. The inability to do this is associated with increased conflict and aggressive, antisocial behaviour outside the home (Garcia *et al.*, 2000).

Of course, sibling relationships are not completely characterised by conflict. Siblings provide a source of emotional and social comfort to each other (Vandell, 2000). Older siblings often act as surrogate parents: one study found that in 57 per cent of 186 cultures studied, older siblings were the primary caregivers for younger siblings (Weisner and Gallimore, 1977). Older siblings are also often role models for their brothers and sisters and are often imitated by their younger siblings (Abramovitch *et al.*, 1980).

A recent study suggests that having a sibling can moderate the effects of stressful life events (Gass *et al.*, 2007). One hundred and thirty-two families participated – the

average age of the youngest sibling at the first time of testing was 4.9 years (the average age difference between siblings was 5.6 years). The study found that having an affectionate older sibling was associated with less internalising behaviour following a stressful event.

Another study has found that intimacy between siblings is greatest in sisters during middle childhood and adolescence (Kim *et al.*, 2006). In a study of 200 white middle- and working-class families, intimacy in same-sex sibling relationships was found to be fairly stable across this period but mixed-sex sibling relationships showed a decline in intimacy across childhood and adolescence until mid-adolescence when intimacy increased. One reason for this is that middle adolescence heralds an interest in the opposite sex and having a sibling of the opposite sex might, therefore, be a useful sounding board for advice and strategy. First-borns experienced more conflict in early adolescence, second-borns experienced more conflict in middle childhood.

Finally, some children have no siblings because they are an only child. Do these children differ in some psychological way from children with brothers and sisters? Studies of only children have shown them to be high in self-esteem and in motivation to achieve; they are also more obedient and more intellectually able than children with siblings (Falbo and Polit, 1986; Falbo, 1992). Interestingly, one country has provided some useful data on the development of only children. In 1979, the People's Republic of China implemented a family planning policy stating that families should produce only one child. When these children were studied, their profile was comparable to their Western counterparts but they had higher scores on tests of intelligence and were more academically successful than their equivalents with siblings (Falbo and Poston, 1993).

Relationships with others

As well as forming relationships with parents and siblings, children also develop relationships with their peers, usually with children who are similar to them in terms of age and sex. The development of friendships marks an important trait in the child's life: the development of cooperation. Friends who play with each other are more likely to be cooperative than children who are not friends; friends also play in a more complex way than non-friends (Hinde *et al.*, 1985). On the other hand, such close relationships also lead to conflicts: these are more common among friends than among non-friends (Hartup and Laursen, 1992), clearly because they spend more time with each other. However, when conflicts do occur, friends make greater attempts at negotiation when solving disputes.

As relationships develop, children also show evidence of prosocial behaviour – they will automatically help another child. For example, if a child sees another crying, they will comfort that child, even before being taught to behave this

Social organisation – An international perspective

Do children from different cultures interact differently when in social groups? Children living in the US from Mexican families with mothers who had received limited schooling, US children whose mothers' had extensive schooling, and children of Mexican families with mothers who had extensive schooling were studied. Three children from each group were given a task – following instructions for origami – to complete together (Mejia-Arauz *et al.*, 2007).

The children from Mexican families with mothers who had received limited schooling were more likely to work together

than were the other groups. The US children were more likely to work individually or in pairs – they were also more likely to chat more when interacting than interact non-verbally (which was the common form of interaction in the Mexican children).

The results seem to confirm studies showing that certain cultures – such as those in Mexico – are more likely to show evidence of collaboration on a shared task, even children from those cultures.

positively by a parent. The degree of prosocial behaviour that children show, however, can depend on the degree of encouragement they are given or on the prosocial disposition of the parents. Children who see others behaving in a generous and helpful way are more likely to be helpful and generous themselves (Eisenberg and Fabes, 1998). However, the father seems to be the more important role model for children: a positive correlation between the father's prosocial behaviour and the child's has been reported, but there was no such correlation found between the mother's and the child's (Eisenberg *et al.*, 1992).

Disorders of social cognition and emotion

You saw in Chapters 3 and 10 that some children are born with disorders associated with mental retardation (such as Down syndrome); or they can develop reading disorders that seem unrelated to the educational opportunities available to the child and to any underlying brain damage (such as developmental dyslexia). If there is no underlying intellectual retardation or physical cause, cognitive and emotional disorders are sometimes described as specific developmental disorders or disorders of psychological development (Rispen and van Yperen, 1997).

In earlier chapters, we discussed some disorders of childhood in some detail. This section describes disorders we have not come across yet: autism, conduct disorder and attention deficit hyperactivity disorder, and disorders of emotional regulation.

Autism

Characteristics of autism

Autism is a developmental disorder characterised by three features: social abnormality, language abnormality, and

stereotypical and repetitive patterns of behaviour (Frith, 1989; Happé, 1994; Bailey *et al.*, 1996), all of which can extend to adulthood (Gillberg, 1991). Autism was originally reported in 1943 by Leo Kanner in an article in which he described 11 cases of 'autistic disturbance of affective contact and . . . desire for preservation of sameness'. The symptoms he described form the core of the classification of autism today.

The social abnormality includes the child's inability to reciprocate in social interactions, to form or develop loving relationships and to interact spontaneously with others. Autistic children and adults have an impairment in the appreciation of social cues.

One characteristic feature of autism is the inability to look for emotion in the behaviour or expression of others; this may give autistic children an aloof and cold demeanour because they may be judged emotionally unresponsive. In an experiment in which autistic and control children were asked to sort pictures of individuals according to a category, autistic children would sort by appearance (hat) rather than emotion (Weeks and Hobson, 1987). The impairment in interpersonal communication, however, appears to be limited to interpersonal understanding – not all social communication is impaired (Mundy *et al.*, 1986; Sigman, 1995).

Language development in autism is severely delayed and about half of autistics do not develop useful language. In addition to this delay, there is evidence of deviant communication in the form of the idiosyncratic use of language, the making up of new words (neologising) and little engagement in social chat. Rutter (1987) has argued that such poor communication skills arise from the autistic's impaired ability to use feedback. Other examples of deviant language use include a difficulty in maintaining a topic of conversation (Bailey *et al.*, 1996). There is also an impaired ability to play spontaneously with toys, possibly because autistic individuals do not know what the toys mean.

Stereotypical and repetitive behaviour includes an over-reliance on routines or rituals and an abnormal attachment to objects.

The development of autism

Autism develops in the first two years of a child's life and is four times as common in boys as it is in girls (Gillberg and Coleman, 1992; Rapin, 1997). The prevalence of the disorder is 1 in 1,000 across most of the countries in which autism has been studied (Bryson *et al.*, 1988; Gillberg and Coleman, 1992; Sugiyama *et al.*, 1992). Autism may recede when the child develops language and uses it to communicate socially.

Early signs of the disorder include a failure to maintain eye-to-eye contact, to reach out to familiar persons (Swettenham *et al.*, 1998), and to imitate (Klin *et al.*, 1992). Baron-Cohen's 'reading the mind in the eyes' test asks participants to judge the emotion emitted in a photograph that shows the eye region of a human face only. Baron-Cohen *et al.* (2001) administered the test to people with Asperger's syndrome and to high-functioning autistic individuals (people of normal intelligence who show autistic characteristics) and compared the performance of these groups with that of a control group. The performance of the experimental groups was significantly more impaired than that of the control group.

There are checklists available which enable parents to determine whether their child is exhibiting autistic tendencies and such checklists include Baron-Cohen *et al.*'s (1992) Checklist for Autism in Toddlers (CHAT) which aims to identify those at risk of developing the disorder. Mental retardation is common in cases of autism and is estimated to occur in 75 per cent of cases (Rutter, 1979; Rapin, 1997). Whereas performance on some cognitive tasks is low (such as comprehension), performance on others is high (such as block design) (Venter *et al.*, 1992). Some autistics also exhibit exceptional abilities in specific domains such as reading, spelling, maths and music. When these abilities become extreme and highly remarkable, autistic individuals are called 'idiot savants', although such exceptional abilities are not unique to autism (O'Connor and Hermelin, 1988).

Some researchers have also suggested that autism may be an inherited disorder because there is a high incidence of fragile X disorder in autistic children (Bailey *et al.*, 1996). Twin studies suggest a higher concordance rate in identical than fraternal twins (Steffenburg *et al.*, 1989; Bailey *et al.*, 1995). Currently, however, there is no evidence that autism is a simple inherited disorder and there is no clear-cut evidence for a genetic component (Rutter, 1994).

The outcome for autism is varied – some individuals develop little language whereas others are able to go on to full-time education, get married and start families (Rapin, 1997). The most important therapeutic interven-

Kim Peek, thought to be the inspiration for Dustin Hoffman's character, Ramond Babbitt, in *Rain Man* (although the character is not based on Peek) is an example of an autistic savant. He was able to read a Tom Clancy novel in under an hour and a half and name the Russian radio operator character from the book four months later (as well as give the page number of the passage describing the character). He memorised his first book at the age of 18 months and has learned 9000 to date, including Shakespeare and maps of all major US cities. He can read a page in 10 seconds. Not surprisingly, his friends have nicknamed him, 'Kim-puter'. Kim Peek's brain is unusual because his corpus callosum is absent.

tion appears to involve intensive education aimed at changing the behavioural and communication problems. As such, most interventions are designed for use by parents and teachers who have greatest contact with the children. Medical interventions have also been developed but these appear to be more effective in improving attention than in eliminating all the characteristics of the disorder (Cohen and Volkmar, 1997).

Autism and theory of mind

In the late 1980s a theme emerged in autism research which suggested that autistic children had an impaired ability to make inferences about other people's mental states; that is, these children lacked, or had a defective, **theory of mind** (Leslie, 1987). According to this early model, a 2-year-old child can pretend play and understand others' mental states, desires and beliefs, but in autistic children the mechanism which allows this is impaired. As a result, the lack of pretend play would also be accompanied, later on, by an inability to interpret others' mental states.

Cutting edge – Loneliness and autistic tendency

A study from the US has associated autistic traits with loneliness (Jobe and White, 2007). Undergraduates who showed autistic characteristics such as rigidity, high attention to detail and preference for sameness, reported greater loneliness and fewer and shorter friendships than those who did not. These characteristics also correlated with the length of romantic

relationships – the greater the autistic tendency, the longer the relationship (18.8 months, on average, compared to 11.3 months in people who showed less of a tendency to autism). This suggests that the preference for sameness may extend, in particular, to preference for romantic partner.

For example, Baron-Cohen *et al.* (1985) reported a study in which a child saw the unexpected transfer by a third person of an object from the location in which it was placed by the experimenter to a different location. The child's task was to predict where the experimenter would look for this object. Such tasks are now called 'theory of mind' tasks or tests of false belief. Four-year-old children could correctly indicate that the experimenter would look in the original location for the object; autistic children, however, could not, and predicted that the experimenter would look in the new location. The children seemed unaware that the experimenter would not know about the transfer of the object – they could not imagine the task from the other person's perspective. Baron-Cohen (1995) later used the term 'mindblindness' to refer to such inabilities to understand the thoughts of others. Deaf children perform significantly worse on false-belief tests than do hearing children, with older deaf children performing better than the younger deaf children, suggesting that there may be developmental delay in the ability to perform theory of mind tasks (Russell *et al.*, 1998). A study of deaf children from hearing families has found that their theory of mind ability develops significantly more slowly than those of deaf children from deaf families, whether they used spoken English or American Sign Language (Schick *et al.*, 2007). Curiously, when the language demands of a theory of mind task were reduced, deaf children from hearing families still performed less well.

A meta-analysis of studies examining the effect of age and language acquisition on understanding of theory of mind (measured via false-belief tasks) has found that theory of mind is associated with language ability, but not age (Milligan *et al.*, 2007). The more advanced the language understanding (general language, semantics, receptive vocabulary, syntax), the greater the false-belief understanding.

One view of theory of mind proposes that the child is a scientist, exploring the environment and constructing and testing hypotheses. This is Karmiloff-Smith's theory of representational redescription (Karmiloff-Smith, 1988, 1992). The child is seen as a theoretician who builds theories and explains events or stimuli that cannot be explained by sim-

plifying them. To become an expert 'scientist' the child passes through a series of stages that involve the child constructing representations of stimuli around them. In the beginning, behaviour is externally driven and the child makes many mistakes before getting better. This process involves reconstructing or redescribing representations (hence, theory of representational redescription) as development occurs. This perspective on theory of mind, however, has been challenged (Gellatly, 1997). Gellatly argues that this theory sees the child as an isolated individual, not as part of a community; he also suggests that the concept of 'scientific thinking' which the child is thought to develop, is too simplistic and assumes that all scientific thinking occurs in the same way.

Some researchers also suggest that theory of mind deficits are not common to all autistic individuals (Happé, 1993, 1994). The major deficit in autistic children, according to Frith and Happé (1994) is not impaired theory of mind but the inability to see situations and objects as wholes. Most of us see images and events as global images and events – we attend to the detail later. When you look at the television screen you do not attend to each individual detail of the image consciously (although your brain does do this), but you perceive a global image. The problem with autistic individuals, according to this view, is that they process information piecemeal and not in the context in which it appears.

There appears to be some evidence for this hypothesis. In experiments where participants have to find images within larger, more complex images, autistic children do very well (O'Riordan and Plaisted, 2001). An example of one of these exercises is shown in Figure 12.13.

Most normal participants have difficulty ignoring the large global image in which the 'hidden' image is embedded. Autistic children are also better than controls at discriminating among novel stimuli (but not familiar ones), indicating that they attend to specific features of stimuli (Plaisted *et al.*, 1998).

Frith and Happé (1994) suggest that two cognitive systems may be impaired in autism: one which normally allows theory of mind and another which determines the way in which information is processed. This model has

Figure 12.13 An example of the Embedded Figures Test. The task is to find the shape on the left which is embedded in the more meaningful, global image on the right. Autistic individuals are better at this task than non-autistic individuals.

the benefit of accounting for the theory of mind deficits and the tendency of autistic individuals to segment information instead of perceiving it globally. However, the model does not explain why such impairments arise in the first place. One source of information suggests that this impairment may be neurological in nature, as the section below highlights.

Neuropsychology of autism and theory of mind

The idea that the frontal cortex is involved in theory of mind has received some support from studies in which patients with frontal lobe damage show evidence of poorer ability to draw inferences about other people's point of view than patients with damage to other brain areas (Stuss *et al.*, 2001). Rowe *et al.* (2001) found that patients with damage to the left and the right frontal lobes showed specific theory of mind deficits.

A review of neuroimaging data has concluded that a reduction in frontal lobe size and activation are some of the more consistent neuropsychological characteristics of autism (Deb and Thompson, 1998). Studies have reported reductions in the neurotransmitter dopamine in the prefrontal cortex only (Ernst *et al.*, 1997) and have found decreased volume in the frontal lobes of autistic individuals (Piven *et al.*, 1995). These features are more robust than most others and are consistent with a theory of autism that attributes impaired planning and organisation to frontal lobe dysfunction (Hughes *et al.*, 1994).

A single-case study, however, challenges this view. Bird *et al.* (2004) studied patient GT who had suffered brain damage as a result of stroke. There was extensive bilateral damage to the medial frontal lobes exclusively. GT showed the typical frontal lobe symptoms – impairments in planning and memory – but showed no evidence of impairment on 'theory of mind' tasks. This suggests that the medial frontal lobe may not be necessary for performing theory of mind tasks. Why, therefore, does neuroimaging evidence and some clinical neuropsychological evidence suggest otherwise? Bird *et al.* suggest that this could be because the medial frontal lobes are necessary for the acquisition of theory of mind but not for implementing theory of mind functions.

A similar idea was behind a neuroimaging study of high functioning autistic adults (Kennedy and Courchesne, 2007). The study referred to the idea that there are two different networks in the brain which perform different functions. One is thought to be impaired in autism; the other is intact. One network is responsible for doing cognitively demanding tasks and for engaging in externally directed behaviour. The second was activated when a person engaged in behaviour that involved a social or emotional component or which is introspective in nature (such as theory of mind). This is called the Task-Negative Network because there is a decrease in activation in specific brain areas during the performance of social or emotional tasks. This is the network that is affected in autism and this is what Kennedy and Courchesne (2007) found in their participants. The Task-Positive Network was unaffected.

Another region thought to be involved in autism is the amygdala. People with damage to the amygdala, as you will see in Chapter 13, have severe difficulties in recognising emotion, specifically fear. These patients also have difficulty in making complex social judgements such as assessing trustworthiness in someone's face. Autistic individuals are able to recognise basic emotions, unlike patients with bilateral amygdala damage, and discriminate between the intensity of emotions expressed through facial expression (Adolphs *et al.*, 2001). However, they are impaired at making social judgements about emotional facial expressions. For example, they rate faces as significantly more trustworthy than do control groups. The authors suggest that autistic individuals are capable of making perceptual judgements about faces and are capable of recognising basic emotions but are incapable of linking the perception of the face with the appropriate social judgement. Perhaps normal retrieval of social knowledge cued by faces is impaired or normal social knowledge has not been acquired. Critchley *et al.* (2000) found that although autistic individuals performed above chance levels when identifying emotional facial expressions, they performed more poorly than a control group. Autistic individuals did not activate the brain's 'face area'

or the cerebellum when making judgements about emotional facial expression.

People with early damage to the amygdala are significantly impaired at theory of mind tests that require sophisticated understanding of communication (e.g. detecting tactless/ironic remarks and interpreting metaphors) (Shaw *et al.*, 2004). People with damage sustained during adulthood, however, performed no worse than the control groups. The findings suggest that the amygdala may be necessary for the development of theory of mind but may not be responsible for the ongoing reasoning involved in theory of mind tasks.

There may also be an association between autism and the levels of testosterone in the foetus. Auyeung *et al.* (2009) asked mothers to use two standard measures of autism to rate their children (aged between 6 and 10 years). These scores were then correlated with levels of testosterone measured from amniotic fluid during amniocentesis while the child was a foetus. The researchers found that levels of foetal testosterone were positively associated with the autism test measures: the higher the testosterone, the higher the score.

Finally, some researchers have hypothesised that autism may involve a dysfunction in the so-called mirror neuron system. Remember from Chapter 4 that these are neurons that fire when an organism reaches, for example, but also when the organism watches another reaching (hence,

‘mirror’). The ‘broken mirror’ theory of autism suggests that the inability of autistic people to imitate is due to the dysfunction or impairment in these neurons (Williams *et al.*, 2004). However, imitation involves more than matching an action but visual analysis, selecting what is to be imitated and when to imitate it (Southgate and Hamilton, 2008). Different types of imitation are, therefore, possible. Researchers have also queried whether the imitation deficit in autism is robust and consistent. Some studies show that if an autistic child is instructed to imitate, he or she will (Hamilton *et al.*, 2007). They may fail to imitate meaningless action and facial expression, but they are able to imitate automatically (Bird *et al.*, 2007). It may be that normal children use cues from others to influence imitation – and when and what to imitate – but autistic children do not. That may be the failure in autism, not a failure to imitate itself (and, by extension, a failure of the mirror neuron system).

Asperger’s syndrome

One disorder that is closely linked to autism is **Asperger’s syndrome**. According to Asperger (1944), some individuals exhibit ‘autistic psychopathy’ that is reflected in poor social functioning and interpersonal communication; individuals usually have an obsessional and narrow range of interests. Because of these characteristics, some researchers

Theory of mind – An international perspective

In a typical false-belief task, person A places an object in a cupboard and leaves the room. Person B enters, puts the object in a different location and leaves the room. Person A re-enters, and the participant is asked where person A will look for the object.

Previous studies had shown that 5–6-year-olds can answer this question correctly – person A would look for the object in the cupboard. Younger children, however, make false-belief errors: they would answer that person A would look in the location to which the object had been moved. Recent studies, however, have shown that even 3-year-olds could perform such tasks successfully or improve on them.

In order to address these inconsistencies, Wellman *et al.* (2001) conducted a meta-analysis of 178 separate studies of theory of mind. A difficulty in comparing a few studies reporting inconsistent findings is that the studies may not be comparable – different methods, tests, measures, samples and so on are used. Meta-analyses take such inconsistencies into account by observing general patterns of results.

Their analysis showed that the results of the studies were consistent and robust. Children improved on false-belief tasks

from age 3 to 5. The understanding of belief and false belief was also found to be culture-free (at least, not specific to the cultures included in the analysis). Whether European, North American, East Asian, Australian or African, children acquired understanding of others’ beliefs at around the same time. Some forms of task do improve performance when compared with others, however. There could be two reasons for this: either these forms are a more sensitive measure of theory of mind, or they are artefactually easy. The researchers, however, admit that the results of the meta-analysis cannot distinguish which explanation is correct. When studies across the developmental trajectory are analysed, there is a significant and discernible improvement with age, for easy and difficult tasks.

When the reliability of false-belief tasks was analysed, good reliability for judgements made within sessions was found, suggesting that a performance on one version of the task would be comparable to performance on another. The researchers conclude that one of the questions that the meta-analysis does not answer is how the developmental change in understanding of belief occurs.

have suggested that Asperger's is a milder form of autism (Schopler, 1996). There appears to be some support for this notion. When Asperger's original four cases were re-analysed, for example, they met current *DSM-IV TVR* criteria for autistic disorder, not Asperger's (Miller and Ozonoff, 1997). However, this finding could simply reflect the ways in which criteria for diagnosis have changed over the years. One way of determining the validity of a disorder would be to see if it was characterised by different features from those of related disorders.

Autistic individuals perform well on tasks that require them to assemble objects or to form a target abstract pattern from a set of blocks. If Asperger's syndrome is similar to autism, then we should see the same superior performance in both disorders. In a study comparing 120 Swedish individuals with Asperger's syndrome, autistic disorder or attention disorder on a range of tests from the *WAIS-R*, autistic individuals did better at the block design task and Asperger's individuals performed better at the verbal tasks and poorly at the object assembly task (Ehlers *et al.*, 1997). The result would suggest, therefore, that Asperger's can be distinguished from autism on the basis of spatial performance. However, whether this difference is meaningful is questionable. Abstract and portrait painters might be distinguished by some underlying characteristic, for example, but this does not negate the fact that they are both groups of artists using the same visuospatial and motor abilities. The fact that they differ on one dimension, does not make them totally different.

30–50 per cent of affected adolescents show symptoms in adulthood. So, although the disorder recedes, it persists in a high percentage of cases. Because of the nature of the disorder, the problems associated with it can be cognitively damaging. ADHD has been associated with low academic achievement, school performance, suspension/expulsion from school, poor family and peer relationships, mental disorder and substance abuse (Barkley, 1997). Most of the 'treatment' approaches to the disorder involve some form of counselling, behaviour management and, sometimes, psychoactive medication (Toplak *et al.*, 2008). Some examples include managing behaviour in the classroom using praise, giving rewards to increase positive behaviour and ignoring inappropriate behaviour. This has met with some success (Chronis *et al.*, 2006). A treatment designed to normalise EEG frequencies that are dysfunctional in ADHD has also reported a decrease in the symptoms of inattention and hyperactivity (Heinrich *et al.*, 2004).

The causes of ADHD are unclear. Some biological evidence has associated the disorder with a problem in the connections between the frontal lobe, the cerebellum and a region called the striatum. Some studies have shown that brain volume – in the cortex and the cerebellum – is smaller in children with ADHD and that activation is more diffuse when participants complete a cognitive task (Durston, 2003). Cognitive theories attribute some role to disrupted cognitive or executive processes, which explains the involvement of the frontal lobe (Barkley, 2006).

Disorders of emotional regulation

Disorders of emotional regulation refer to problems that the child has in operating at an emotionally normal level. They represent behavioural problems which impair the ability to undertake day-to-day activities (Zeanah *et al.*, 1997). For example, the child may be abnormally distressed, depressed, show sleep disturbance or feeding problems or exhibit anxiety.

The degree of attachment that the child demonstrates towards its caregiver is often used as a good index of these behaviours. Because the child has no sophisticated language, it is difficult to diagnose an emotional disorder in the first three years of life. A depressed person can express their depression verbally (and even suggest causes); this language facility is not available to infants. As a result, emotional disorders tend to be reported by parents who see their child behaving in a way that is out of the ordinary.

Sometimes, however, the child's emotional problems may be associated with those of the carer, especially the mother. Given that the mother makes the greatest investment in caring for the child during its early years, perhaps this is not unexpected. Depressed mothers, for example, have been shown to express more negative emotion, show

Conduct disorder/attention deficit hyperactivity disorder

Conduct disorder is a severe impairment in the ability of the child to inhibit its own behaviour and, specifically, to inhibit antisocial and deviant behaviour (Nicol, 1998). It is related to a specific disorder termed **attention deficit hyperactivity disorder (ADHD)** whose main features are poor sustained attention, impulsiveness and hyperactivity (Barkley, 1997). Recent conceptions of ADHD identify three types: Inattentive, Hyperactive/Impulsive and Comorbid. The inattentive type is more likely to have problems performing executive or cognitive tasks than are the other two.

There is evidence that ADHD runs in families, especially behaviourally disordered families (Faraone *et al.*, 1997), and that conduct disorder is six times more common in children who have been sexually abused (Fergusson *et al.*, 1996; Herrenkohl *et al.*, 1997).

ADHD occurs in 3–7 per cent of the child population, with three times as many boys as girls exhibiting the disorder. Between 50 and 80 per cent of children with the disorder continue showing symptoms into adolescence;

less positive engagement with, and less sensitivity to the child's behaviour during interactions with the child (Lyons-Ruth *et al.*, 1990). Mothers can be hostile, withdrawn and disengaged, and the child's interaction suffers accordingly. The child avoids the mother and shows great distress. If the mother is depressed for longer than three months after the birth of the child, the child can show developmental and growth delay (Field, 1992). Infants who interact with a nursery school teacher or non-depressed fathers have been found to show more positive and expressive behaviours than when interacting with their depressed mother (Pelaez-Nogueras *et al.*, 1994).

Murray *et al.* (1999) found fairly robust effects of the mother's depression on the long-term emotional adjustment of the child. The researchers looked at mother-child interaction and the ability of the child to adjust socially and behaviourally using reports from the mother, child and observation of the child playing freely. The children were studied at 18 months and 5 years after birth.

The mother's depression was associated with impaired relations between mother and child, behavioural disturbance at home and the child's impaired pattern of play. The quality of attachment at 18 months was the best predictor of the child's relationship with the mother. The findings suggest that early infant-mother relationships can have a significant impact on the child's behaviour later in childhood.

Emotion, attachment and hemispheric asymmetry

One model of emotional expression suggests that different sides of the frontal lobes regulate our experience of positive and negative emotions (you'll find more on this model in the next chapter). The left frontal region is thought to be responsive to positive emotion and the right frontal region is thought to be more responsive to negative emotion. Negative emotion may also be associated with reduced activity in the left frontal cortex (Davidson and Sutton, 1995).

Studies of distressed infants have highlighted similar asymmetries. For example, Davidson and Fox (1989) measured EEGs from infants they characterised as criers and non-criers (criers were those who became distressed when separated from their mother). The criers were distinguished from the non-criers by greater right-sided frontal EEG activation. Dawson *et al.* (1997) reported that the infants of depressed mothers (as well as the mothers themselves) showed reduced left frontal EEG activity. These asymmetries have also been found in studies comparing 4-year-old infants who are either happy and sociable or unhappy and unsociable. The sociable children showed greater left frontal activation (Fox *et al.*, 1995).

Behavioural inhibition in toddlers and infants refers to a temperamental pattern characterised by increased vigilance and decreased motor behaviour when children are confronted with a novel stimulus. These children are also more likely to avoid unfamiliar adults, show little spontaneous behaviour in the presence of unfamiliar peers and are regarded by their parents and peers as anxious and fearful. Children showing this pattern of behaviour also seem to show characteristic patterns of physiological and neural activity; some studies show that behavioural inhibition in children can be predicted by these physiological measures.

Depressed mothers who breastfed were more likely to raise infants who had a less negative temperament. These infants were also less likely to show increased right-sided EEG activation (characteristic of expressing negative emotion) than were infants of depressed mothers who breastfed less consistently. One reason for the interaction may be that the physical closeness of the mother and infant during breastfeeding offsets the negative temperament that might be provoked by a depressed mother who is less close to her child.

Four-month-old infants who display a consistent pattern of right frontal EEG activity are more likely to be behaviourally inhibited (Fox *et al.*, 2001). The EEG pattern was evident even at 9 months. Children who were initially assessed as inhibited but later became non-inhibited did not show this characteristic pattern of right-sided EEG activity. The researchers suggest that infants showing an increase in left-sided activity use approach (positive) behaviour to modulate negative affect; those infants who show right-sided activity are less likely to do this.

What seems unclear in these EEG studies, however, is the nature of cause and effect. Does the distress cause the EEG asymmetry or does the EEG asymmetry cause the distress? Does the asymmetry predispose the infant to distress? These are interesting and important questions. Because they have implications for theories of the nature of emotion and the neuropsychology of emotion, we discuss these in more detail in the next chapter.

The frontal lobes, as you saw in Chapters 4 and 11, also are involved in executive functions such as regulating behaviour (planning, changing strategies, responding emotionally). A study by Hughes *et al.* (1998) compared the performance of 3- or 4-year-old children, described as 'easy' or 'hard to manage', on a series of theory of mind, emotional understanding and executive function (frontal lobe) tasks. They found that the disruptive children showed poorer understanding of emotion and less successful performance on the theory of mind tasks.

If regional brain activity can discriminate sociable from non-sociable children, what do you think would be the implications of this for child welfare and education?

Development of sex roles in childhood

Physical development as a male or a female is only one aspect of sexual development. Social development is also important. A person's **sexual identity** is one's private sense of being a male or female and consists primarily of the recognition of membership in a particular group of people: males or females. Acceptance of this membership does not necessarily indicate acceptance of the sex roles or sex stereotypes that may accompany it. For example, a dedicated feminist may fight to change the role of women in her society but still clearly identify herself as a woman. **Sex roles** are cultural expectations about the ways in which men and women should think and behave.

Closely related to them are **sex stereotypes**, beliefs about differences in the behaviours, abilities and personality traits of males and females. Society's sex stereotypes have an important influence on the behaviour of its members. In fact, many people unconsciously develop their sex identity and sex roles based on sex stereotypes they learned as children.

Development of sexual identity

According to Kohlberg (1966), the ability of children to identify with their sex is determined in large part by their ability to classify objects as being boys' objects or girls' objects, that is, they begin to identify their own sex by observing how others class objects and people. In Kohlberg's model, the child undergoes three stages of sexual identity development: gender labelling, gender stability and gender consistency.

- **Stage 1 Gender labelling.** At the age of 2–3½ years, the child learns that they are of one sex. Labels that other people apply to them are learned and they attach these same labels to people of the same sex or objects associated with a sex.
- **Stage 2 Gender stability.** Between the ages of 3½ and 4½, children begin to realise that their sex is a constant and that this feature can often be seen in other's physical appearance. This time, therefore, is characterised by an increase in awareness of others' physical features.
- **Stage 3 Gender consistency.** At the age of 4½, children discover that people's sex does not change and that physical appearance does not affect their sexual identity. If a girl or boy dresses up as a member of the opposite sex, they are still regarded as a girl or boy despite their appearance.

By 2 years of age children begin to perceive themselves as being a boy or a girl. In the process of learning what it means to be boys or girls, children associate, in a stereotypical manner, certain toys, games, attitudes and behaviours, such as being aggressive or compliant, with one sex or the other (Huston, 1983; Jacklin and Maccoby, 1983; Picariello *et al.*, 1990). For example, consider an experiment conducted by Montemayor (1974), who invited children between the ages of 6 and 8 years to play a game that involved tossing marbles into a clown's body. Some of the children were told that they were playing a 'girl's game', some were told it was a 'boy's game', and others were told nothing. Boys and girls both said that the game was more fun when it had been described as appropriate to their sex, and they even attained better scores when it was.

Kohlberg's notion of identity development is echoed in recent work that tries to explain how this development occurs. **Gender schema theory**, for example, argues that children construct a 'schema' – a mental representation – of male and female and pay especial attention to features of their own sex (Bem, 1981; Martin and Halverson, 1981). Children's perception of sex is matched with information about others' sex that the child has already processed and understood (Ruble and Martin, 1998).

The ability to identify others' and the child's own sex emerges between the ages of 1 and 3 years. Usually, this is determined by asking children to look at photographs of boys and girls and to point to the person who is a boy or a girl or who is most like the child doing the looking (Etaugh *et al.*, 1989; Fagot and Leinbach, 1989). Children as young as 30 months can complete this task successfully and children as young as 36 months can sort photographs of boys and girls into two piles, without instructions to sort them according to sex.

By the age of 2, children are already beginning to spend more time preferentially playing with their own sex, with the time spent playing with the same-sex child multiplying eleven-fold by the time children reach 6 years (LaFreniere *et al.*, 1984).

Sexual identity and play

Sexual identity is also thought to emerge during play. Preschoolers, for example, will engage in role-play but in a sex-typical way: boys will play at being mechanics and bus drivers whereas girls will play at being teachers and cooks (Garvey, 1977). By the age of 1, children will play with sex-typical toys with their parents; by the age of 2, they may engage in this spontaneously without the interference of a parent (Fagot *et al.*, 1986; Roopnarine, 1986).

Some researchers, however, have noted that while children learn that the sexes differ on some dimensions, such as physical appearance, they do not differ on others

(Campbell *et al.*, 2002). Campbell *et al.* argue that sexual differentiation does not occur in all domains at certain age points. For example, they point to studies showing that children's ability to divide toys into 'girl' toys and 'boy' toys can be unrelated to the children's actual preference for those toys (Perry *et al.*, 1984). Furthermore, children who show sex-typed behaviour in one domain may not show it in another (Turner *et al.*, 1993).

To discover how well children could sex-type according to different behaviour domains, Campbell *et al.* studied 56 2-year-old children in various experimental conditions. In one condition, the child's mother would ask it to point to a male- and female-related stimulus that could be a toy or an activity. Male toys were described as cars, trains, water-pistols, blocks and balls whereas female toys were described as toasters, cookers, dolls, dustpans and brushes, and combs. Some of the female activities were described as drawing, whispering, playing with dolls or playing pat-a-cake; some of the male activities were described as chasing, jumping, climbing, wrestling and playing cowboys. In another condition, the child was presented with a photograph of itself and a photograph of a child of the opposite sex and was asked to point to the picture of the girl or boy. Finally, the children were observed in naturalistic settings. In one of these, a child was allowed to play with a selection of toys with the parent. In another, the child played with another child and their interaction was videotaped.

The researchers found that two-thirds of children could identify themselves as male or female, a finding supported by other studies of 3-year-old children (Fagot, 1985). About half of the group were able to point to the face of a boy or a girl accurately in photographs and around a quarter were able to differentiate toys according to whether they were boys' toys or girls' toys. Only one child in eight was able to identify activities according to their sex-type.

On the basis of these results, the researchers suggest that the child's awareness of its own sex and that of others is a 'developmental precursor' to the later sex-typing of toys and activities. The children in the study did prefer to play with sex-typed toys, however, whether they played alone or with another child. Lloyd and Duveen (1990) found that whereas 1½ to 3½ year-old boys played with boys' toys more than girls' toys, the girls played equally with boys' and girls' toys. When the children were paired with a same-sex partner, both sexes spent more time playing with their sex-typed toys.

According to Miller (1987), boys and girls are sensitive to the properties of toys that allow them to engage in specific behaviours. Thus, guns and swords offer the boy an opportunity for conflict whereas dolls and dolls' houses offer the girl an opportunity to nurture. Others, however,

have noted that the attributes of objects may be related to sex but not to what the object actually does (the technical term for this is affordance). For example, when a typically female object such as a teapot was masculinised by painting it brown and covering it with spikes, boys were more inclined to play with it than were girls (Leinbach *et al.*, 1997). Furthermore, when a 6-month-old baby is dressed in either pink or blue (its actual sex is not apparent) and parents are asked to give it either a train (a boy's toy), doll (a girl's toy) or fish (a neutral toy), the baby in pink would be given the doll more often than would the baby in blue. The baby in pink was also smiled at more often (Will *et al.*, 1976).

Where do children learn sex stereotypes?

Parents play an especially important role in the development of sex stereotypes: they tend to encourage and reward their sons for playing with 'masculine' toys such as cars and trucks and objects such as baseballs and footballs (Fagot and Hagan, 1991) and encourage baby boys to generate gross motor activity, whereas they are more soothing and calming with baby girls (Smith and Lloyd, 1978). Parents also tend to encourage and reward their daughters for engaging in 'feminine' activities that promote dependence, warmth and sensitivity, such as playing house or hosting a make-believe tea party (Dunn *et al.*, 1987; Lytton and Romney, 1991). Parents who do not encourage or reward these kinds of stereotypical activity tend to have children whose attitudes and behaviour reflect fewer sex stereotypes (Weisner and Wilson-Mitchell, 1990).

In supposedly 'masculine' academic subjects, girls are perceived as performing less well than boys. Many reasons have been suggested for the discrepancy but one of the most frequently cited is socialisation: that is, parents and teachers are more likely to engage boys in science and scientific explanations than they are girls.

In an ingenious experiment to test this hypothesis, Crowley *et al.* (2001) sought the permission of parents visiting a Californian children's museum to film and record their interactions with their children as they made their way around the exhibitions. Data were collected from 298 interactions between mothers and fathers and their daughters and sons on 26 days over a 30-month period. Conversations were rated according to whether they involved explanations, descriptions of or directions for exhibitions.

The researchers found that parents were more likely to explain exhibits to their sons than to their daughters. If the behaviour of parents helps shape the behaviour of their children, the researchers suggest that this disparity could have a significant effect on the child's interest in and knowledge of science.

Moral development

The word ‘morality’ comes from a Latin word that means ‘custom’. Moral behaviour is behaviour that conforms to a generally accepted set of rules, although whether these rules generally are accepted is quite controversial. With few exceptions, by the time a person reaches adulthood, they have accepted a set of rules about personal and social behaviour. These rules vary in different cultures and may take the form of laws, taboos and even sorcery (Chasdi, 1994). How does a child acquire morality?

Piaget’s theory of moral development

According to Piaget, the development of morality occurs in three general stages: the premoral stage, the moral realism stage and the moral relativism stage. Table 12.3 outlines the features of each stage.

The first stage of moral development (ages 0–5 years) is **premoral**. During this period the child has little conception of rules or principles. The second stage, however, sees the beginning of rule adherence. This stage, **moral realism**, is characterised by egocentrism, or ‘self-centredness’, and blind adherence to rules.

Egocentric children can evaluate events only in terms of their personal consequences. Their behaviour is not guided by the effects it might have on someone else, because they are not capable of imagining themselves in the other person’s place. Thus, young children do not consider whether an act is right or wrong but only whether it is likely to have good or bad consequences personally. Punishment is a bad consequence, and the fear of punishment is the only real moral force at this age. A young child also believes that rules come from parents (or other authority figures, such as older children or God), and that rules cannot be changed.

Older children and adults judge an act by the intentions of the actor as well as by the consequences of the act. A young child considers only an act’s objective outcomes, not the subjective intent that lay behind the act. For example, Piaget told two stories, one about John, who accidentally broke fifteen cups, and Henry, who broke one cup while trying to do something that was forbidden to him. When a young child is asked which of the two children is the naughtiest, the child will say that John is, because he broke fifteen cups. They will not take into account the fact that the act was entirely accidental.

As children mature, they become less egocentric and more capable of empathy. Older children (older than age 7) can imagine how another person feels. This shift away from egocentrism means that children’s behaviour may be guided not merely by the effects that acts have on themselves but also by the effects they have on others. At around 10 years of age, children enter Piaget’s third stage of moral development, **moral relativism**, during which rules become more flexible as the child learns that many of them (such as those that govern games) are social conventions that may be altered by mutual consent.

Kohlberg’s theory of moral development

Piaget’s description of moral development was considerably elaborated on by Lawrence Kohlberg (1927–1987). Kohlberg (1971) had argued that, ‘All individuals in all cultures go through the same order or sequence of gross stages of development, though they vary in rate and terminal point of development.’ He studied boys of between 10 and 17 years of age, over the course of several years, by presenting them with stories involving moral dilemmas (Kohlberg, 1966; 1982). For example, one story described a man called Heinz whose wife was dying of a cancer that could only be treated by a medication discovered by a chemist living in the same town. This was the dilemma in full:

Table 12.3 Piaget’s stages of moral development

Stage	Description
Premoral (0–5 years)	The child shows little understanding of rules or principles
Moral realism (5–10 years)	Rules are obeyed quite rigidly The child judges a person’s action by its consequences The child develops a belief in punishment and justice
Moral relativism (10 years and over)	The child becomes more flexible in interpreting moral issues The child becomes aware that moral responses are relative, that rules can be broken and that people are not always punished

A woman is near death from cancer. One drug might save her, a form of radium discovered by a chemist living in the same town, who is selling the drug at ten times what it cost him to manufacture it. The sick woman's husband tried to borrow the money but could raise only half the price. He told the chemist that his wife was dying and asked him to sell the drug more cheaply or, at least, let him pay later, but the chemist refused. The desperate husband broke into the chemist's shop to steal the drug for his wife. Should he have done that?

For this dilemma and others, there is no correct answer. It is designed to discover more about how people engage in moral reasoning. On the basis of his research using such dilemmas, Kohlberg argued that moral development comprised three levels and seven stages (see Table 12.4). These stages are closely linked to children's cognitive development as outlined by Piaget.

The first two stages belong to the **preconventional level**, during which morality is externally defined. During stage 1, morality of punishment and obedience, children blindly obey authority and avoid punishment. When asked to decide what Heinz should do, children base their decisions on fears about being punished for letting one's wife die or for committing a crime. During stage 2, morality of naive instrumental hedonism, children's behaviour is guided egocentrically by the pleasantness or unpleasantness of its consequences to them. The moral choice is reduced to a weighing of the probable risks and benefits of stealing the drug.

The next two stages belong to the **conventional level**, which includes an understanding that the social system has an interest in people's behaviour. During stage 3, morality of maintaining good relations, children want to be regarded by

people who know them as good, well-behaved children. Moral decisions are based on perceived social pressure. Either Heinz should steal the drug because people would otherwise regard him as heartless, or he should not steal it because they would regard him as a criminal. During stage 4, morality of maintaining social order, laws and moral rules are perceived as instruments used to maintain social order and, as such, must be obeyed. Thus, both protecting a life and respecting people's property are seen as rules that help maintain social order. This stage required people to expand their social perspectives, a requirement which was assisted by having attended university or working in a work setting that involved complex reasoning (Mason and Gibbs, 1993).

Kohlberg also described a final level of moral development – the **postconventional level**, during which people realise that moral rules have some underlying principles that apply to all situations and societies. During stage 5, morality of social contracts, people recognise that rules are social contracts, that not all authority figures are infallible, and that individual rights can sometimes take precedence over laws. During stage 6, morality of universal ethical principles, people perceive rules and laws as being justified by abstract ethical values, such as the value of human life and the value of dignity. In stage 7, the morality of cosmic orientation, people adopt values that transcend societal norms. This stage represents the zenith of moral development. Kohlberg believed that not all people reach the postconventional level of moral development.

Evaluation of Piaget's and Kohlberg's theories of moral development

Piaget's and Kohlberg's theories have greatly influenced research on moral development, but they have received some criticism. For example, Piaget's research indicated

Table 12.4 Levels and stages of Kohlberg's theory of moral development

Level and stage	Highlights
Preconventional level	
Stage 1: Morality of punishment and obedience	Avoidance of punishment
Stage 2: Morality of naive instrumental hedonism	Egocentric perspective; weighing of potential risks and benefits
Conventional level	
Stage 3: Morality of maintaining good relations	Morality based on approval from others
Stage 4: Morality of maintaining social order	Rules and laws define morality
Postconventional level	
Stage 5: Morality of social contracts	Obey societal rules for the common good, although individual rights sometimes outweigh laws
Stage 6: Morality of universal ethical principles	Societal laws and rules based on ethical values
Stage 7: Morality of cosmic orientation	Adoption of values that transcend societal norms

that children in the second stage (moral realism) respond to the magnitude of a transgression rather than to the intent behind it. But even adults respond to the magnitude of a transgression. The theft of a few postage stamps by an office worker, for example, is not treated the same way as the embezzlement of thousands of pounds. In this sense, children's morality is quite adult-like.

While stages one to four of Kohlberg's model appear to be universal, the appearance of the later stages of moral reasoning seem to be culture-specific. Urban populations tend to express more mature moral judgements, i.e. reach the later stages of reasoning, than rural populations. For example, stages 5 and 6 are absent in semi-literate, peasant cultures (Kohlberg, 1969) and in folk villages (Snarey, 1985). One conclusion from this is that the stage model does not classify modes of reasoning that involve the types of collective reasoning seen in less literate cultures (Snarey, 1985). For example, one 50-year-old Indian man justified Heinz's theft to save the life of a pet in terms of the 'unity of life' – all human life was sacred and needed to be preserved if possible. When Japanese and North American adults were given the Heinz dilemma, there was no difference in the moral stages of the two groups but the reasons for their decision were different (Isawa, 1992). Americans believed that the wife should live and that Heinz was right to steal the drug; the Japanese, however, were more concerned with the purity and cleanliness of life and decided that Heinz should not steal the drug.

Sobesky (1983) found that changes in the wording of Heinz's dilemma would drastically change people's responses. If the possibility of imprisonment was underscored, people tended to make more responses belonging to the preconventional level. Many researchers agree with Rest (1979), who concluded that Kohlberg's 'stages' are not coherent entities but do describe a progression in the ability of children to consider more and more complex reasons for moral rules.

A different type of criticism was levelled by Gilligan (1977, 1982), who suggested that Kohlberg's theory is sex-biased. According to her, Kohlberg's studies seem to suggest that men (in general) adhered to universal ethical principles, whereas women (in general) preferred to base their moral judgements on the effects these judgements would have on the people involved. Men's judgements were based more on abstract ideas of justice, whereas women's judgements were based more on concrete considerations of caring and concern for relationships. The criticism has some validity in the sense that the moral stages which Kohlberg suggested were based on data collected exclusively from boys: results show that when men and women study these dilemmas, their decisions place women at stage 3 and men at stage 5.

However, most researchers have not found that men's and women's moral judgements tend to be based on different types of values. For example, Donenberg and

Hoffman (1988) found that boys and girls were equally likely to base their moral judgements on justice or caring and that the sex of the main character in the moral dilemma had no effect on their judgements. Adolescent girls reach the third stage of reasoning more quickly than do boys (Silberman and Snarey, 1993) and girls and women, across most cultures but not all, appear to express more care-related concerns when making moral judgements (Jaffe and Hyde, 2000; Leenders and Brugman, 2005; Raynauld *et al.*, 1999). Johnson (1998), in a study of adults, also found that both sexes were capable of moral reasoning based on justice and caring. Walker (1989) tested 233 subjects ranging in ages from 5 to 63 years and found no reliable sex differences. However, while the available evidence does not appear to support Gilligan's conclusion that such concern is related to a person's sex, some studies do show sex differences in the type of real-life dilemmas. For example, women are more likely to report relationship-based dilemmas whereas men are more likely to report impersonal dilemmas when asked to describe actual moral dilemmas they have faced (Walker *et al.*, 1987).

Alternative models of moral development

Although Kohlberg's model has been one of the most influential and widely studied models of moral reasoning, it is not the only one. Other models of moral development have focused on specific types of moral behaviour. For example, Damon (1977, 1980) has explored children's concept of sharing and distributing resources. In a typical scenario, a child is told that a class of children has received some money from the sale of paintings that the whole class had made. The child is given examples of how the money could be distributed – it could be distributed according to merit, need, equality or sex – and is asked which criterion is most appropriate. Based on responses to this scenario, Damon proposed that the child goes through four levels of moral reasoning, summarised in Table 12.5.

In Damon's model of distributive justice, the child begins the process of moral development by making decisions about sharing based on egocentric considerations. The child will make decisions based on their own desires and perspectives. This stage of reasoning occurs during the pre-schooler stage. Towards the end of this stage, children begin to introduce external factors into their reasoning and may distribute/share resources according to the size or ability of the recipient group. The second stage is observed in primary school children and is characterised by an increase in equality-based judgements, that is, the child believes that everybody should share in a reward regardless of their ability or merit. The third stage finds the child considering the merit and the achievement of others when deciding how to distribute resources. The

Table 12.5 Damon's model of distributive justice

Stage	Description
1	Pre-schoolers' decisions are based on their feelings and perspectives; decisions are egocentric At the end of the stage, external considerations influenced reasoning
2	Primary school children base their decisions on notions of equality
3	Equality gives way to considerations of merit and notions of reciprocity The distribution of resources is based on other's achievements
4	At age 10 to 11, the child exhibits evidence of fairness

fourth and final stage, which occurs at age 10 to 11 years, sees the child considering a large number of factors that could influence their judgements about distribution; at this stage, the children show evidence of the moral concept of fairness.

Damon's stages model finds considerable support in real-life decision-making by children. This type of thinking appears to follow a similar pattern, but the children exhibit greater levels of self-interest (Gerson and Damon, 1978). They will, for example, indicate that resources should be distributed according to merit if they themselves are seen as showing merit.

An alternative method of measuring moral reasoning and development is the socio-moral reflection method (SRM) of Gibbs *et al.* (1982). This is a dilemma-free measure which evaluates the importance of those issues, values and institutions that arise in Kohlberg's model and which are seen in every society and culture – contracts, truth, affiliation, life, property, law and legal justice (Gibbs *et al.*, 2007). For example, people's view of truth and contract might be prompted by the statement: 'Think about when you've made a promise to a friend'; affiliation would be explored by statements such as: 'Let's say a friend of yours needed help and may die and you're the only person who can save him or her.'

While this and other models have attempted to create chronologies of moral development, some researchers have questioned the catch-all nature of the term 'moral development'. For example, a distinction has been made between 'moral' and 'socio-conventional' reasoning (Turiel, 1998). Moral reasoning involves making decisions where the consequences of actions could lead to another person being physically or psychologically harmed. Socio-conventional reasoning concerns issues regarding conformity to social norms or conduct such as how to address others, how to behave at a dinner table. Both types of reasoning follow a rule system of some kind but the two are different in terms of their comparative moral importance. It is thought that children can make the distinction between these two types of reasoning by 6 or 7 years.

Adolescence

After childhood comes adolescence, the threshold to adulthood (in Latin, *adolescere* means 'to grow up'). The transition between childhood and adulthood is as much social as it is biological. In some societies, people are considered to be adults as soon as they are sexually mature, at which time they may assume adult rights and responsibilities, including marriage. In most industrialised societies, where formal education often continues into the late teens and early twenties, adulthood officially comes several years later. The end of adolescence is difficult to judge because the line between adolescence and young adulthood is fuzzy: there are no distinct physical changes that mark this transition. Erikson (1968) described adolescence as a 'psycho-social moratorium': a period in which the child begins to experiment with life and with living, testing social and emotional boundaries to see what is acceptable and what is not.

Physical development

Puberty (from the Latin *puber*, meaning 'adult'), the period during which a person's reproductive system matures, marks the beginning of the transition from childhood to adulthood. Many physical changes occur during this stage: people reach their ultimate height, develop increased muscle size and body hair, and become capable of reproduction. There is also a change in social roles. As a child, a person is dependent on parents, teachers and other adults. As an adolescent, they are expected to assume more responsibility. Relations with peers also suddenly change; members of one's own sex become potential rivals for the attention of members of the other sex.

Sexual maturation

The internal sex organs and external genitalia do not change much for several years after birth, but they begin to develop again at puberty. When boys and girls reach about

11–14 years of age, their testes or ovaries secrete hormones that begin the process of sexual maturation. This activity of the gonads is initiated by the hypothalamus, the part of the brain to which the pituitary gland is attached. The hypothalamus instructs the pituitary gland to secrete hormones that stimulate the gonads to secrete sex hormones. These sex hormones act on various organs of the body and initiate the changes that accompany sexual maturation.

The sex hormones secreted by the gonads cause growth and maturation of the external genitalia and of the gonads themselves. In addition, these hormones cause the maturation of ova and the production of sperm. All these developments are considered primary sex characteristics, because they are essential to the ability to reproduce. The sex hormones also stimulate the development of secondary sex characteristics, the physical changes that distinguish males from females. Before puberty, boys and girls look much the same, except, perhaps, for their hairstyles and clothing. At puberty, young men's testes begin to secrete testosterone; this hormone causes their muscles to develop, their facial hair to grow, and their voices to deepen. Young women's ovaries secrete oestradiol, the most important oestrogen, or female sex hormone. Oestradiol causes women's breasts to grow and their pelvis to widen, and it produces changes in the layer of fat beneath the skin and in the texture of the skin itself.

Development of the adult secondary sex characteristics takes several years, and not all characteristics develop at the same time. The process begins in girls at around age 11. The first visible change is the accumulation of fatty tissue around the nipples, followed shortly by the growth of pubic hair. The spurt of growth in height commences, and the uterus and vagina begin to enlarge. The first menstrual period begins at around age 13, just about the time the rate of growth in height begins to decline. In boys, sexual maturation begins slightly later. The first visible event is the growth of the testes and scrotum, followed by the appearance of pubic hair. A few months later, the penis begins to grow, and the spurt of growth in height starts. The larynx grows larger, which causes the voice to become lower. Sexual maturity – the ability to father a child – occurs at around age 15. The growth of facial hair usually occurs later; often a full beard does not grow until the late teens or early twenties.

In industrialised societies, the average age at the onset of puberty has been declining. For example, the average age at the onset of menstruation was between 14 and 15 years in 1900 but is between 12 and 13 years today. The most important reason for this decline is better childhood nutrition. It appears that this decline is levelling off in industrialised societies, but in many developing countries, the age of the onset of puberty is beginning to fall as these countries enjoy increasing prosperity.

Behavioural effects of puberty

The changes that accompany sexual maturation have a profound effect on young people's behaviour and self-concept. One pronounced change is sensitivity about their appearance. Many girls worry about their weight and the size of their breasts and hips (Kloep, 1999). Many boys worry about their height, the size of their genitals, their muscular development and the growth of their beards (Alsaker, 1996). At around the age of 13, girls have consistently more negative views of their body image than do boys (Kloep, 1999; Wichstrom, 1999). Findings such as these have been linked to the higher incidence of eating disorders such as anorexia nervosa and bulimia nervosa in girls (we return to the characteristics of anorexia and bulimia and their possible causes in much more detail in Chapter 13). In Europe, for example, between 1 and 3 per cent of girls are reported to show symptoms of one of these two disorders (Barnombudsmannen, 1997). A study of Scottish children found that although many of them considered themselves to be 'too fat', they were not significantly overweight for their age, showing an average body shape (Shucksmith and Hendry, 1998). The results indicate that puberty and the short period following it are characterised by a concern with body image, but a concern which does not appear grounded in reality.

An Australian study asked over five hundred 8–11-year-old boys and girls what they thought of their body image and whether they engaged in any thinking or behaviour that could lead to weight loss or muscle gain (McCabe and Ricciardelli, 2003). Body Mass Index was measured (see Chapter 13 to see how this is calculated), as was self-esteem.

As might be expected, children with high BMIs were those most concerned with losing weight and their self-esteem was associated with their body satisfaction. The poorer the self-esteem, the greater the dissatisfaction. Boys were more likely than girls to think about, and put strategies in place towards, increasing muscle. However, even girls were engaged in thinking about increasing their muscles. The study shows that even quite young children are concerned with their body image and already think about strategies for losing weight and/or increasing muscle.

In an American study of 165 girls and 139 boys with an average age of 15 years, Jones (2004) found that girls became increasingly dissatisfied with their bodies primarily through talking about their appearance with friends and comparing themselves with desirable others. As time progressed, the girls became highly preoccupied with their appearance and this preoccupation was related to the increase in dissatisfaction. Boys, however, seemed less concerned with making direct comparisons between themselves and their peers. Instead, those boys who reported being most dissatisfied with their bodies had an

‘internalised’ ideal of what a muscular body looked like: it was against this ideal that they compared themselves.

A more extensive study investigated how body image changed across almost two decades. The cross-sectional study of 3,127 college students from a North American university who completed body image questionnaires from 1983 to 2001 found that body image changed significantly across these years, especially in women (Cash *et al.*, 2004). White women, in particular, reported negative assessments of their body image and a preoccupation with being overweight in the 1980s and early 1990s. Their satisfaction with their upper and mid torso as well as their overall appearance declined over the period. Women who completed assessments more recently – mid-1990s onwards – reported more favourable body image and less concern with being overweight (despite being heavier than the 1980s, cohorts). Men were relatively unaffected over the years, with their body image remaining relatively stable.

In addition to concerns with bodily appearance, most adolescents display a particular form of egocentrism that develops early in the stage of formal operations: self-consciousness. Some developmental psychologists believe that self-consciousness results from the difficulty in distinguishing their own self-perceptions from the views other people have of them.

Because the onset of puberty occurs at different times in different individuals, young adolescents can find themselves to be more or less mature than some of their friends, and this difference can have important social consequences. Early-maturing boys feel more confident about themselves than do late-maturing boys and are also more satisfied with their looks and musculature (Cok, 1990). Early-maturing girls, however, seem to exhibit greater depression and unhappiness, although the evidence for this is mixed (Alsaker, 1992). Early-maturing girls do appear to have greater eating concerns (Brooks-Gunn, 1988) and show greater variability in self-esteem.

How do adolescents view puberty?

Adolescent boys and girls have different views of puberty. Whereas boys seem to look forward to the increasing strength, freedom and social status that the change brings, girls see limited benefits. Instead, they regard the onset of becoming a woman as being accompanied by the need to conform to society’s view of women and this view is one that associates being a woman with lower social status (K.A. Martin, 1996). Girls perceive having less freedom than do boys because their parents insist on regulating aspects of their social lives, specifically, protecting them from predatory boys (K.A. Martin, 1996). Girls also seem unhappier at this time than are boys. Depression, for exam-

ple, appears to be more common in girls than in boys at puberty (Wichstrom, 1999). One possible reason may be their consistent concern over body image and the need to maintain a level of physical attractiveness – in short, the beginning of the development of sexual identity – two features that could meet with as much acceptance as rejection. As Figure 12.14 shows, girls become increasingly concerned with their weight and shape after the onset of puberty.

Changes in leisure activities reflect the move into young adulthood

One of the factors in an adolescent’s life that marks the transition from childhood to adulthood is the type of leisure activity they engage in. The ways in which children engage in leisure activities before and after puberty seem to reflect an increased concern with becoming an adult and with divesting themselves of the clothes of childhood. In

Figure 12.14 (a) Plots of three groups of girls’ actual mean body weight (orange) against their preferred mean body weight (purple). Data came from a study of girls in London in 1972 (the line with the triangle), London in 1990 (the line with the circle) and Ottawa (Canada) in 1990 (the line with the square). **(b)** How the proportion of girls who wish to be thinner increases after puberty. Data came from the same samples as those used for part (a).

the early stages of adolescence, children might engage in social activities organised for them by adults, such as group- or club-based activities (the Brownies, Scouts, sports clubs, and so on). As the children progress through their teenage years, these activities are perceived as too controlling and as less exciting than they originally were. Instead, activities which children themselves control become more prominent; children will hang around street corners, shopping centres and parks, for example, or drink alcohol.

Studies of Swedish, Scottish and Norwegian children have all demonstrated that the two reasons that children consistently give for drinking alcohol are that either it makes them look more like an adult or it makes them more accepted as an adult (Kloep *et al.*, 2001). Eventually, after the initial experimentation with alcohol – which may lead to excessive and painful consumption – most learn to consume drink sensibly.

Psychology in action – Adolescents and the internet

Once there were pigeons, then the printing press, then Roland Hill's Penny Post, followed by television and telephony, and, in another technological upheaval, the internet. Humans create some enormously inventive ways of communicating with each other. In the 1980s and 1990s, the internet was a largely passive affair – we surfed to find things and to buy things. The past 10 years have seen the arrival of Web 2.0. The internet became interactive: Facebook, Flickr, Friends Reunited, YouTube, Skype, MSN messenger, Twitter and the like blossomed and the internet underwent another, small revolution.

Online communication has now become one of the most popular means whereby one human being communicates with another, especially if that human being is pubescent or pre-pubescent. Van den Eijnden *et al.* (2008) cite a study reporting that 84 per cent of Dutch adolescents were found to have used instant messaging or internet chat rooms. In 2007–08, serious concerns were raised about adolescents' and young people's use of the internet when a spate of 17 suicides in the town of Bridgend, South Wales were linked with the use of social networking sites. There was no evidence that these sites

encouraged these suicides and it was more likely that the publicity generated on television and in newspapers provided more obvious encouragement.

This type of communication, however, is largely sterile and devoid of human contact. It may also be used by the lonely. Van den Eijnden *et al.*, therefore, sought to investigate whether online messaging was associated with any negative (or positive) effect on well-being.

They monitored instant messenger use and chat room visits by 663 12–15 year olds at two time points, separated by six months. Measures of loneliness and depression as well as compulsive internet use were administered at each session.

Using instant messaging and frequenting chat rooms – but not emailing – was positively related to compulsive internet use six months later: the greater the involvement in the former, the greater the compulsive internet use 6 months later. However, messenger use (but not chat room use or emailing) was also associated with increased depression six months later whereas loneliness was inversely related to instant messenger use. That is, those who reported being most lonely were less likely to use instant messaging, possibly because these lonely adolescents were adopting an 'avoidant' coping style (avoiding communication); research suggests that lonely people use the internet for entertainment, rather than contact (Seepersad, 2004).

Why was there an increase in reported depression? Perhaps depression arises because the person's social support is provided by online strangers. Such weak relations can not provide the social support that human contact can.

It seems, however, that adolescent boys can benefit more from this online communication than can girls – they feel that they are able to disclose more in an environment where there is no face-to-face or physical contact (Schouten *et al.*, 2007). The notion that the typical adolescent internet user is a generally lonely geek also appears to be a myth. Adolescents who are socially competent in 'real life' are more likely to use the internet – via messaging services, for example – to keep in touch with people (Bryant *et al.*, 2006).

Twenty years ago there was no internet as we know it. Now, this is an essential part of life, from childhood onwards.

Social development, peer relations and delinquency

During adolescence a person's behaviour and social roles change dramatically. Adolescence is not simply a continuation of childhood; it marks a real transition from the dependence of childhood to the relative independence of adulthood. Adolescence is also a period during which many people seek out new experiences and engage in reckless behaviour – behaviour that involves psychological, physical and legal risks for them as well as for others (Arnett, 1995). Norm-breaking such as this is related to the adolescent's social network (Magnusson *et al.*, 1986). For example, early-maturing girls have been found to have older female friends who engage in more adult behaviour (such as drinking and smoking). Such girls are also likely to regard themselves as more accepted by older girls, to date more (Stattin and Magnusson, 1990), and be more sexually active. The picture in boys is unclear; there is no such consistent pattern in the nature of their peer network or their behaviour.

Early- and late-maturing 14-year-old boys report being involved in more crime and being more rebellious in school, such as being sent out of class, swearing at a teacher, expulsion from school and so on (Williams and Dunlop, 1999). Early and late maturers may engage in delinquent behaviour for different reasons – early maturers drink alcohol because this is what their peers do; late maturers drink in order to attract attention and gain popularity.

Of course, we cannot stop puberty, but we can try to stop delinquent behaviour. One way to do this is by trying to understand why such delinquent behaviour occurs. Delinquent behaviour can lead to further mental problems when the delinquent child becomes an adult. Researchers at the University of Rotterdam have reported that emotional and behavioural problems characteristic of delinquency in 706 Dutch 11–16-year-olds were significantly related to the development of psychopathology (according to psychiatric diagnostic criteria) when these children became adults (Ferdinand *et al.*, 1999). The children were followed up for almost nine years, making this longitudinal study of particular value. It does not suggest that the delinquency caused later psychopathology (because correlation does not mean causation), but those children characterised by behavioural or emotional disturbances later showed behaviour characteristic of mental disorder. The finding suggests that if the delinquency can be identified early enough, reducing the delinquent behaviour may lead to a healthier adult mental life.

Delinquency is associated with a range of intellectual problems. Children with conduct disorder, for example, may have low verbal IQ, impaired language ability and poor executive function, as you saw earlier. Although this pattern has been seen in young and adolescent children, a near identical pattern of intellectual impairment

is seen in pre-school clinic-referred boys who met the standard criteria for conduct disorder (Speltz *et al.*, 1999). It would seem that the routine language testing of pre-school children exhibiting conduct disorder would be helpful in halting the decline in verbal IQ and language skill in these children.

Adolescence and mental health

Rates of depression increase in adolescence. Some studies have found that the prevalence increases from 1 per cent in children under 12 years of age to over 20 per cent by the end of adolescence (Kessler *et al.*, 2001). The biggest increase is seen between the ages of 15 and 18 (Hankin *et al.*, 1998), is twice as likely in girls (Glowinski *et al.*, 2003) and is even higher in pairs of female twins.

While some of the variance in mental health can be attributable to the momentous physical and social changes that the adolescent is going through, there are risk factors which can increase the likelihood of depression emerging. Sexual abuse, for example, (Putnam, 2003), is a serious risk factor for later depression which has also been associated with altered brain development (Teicher *et al.*, 2006). Studies have found that abuse experienced in childhood is associated with reduced hippocampus, corpus callosum, and frontal cortex grey matter (Andersen *et al.*, 2008). Depression, as you will see in the last chapter in the book, is associated with reduced hippocampal volume in adults. The pattern in depressed adolescents, however, is inconsistent. Some studies report a decrease in older adolescents who have major depression while others, fewer of them, show no reduction in adolescents with comparable problems (Andersen and Teicher, 2008).

Friendship

Friendship in childhood appears to have greater long-term consequences than might first be apparent (Newcomb and Bagwell, 1995). For example, pre-adolescent friendship and peer rejection are significant predictors of adult adjustment. Poor peer relations are associated with later maladjustment and mental health problems (J.G. Parker *et al.*, 1995). In an extensive longitudinal study, Bagwell *et al.* (1998) tracked 60 individuals from school age to 12 years after (when the mean age was 23 years 3 months). These researchers found that lower levels of pre-adolescent peer rejection predicted overall adjustment. Those with friends reported higher self-esteem as adults, whereas peer rejection and friendlessness was associated with mental disorder, especially depression. This evidence suggests that peer support and approval are important determinants of the adolescent's happiness and later adjustment. However, approval or rejection may not necessarily be causes of later adjustment or maladjustment. Perhaps these factors help to moderate maladjustment.

Psychology in action – Bullying

Bullying

Until relatively recently, the topic of bullying of schoolchildren by other schoolchildren featured briefly, if at all, in textbooks of social or developmental psychology. Aggression by children has always been a topic mined by psychology, but within the context of schooling it was largely ignored. In parts of Europe, however, there has been considerable research on bullying in the workplace: who bullies, why bullies do it, and how they get away with it. This research prompted others to explore the incidence, cause and prevention of bullying in school and an extensive research now exists in countries such as Australia, Canada, Norway, Sweden, the UK and the USA.

How common is bullying?

The incidence of bullying in secondary schools is high and is regarded by children themselves as a common problem (Smith *et al.*, 1999). According to Nicolaides *et al.* (2002, p. 106), bullying is 'a form of aggressive behaviour that causes injury or distress to the individual to whom it is directed'. This aggression can be physical (actual bodily violence), verbal, or psychological (such as social exclusion). The relationship between the bully and the victim is also unequal: perceived power tends to reside with the bully and bullies usually act repeatedly against their victims. The victim of a bully, therefore, is likely to be bullied on more than one occasion.

In a survey of bullying in English schools, Whitney and Smith (1993) reported the general incidence of bullying, who does the bullying and who becomes the victim. The study found that:

- 10–27 per cent of children reported being the victim of bullying at some time during school time.
- 6–12 per cent reported taking part in bullying at least once.
- Self-reports of bullying and being bullied declined as the children grew older (from 8 to 16 years).
- Boys were twice, and sometimes three, times as likely to be bullies as were girls.
- 35 per cent of bullies were spoken to by their teacher about their conduct.
- 30–35 per cent of victims spoke to teachers about their being bullied.
- 60 per cent of children reported disliking bullying.
- 20 per cent of children indicated that they would be willing to join in with bullying.

Since September 1999, it has been a legal requirement in England and Wales for schools to have an anti-bullying programme. Such programmes have been increasing across Europe, and Norway and Sweden have well-publicised anti-bullying campaigns. Such initiatives are considered important because studies have suggested that when schools are com-

placent about their bullying children or when the school's climate encourages bullying, then social relationships are harmed and the education that children in such schools receive is poor (Olweus, 1993; Rigby, 1997).

Boys are more likely to be physical bullies than are girls; girls are more likely to engage in 'psychological' bullying such as name-calling and excluding others. Teachers' perceptions of bullying and their awareness of the findings about bullying have generally been found to be accurate, but they usually under-report the incidence of bullying in their schools. One study found that teachers' estimate was 5–10 per cent, but the pupils' reports indicated that the incidence was over twice as high at 26 per cent (Pervin and Turner, 1994). The age and sex of the teacher also seems to be important: female teachers are more likely to have negative attitudes towards bullying and more positive attitudes towards the victim, but longer-serving teachers have a less positive attitude to the victim (Boulton, 1997).

Transitional life events, social dominance and bullying

Some psychologists have suggested that bullying becomes more prevalent during early adolescence and during transitional periods in the children's lives, for specific reasons. For example, aggression in early adolescence is viewed more positively by children's peers than it is later in adolescence (Bukowski *et al.*, 2000). According to Pellegrini and Long (2002), certain factors promote an increase in aggression at this time. They point to the obvious physical changes that occur, especially in boys. Hormonal changes lead to body size increase, the beginning of a sexual interest in the opposite sex and the visible expression of secondary sexual characteristics which mark the onset of young adulthood. The increase in body size, some researchers argue, leads to boys reviewing their position in their social environments and expressing a need for dominance within their social group (Hawley, 1999). One way of expressing this dominance is to use aggression, usually with the approval of peers (Maccoby, 1998).

Pellegrini and Long (2002) also note that, in addition to establishing social dominance, young adolescents also undergo a physical transition in their lives: moving school. This move appears to coincide with an increase in antisocial behaviour. In primary school, children are taught in well-established, close, friendly groups. The move to secondary school usually leads to the break-up of this close group and the child has to find new friends in a much bigger environment. Pellegrini and Long argue that if bullying is a way of establishing social dominance, the aggression should increase during this transition from primary to secondary school. Once social groups are established, the incidence of bullying should decrease.

Psychology in action – Continued

During the transition, bullying and aggression increase in the initial period but then decrease. Boys are more likely than girls to be bullies and are more likely to view bullying and aggression positively in the early stage of adolescence. After the transition to middle school, aggression decreased and dominance in social groups increased, providing some indirect evidence for the hypothesis that aggression is used to establish dominance but once dominance is established, continued aggression is unnecessary.

What makes a bully?

Are there personality characteristics that are specific to bullies? In an earlier study of teachers' views of bullies and victims, the personalities of victims were well described but the character of bullies less well-described (Siann *et al.*, 1993). One common view of the bully is of a person who is a lumpen, physically able individual who is socially inept (Nicolaidis *et al.*, 2002). Research suggests, however, that this stereotype is inaccurate. The school bully is likely to be cold, manipulative and very socially adept. This is one reason why they are able to convince others to condone, endorse or join in with the bullying.

To test whether bullies are sensitive to emotional and social events, Sutton *et al.* (1999) first administered a questionnaire to 193 English schoolchildren aged between 7 and 11 years to determine who were bullies, followers, defenders of the victim,

victims, and who did not get involved in bullying. The children then participated in an experiment in which they were read 11 short stories and asked questions about these stories which relied on an awareness of social cognition and manipulation. For example, in one of the studies, 'Mike' has a stomach ache but knows that if his mother sees him in pain, he will not be allowed out to play. He asks his mother if he can. The participants were shown four pictures of Mike's face and asked: (1) which facial expression represents how he really feels (the control question) and (2) which facial expression he shows to his mother when he asks her if he can go out (the experimental question).

The researchers found that bullies who initiated aggression were more accurate in answering social manipulation questions than were bullies who helped or supported the ringleader bullies, the victims, or the defenders. This finding suggests that the bully is not a socially inept individual but one who is aware of the power of manipulation.

A study of American children by Schwartz *et al.* (2000) found that those who were exposed to a harsh, hostile home environment early in life were more likely to be victimised by peers three years later. However, this occurred only in children who had few friends. Those children with hostile family backgrounds but who had numerous friendships experienced little peer victimisation. Friendship may be a moderating factor in peer victimisation, the authors argue.

Relations with parents

Philip Larkin, in his poem *This Be the Verse*, famously remarked, 'They fuck you up your mum and dad/They may not mean to but they do./They fill you with the faults they had/And add some extra just for you.' The relationship between adolescents and their parents can be fractious. As adolescents begin to define their new roles and to assert them, they almost inevitably come into conflict with their parents. Adolescents and their parents tend to have similar values and attitudes towards important issues (Youniss and Smollar, 1985). Family conflicts tend to be provoked by minor issues, such as messy rooms, loud music, clothes, curfews and household chores. These problems tend to begin around the time of puberty; if puberty occurs particularly early or late, so does the conflict (Paikoff and Brooks-Gunn, 1991).

Adolescence is said to be a time of turmoil, characterised by unhappiness, stress and confusion. When McGue *et al.* (2005) asked 1,330 11-year-old twins to rate the warmth and degree of conflict experienced in their relationship with parents and then asked them to do the same three years later (1,176 children did), the children's

perception of their relationship declined significantly in three years – conflicts increased significantly and reported warmth decreased. Girls experienced these changes more significantly than did boys.

Whereas a few adolescents are unhappy most of the time (and most are unhappy some of the time), studies have found that the vast majority of teenagers generally feel happy and self-confident (Offer and Sabshin, 1984; Peterson and Ebata, 1987). But mood states do seem to be more variable during the teenage years than during other times of life. Csikszentmihalyi and Larson (1984) randomly sampled the mood states of a group of teenage students. They gave them electronic beepers that sounded at random intervals that were, on average, two hours apart. Each time the beepers sounded, the students stopped what they were doing and filled out a questionnaire that asked what they were doing, how they felt, what they were thinking about, and so on. The investigators found that the students' moods could swing from high to low and back again in the course of a few hours. The questionnaires also revealed conflicts between the participants and other family members. Although the subjects of the conflicts were usually trivial, they nevertheless concerned the teenagers deeply.

The degree of parental conflict the child is exposed to can have devastating consequences later in life, especially in terms of the child's adjustment (Fincham, 1998). Although divorce may seem an obvious cause of problems for the child, evidence suggests that the negative effects of divorce are evident before separation occurs (Doherty and Needle, 1991). Parental conflict has been associated with poor academic performance, depression (Meyer *et al.*, 1993) and antisocial behaviour (Loeber and Dishion, 1983). Longitudinal studies suggest that high degrees of parental conflict at the age of 3 are associated with later adjustment problems in adulthood (Neighbors *et al.*, 1997). Although not all children will be affected detrimentally by parental conflict, this behaviour has consistently clear and negative effects on the child's immediate and future behaviour.

Adulthood: beyond adolescence

It is much easier to outline child or adolescent development than adult development; children and adolescents change faster, and the changes are closely related to age. Adult development is much more variable because physical changes in adults are more gradual. Mental and emotional changes during adulthood are more closely related to individual experience than to age. Some people achieve success and satisfaction with their careers, while some hate their jobs. Some marry and have happy family lives; others are happy to live without children, and others never adjust to the roles of spouse and parent. No single description of adult development will fit everyone. Because of this variability, there is no single 'normative' change that occurs from adolescence onwards: puberty is the last single period during a person's development where significant and consistent changes in physical and cognitive behaviour occur.

Muscular strength peaks during the late twenties or early thirties and then declines slowly thereafter as muscle tissue gradually deteriorates. By age 70, strength has declined by approximately 30 per cent in both men and women (Young *et al.*, 1984). However, age has much less effect on endurance than on strength. Both laboratory tests and athletic records reveal that older people who remain physically fit show remarkably little decline in the ability to exercise for extended periods of time (Spirduso and MacRae, 1990).

Although it is easy to measure a decline in the sensory systems (such as vision, hearing and olfaction), older people often show very little functional change in these systems. Most of them learn to make adjustments for their sensory losses, using additional cues to help them

decode sensory information. For example, people with a hearing loss can learn to attend more carefully to other people's gestures and lip movements; they can also profitably use their experience to infer what is said.

Functional changes with age are also minimal in highly developed skills. For example, Salthouse (1984, 1988) found that experienced older typists continued to perform as well as younger ones, despite the fact that they performed less well on standard laboratory tests of sensory and motor skills, including the types of skill that one would expect to be important in typing. The continuous practice they received enabled them to develop strategies to compensate for their physical decline. For example, they tended to read farther ahead in the text they were typing, which enabled them to plan in advance the patterns of finger movements they would have to make. However, as you saw in Chapter 11, the neurological diseases that accompany ageing can have devastating intellectual and personal consequences.

Middle adulthood: a period of contentment?

By the time people reach middle adulthood, they have achieved or have chosen to achieve, almost all of the major life decisions available to them. Marriage or cohabitation, having children, setting up a home, beginning a career – decisions on all of these major life changes will have been made by the time that people reach their late thirties/mid-forties.

Because the major life decisions have been made, people during this period in life generally feel comfortable and contented, and a conventional way of life becomes the norm. People become quite satisfied with their lives at this time; they feel at their most confident, most in control and most productive (Lachman *et al.*, 1994; Chiriboga, 1997; Tikoo, 1996; Shek, 1996). Depression, for example, although present in the middle-aged, declines during this period in life (Pearlin and Mullan, 1992). Middle-aged women regard themselves as having a better ability to cope with life's difficulties (Stewart and Ostrove, 1998). Women's interest in sex appears to decline from the mid-40s (Helson and Soto, 2005), as Figure 12.15 shows.

Erikson (1968) argued that the adult years consist of three psychosocial stages – intimacy versus isolation, generativity versus stagnation, and integrity versus despair – during which life is reviewed either with a sense of satisfaction or with despair. During intimacy versus isolation, people succeed or fail in loving others; during generativity versus stagnation, people either withdraw inwardly and focus on their problems or reach out to help others; during integrity versus despair, life is reviewed with either a sense of satisfaction or with despair.

Figure 12.15 How interest in sex, as well as occupation with status, varies between the age of 40 and 60.

Source: Helson, R. and Soto, C.J. (2005). Up and down in middle age: monotonic and nonmonotonic changes in roles, status and personality. *Journal of Personality and Social Psychology*, 89, 2, 194–204.

Another attempt to understand stages of adult development is suggested by Levinson *et al.* (1978). They interviewed 40 men – business executives, blue collar workers, novelists and biologists – and analysed the biographies of famous men and examined stories of men's lives as portrayed in literature. They claimed to have discovered a pattern common to most men's lives. Instead of proceeding smoothly, their lives were characterised by several years of stability punctuated by crises. The crises were periods during which the men began to question their life structures: their occupations, their relations with their families, their religious beliefs and practices, their ethnic identities, and the ways they spent their leisure time. During times of transition – which caused considerable anxiety and turmoil – the men re-evaluated the choices they had made and eventually settled on new patterns that guided them through another period of stability. Periods of transition lasted four or five years, whereas the intervening periods of stability lasted six or seven years.

For Levinson *et al.*, the most important crises occur early in adulthood, when choices must be made about career and marriage, and at mid-life (during the early to mid-forties), when realities about one's life structure must finally be faced. Although Levinson and colleagues did not invent the notion of the mid-life crisis, they certainly helped bring it to the attention of the general public and helped make the term a part of everyone's vocabulary. They concluded that the mid-life crisis happened to all men. Men whose life structures do not yet meet their prior goals and expectations realise that the future will probably not bring the success that up until then has eluded them. Men who have succeeded begin to question whether the goals they

had set for themselves were meaningful and worthwhile. All men, successful or not, also begin to confront the fact that they are getting older. They are starting to detect some signs of physical decline, and they are witnesses to the death of their parents or their parents' friends.

Several investigators have defined objective criteria for the presence of a mid-life crisis and have looked for its presence in representative samples of participants. For example, Costa and McCrae (1980) administered a Midlife Crisis Scale to 548 men aged 35–79 years. The scale contained items asking whether the participants were experiencing any of the symptoms of a mid-life crisis, such as dissatisfaction with job and family, a sense of meaninglessness, or a feeling of turmoil. They found no evidence for a mid-life crisis. Some people did report some of the symptoms, but they were no more likely to occur during the early to mid-forties than at any other age. A study of 60 women (Reinke *et al.*, 1985) also found no evidence of a mid-life crisis.

These findings do not mean that middle-aged people do not periodically contemplate or question the important issues in their lives. But there appears to be no crisis – in the dramatic sense – inherent to these reflective periods.

Adult development occurs against the backdrop of what many developmental psychologists consider to be the two most important aspects of life: love and work. For most of us, falling in love is more than just a compelling feeling of wanting to be with someone. It often brings with it major responsibilities, such as marriage and children. Work, too, is more than just a way to pass time. It involves setting and achieving goals related to income, status among peers and accomplishments outside the family.

Parenthood

One of the most significant events in a couple's life is the birth of a child. It brings about an upheaval in the social, emotional and intellectual lives of parents who find that demands on their time become more pressing and who are exposed to the additional stress of having responsibility for the care of another human being.

Generally speaking, mothers assume more responsibilities than do fathers for the day-to-day care of children (Biernat and Wortman, 1991). As a result, they spend more time doing housework and less time talking to their husbands (Peskin, 1982), which can place strain on their marital happiness. However, if husband and wife can find time together in the evenings, and if the husband is able to share in the parenting and household chores, the stress of adapting to family life is lessened considerably (Daniels and Weingarten, 1982). Even men who take parental leave report that they do so to look after their children, not to do housework (Brandt and Kvande, 1998). There seem to be exceptions to this pattern, however. A Danish

study found that if both parents had successful careers, then the housework and childcare were distributed more equitably (Hestbaek, 1998).

The general pattern of greater involvement in the day-to-day running of the household by women may be why they perceive the personal costs of having a child to be greater than those perceived by men (Beckman, 1987). Men's priorities, it seems, remain the same after the birth of the child as they were before: they still want the attention of their wives or partners, they still want to engage in an active social life and they still want the freedom to pursue other interests outside the family (Watson *et al.*, 1995). With the inconvenience of childbirth, it is perhaps not surprising that men regard their marriages as being less satisfactory after the birth of a child (Chalmers and Meyer, 1996). The introduction of another human being into the dyad can also bring clear stresses. Parents may find that the time they have to spend with each other is reduced, especially if their child has additional medical or behavioural problems (Schuchts and Witkin, 1989).

Parenting adolescents

As children grow older and become more self-sufficient in caring for themselves, the day-to-day burdens of raising a family taper off and husbands and wives are able to spend more time with each other. However, adolescents pose new problems for their parents: they may question parental authority, and their burgeoning social agenda may put a wrinkle in their parents' personal and social calendars. For many parents, rearing adolescents, particularly during the time just prior to their leaving home, represents the low point of marital happiness (Cavanaugh, 1990). Most of the tensions revolve around issues of responsibility and mutual respect. The adolescent is slowly groping towards adulthood and wishes to be regarded as an individual who is responsible enough to lead their life without parental interference. Parents, however, still feel that their child requires guidance and has not earned the right to be regarded as fully independent.

Generally speaking, once a family's youngest child has left home, marital happiness increases and continues to do so through the remainder of the couple's life together. The average age of a child when they leave the parental home appears to be getting older, at least in the UK. According to Coleman and Hendry (1999), this age increased from 17 to 23 years in the previous decade. It was once thought that the 'empty nest' posed problems for the middle-aged couple, particularly for the mother, who was thought to define her role solely around her children. Chiriboga (1991) found that mothers undergo a fairly turbulent series of emotions once the child has flown the nest. Initial depression and a feeling of loss lead to further unhappiness but then to a sense of pride when

they see their adult child making a life of their own. These changes do not appear to be seen in fathers.

Although parents may miss daily contact with their children, they also feel happy (not to mention relieved) that a major responsibility of life – raising self-reliant children who become responsible members of society – has been completed successfully. Just as importantly, the parents now have time for each other and freedom to pursue their own interests. It may be true that an empty nest is a happy nest. Research tends to support this statement. In one study, only 6 per cent of empty-nest couples reported that life prior to their last child leaving home was better than their empty-nest experience. Over 50 per cent of the couples interviewed said that their lives were better now than before their children had left home (Deutscher, 1968; Neugarten, 1974).

Parenting during adolescence

Not all parenting is done by adults. There has been an increasing trend for parenthood to occur earlier in life, during the teenage years rather than young or middle adulthood. Childbirth during adolescence has been associated with a multitude of problems – social, educational and practical and, mostly, these are problems for the mother rather than the father. Adolescent mothers may face increased financial hardship and a reliance on state benefits, decreased employment prospects, a disruption in their education and the opprobrium of others who disapprove of their behaviour (Dennison and Coleman, 1998). They also have to cope with the normal disruptions and changes that accompany adolescence itself.

However, the picture is not as gloomy as it first appears. When mothers themselves are asked about how they are coping with the responsibility of raising a child, they report problems but also indicate that the experience can be a positive one (Dennison and Coleman, 1998). Many report coping well, and receive support from their own mothers and family during the pregnancy and after the birth of the child (Phoenix, 1991).

Work

The task of raising a family is balanced with one or both parents having a career. In fact, events that occur in the workplace often affect the quality of home life. A promotion and a pay rise can mean that the family can now do things that they could not before. Working long hours to get that pay rise, however, can decrease the amount of time that a couple can spend together with their children. According to Chiriboga (1997), work is the major source of stress for most men but for only around one-fifth of women.

With the dramatic increase in the number of women entering the workforce since the 1970s many psycholo-

gists have focused their research efforts on understanding dual-earner marriages – those in which both parents work full- or part-time. Compared with single-earner marriages, dual-earner families generally have a better standard of living in terms of material possessions and savings for their children's education and for retirement. Another important benefit accrues, especially to the wife: she is able to achieve recognition and independence outside the home (Crosby, 1991). Most husbands in dual-earner marriages support their wives' working. In addition, they find their wives to be more interesting, essential and helpful (Schaie and Willis, 1992).

Coping with unemployment

When adults find themselves unemployed, however, there may be serious consequences for the person who is made unemployed and their relationships with others. Arguments with a partner can increase, there is less satisfaction with the partnership or marriage and there is a strong likelihood of divorce if the dissatisfaction and arguments continue (Liem and Liem, 1990). Unemployment, however, seems to exaggerate already existing problems. The risk of divorce, for example, occurs primarily in partnerships that have already experienced problems prior to unemployment.

If the unemployed person identifies very closely with their work – in a sense, 'living and breathing' their work – then the consequences of removing the opportunity to do that much-valued work will be psychologically damaging. This is especially true if the person is in middle adulthood rather than young adulthood. A study of middle-aged unemployed Israeli women, for example, found that they were least likely to reject job offers and experienced declining health following unemployment (Kulik, 2000). What may make this life change so difficult to cope with at middle adulthood is the reduced likelihood of re-entry into the workplace. If people over 40 years of age who have been made redundant by their company actively seek work but do not secure employment after a year of searching, they experience feelings of uselessness and resignation (Henkens *et al.*, 1996). These feelings might also lead to increased mental distress, the increase being greater than that observed in younger or older people who have been made unemployed (Theodossiou, 1998).

Men and women seem to respond to unemployment differently, however. Men appear to engage in activities that give structure to their lives, such as claiming state benefit, attending benefit interviews or job hunting, whereas women will engage in more domestic chores. Women will also use this time to engage in self-improvement activities such as seeking out alternative careers or retraining; men, on the other hand, may spend this time watching television or developing hobbies (Walsh and Jackson, 1995). The effects of unemployment on health are considered again in Chapter 17.

Late adulthood and the menopause

One of the inevitable features of ageing is that the process is visible. The outer shell of age is easy to see: a young person may not be served alcohol based on their appearance, and similar judgements – often, more harmful – are made about people as they pass from middle into late adulthood. Although middle-aged and older individuals may feel full of vitality, youth and vigour, this is not the impression their physical appearance indicates to others (Featherstone and Hepworth, 1993). Despite the subjective feeling of vitality, some physical changes are inevitable.

There is also an increase in reported mental health symptoms in the 45–64 year old group, as well as in older samples who are retired or out of work, as Figure 12.16 shows.

At late adulthood the body undergoes a shift, especially in women. Alteration in the endocrine system leads to the pituitary gland and the hypothalamus releasing hormones that prevent the ovaries from controlling menstruation. This physical change is called the menopause and is sometimes accompanied by 'hot flushes', sweating during sleep, fatigue and irritability (Dan and Bernhard, 1989). In one Scottish study, over half of the sample had reported experiencing one of 15 menopause-related symptoms, but only 22 per cent of respondents felt the symptoms to be a problem (Porter *et al.*, 1996). In fact, many women experience and value the sense of freedom that the menopause brings (Robinson, 1996). They feel that this time of life brings enhanced social status and psychological well-being. There are also cross-cultural differences in people's responses to the menopause. Japanese women, for example, report fewer menopausal symptoms than do American or Canadian women (Lock, 1998).

Old age

The contrast between the subjective experience of ageing and actual ageing is clearly illustrated by a quote from Gibson (1992, p. 59) who notes that we do not really have an experience of being old: ‘When they get to a certain age, quite a number of people realise that the whole business of age status is rather an illusion. All their lives, they had expected to be ‘old’ when they reached a certain date on the calendar, but when they reached it, they did not feel different.’

Despite the way people feel, physical deterioration and loss of friends and family become characteristics of old age, a period that begins almost arbitrarily at 65 years. Whereas in young adulthood and middle age, the death of friends is a non-normative event, in old age it becomes normative. Very few milestones, however, mark the transition to old age. There are socially constructed events, such as compulsory retirement from work, which indicate that old age has arrived, but few other events as certain as this mark out the last and longest period in a person’s life (Hendry and Kloep, 2002).

There is a tendency in some people to disguise the effects of old age – they may dress in a way they think young people do or may engage in activities they associate with youth, or attempt to conceal the physical effects of ageing by applying cosmetics. These individuals feel that they still need to compete, to be sexy and to be seen as attractive to younger people rather than accept the ageing process. This is unusual because when people are asked which age they would like to be, the ideal age is quite close to their actual age (Uotinen, 1998). General optimism appears to increase with age, but optimism related to health and thinking declines (Isaacowitz, 2005). Interestingly, when 3,793 adults aged between 34 and 74 years of age were asked to rate how satisfied they were with their life in the past, the present or future, there was little difference between the young and old samples in terms of actual satisfaction but the older participants anticipated their satisfaction would get worse and the younger sample expected it would get better (Lachman *et al.*, 2008). The under 65s found the present more satisfying than the past; the over 65s found the past and present equally satisfying.

What constitutes successful ageing? Researchers and older people alike agree on the principal factors which contribute to successful ageing but laypeople tend to consider more ‘psychological’ factors as additionally important, as Table 12.6 and Figure 12.17 show. Biomedical theorists, for example, emphasise longevity as a measure of successful ageing and focus on the absence of illness/risk factors for illness, as well as the maintenance of cognitive and physical function as important constituents (Bowling and Dieppe, 2005). One study of 601 Australian men in their

Figure 12.17 Most common definitions of successful ageing given by 854 people aged ≥50 in Britain

80s, found that three-quarters of them aged well, mentally, and that education and the degree of physical activity they were involved in were good predictors of successful mental health (Almeida *et al.*, 2006). Psychosocial theorists emphasise older people’s satisfaction with life, personal growth and social participation as important constituents. Laypeople, when asked, highlight social, psychological and physical factors as important to growing old successfully. One study of 854 people aged 50 and over found that 75 per cent of the sample regarded themselves as ageing very well; they cited good health and functioning as a definition of successful ageing (Bowling and Dieppe, 2005).

There is evidence that ageing may not be an entirely negative experience. A study of young people found that not only did they want to be older but also that they were less positive about their own age and worried about their personal inadequacies (Montepare, 1991). Older people who accepted the process of ageing, on the other hand, felt good about themselves, feared ageing less and were more satisfied with life (Montepare and Lachman, 1989). Data from the Amsterdam Longitudinal Aging Study suggest that having a partner, a good family, social support and high self-esteem can lead to better coping with chronic illness in old age (Penninx *et al.*, 1998), which indicates that there are factors which can mitigate the effects of old age.

There is an element of loss of power in old age, however. Compulsory retirement from work – a milestone introduced by the German chancellor, Bismarck, in the nineteenth century – is the first step to removing a sense of power from old people. There is no relationship between a person’s ability to function as an employee and their age

Table 12.6 View of what constitutes successful ageing**Theoretical views**

(Salthouse and Maurer, 1997), but almost all professions have a compulsory retirement age. In fact, politicians are one of the few professions not to have such a compulsory milestone, an irony given that the original compulsory retirement age was determined by a politician. If there is no relationship between an employee's work performance and their age, how can a retirement age be justified?

At retirement, old people may become eligible for state benefits and other monetary or social benefits that the state sees fit to bestow on them. Because of this dependence, old age is sometimes characterised as a 'second childhood' (Hockey and James, 1995). As Jacques says in his seven ages of man speech in *As You Like It*, (II, VII, 163–6):

Last scene of all,
 That ends this strange eventful history,
 Is second childishness and mere oblivion;
 Sans teeth, sans eyes, sans taste, sans everything.

Old people fear becoming a burden to others and fear the loss of autonomy that old age can bring (Dittman-Kohli, 1990). The prejudice that they may face can also be problematic and can become a self-fulfilling prophecy. If old people are presented with subliminal messages that are derogatory about old people's abilities, for example,

they perform less well on a subsequent task of cognitive ability than would those old people not exposed to such messages (Levy, 1996).

How language use changes as we get older

While research suggests that we respond to negative emotion less readily as we get older, research into the psychology of expressive writing also suggests that we become less egocentric. Pennebaker and Stone (2003) compared the language used in written or spoken expression by people who had taken part in 32 experiments in which they expressed how they feel and think about a recently experienced trauma. This technique, and what it is used for, is discussed in more detail in Chapter 18.

These experiments require participants to write about personal and traumatic experiences. There were 1,925 participants in the 15–24-year-old group, 494 in the 25–39 group, 132 in the 40–54 group and 62 in the 55–69 group. In a follow-up experiment, the researchers also followed the linguistic development of ten established, professional writers including Shakespeare, Austen, Dickens, George Eliot and Wordsworth.

One of the most pronounced differences in young and older authors' and speakers' language development was the use of the first person singular: I. There was a significantly lower tendency to use 'I' in communication in the older groups, suggesting that as people get older, they become more topic-focused and less self-referential. The same reduction in the use of 'I' seen in the experimental samples is also seen in the samples of fiction studied, particularly in Austen's and Wordsworth's work.

In the older samples, there was also significantly less evidence of referring to other people. In the younger samples there was a significantly greater reference to other people. Perhaps this change reflects the possibility that as we grow up, we are much closer to and dependent on other people and refer to ourselves in terms of others' behaviour or expectations (such as those of parents or older siblings).

Older participants in both studies made more use of the future-tense than did the younger ones while using fewer past-tenses. Conversely, the youngest sample made the greatest use of the past-tense and least use of the future-tense. Time references (such as day, minute and clock) were more common in the younger samples whereas the use of words of six letters or more was more common in the older samples (but there were no differences between groups for fiction, perhaps reflecting the probability that professional authors' vocabulary is already fairly well-developed at the beginning of their writing career).

Although the largest portion of the study was cross-sectional, it suggests that older people's use of language differs in significant and interesting ways from that of younger samples. The most important of these differences is a reduction in the egocentric use of 'I' in older people.

Death and bereavement

'I'm not afraid of death,' said Woody Allen. 'I just don't want to be there when it happens.' Death is the final event of life. It is a biological and social event – family and friends are emotionally affected by the death of a loved one. Although a death may claim a life at any time, most people die when they are old. One question that developmental psychologists have asked about death and dying among the elderly is, how do old people view the inevitability of their own death?

As you might expect, elderly people contemplate their death more often than do younger people but, generally speaking, they fear death less than do their younger counterparts (Kalish, 1976) and tend to cope better with loss (McCrae and Costa, 1993). Although depression can occur immediately someone close dies, this decreases over the next one to two years (Thompson *et al.*, 1998). No one knows why this is so, but a tentative explanation may be that older people have had more time to review the past and to plan for the future knowing that bereavement is close at hand. Thus, they are able to prepare themselves psychologically (and financially) for death. The sense of loss, however, can continue until the bereaved die (Wortman *et al.*, 1993).

Contemplating and preparing for death, though, is not like knowing that you are actually dying. The changes in attitude that terminally ill people experience, have been

studied by Kübler-Ross (1969, 1981). After interviewing hundreds of dying people, she concluded that people undergo five distinct phases of psychologically coping with death. The first stage is denial. When terminally ill people learn of their condition, they generally try to deny it. Anger comes next – now they resent the certainty of death. In the third stage, bargaining, people attempt to negotiate their fate with God or others, pleading that their lives might be spared. While bargaining, they actually realise that they are, in fact, going to die. This leads to depression, the fourth stage, which is characterised by a sense of hopelessness and loss. According to Kübler-Ross, 'When the terminally ill patient can no longer deny his illness, when he is forced to undergo more surgery or hospitalization, when he begins to have more symptoms or becomes weaker or thinner, he cannot smile it off anymore.' The fifth and final stage, acceptance, is marked by a more peaceful resignation to the facts or 'positive submission'. 'It is as if the pain had gone,' according to Kübler-Ross, 'the struggle is over.'

Kübler-Ross's work highlights the psychological factors involved in dying and has provided an initial theory about how the dying come to grips with their fate. Her work, though, has not been accepted uncritically. Her research was not scientific – her method for interviewing people was not systematic, and her results are largely

Elizabeth Kübler-Ross (1926–2004), psychiatrist.

Source: Press Association Images.

anecdotal. Moreover, of the five stages, denial is the only one that appears to be universal. Apparently, not all terminally ill people have the same psychological response to the fact that they are dying.

However, despite its flaws, Kübler-Ross's work is important because it has prompted an awareness, both scientific and public, of the plight of the terminally ill. The scientific response, as you might guess, has been to do more medical research in the hope of prolonging the life of people with cancer or other terminal illness. The public response has involved the attempt to provide support for the dying and their families through hospice services (Aiken, 1994). In the past, hospices were places where strangers and pilgrims could find rest and shelter. Today, hospices are special places that provide medical and psychological support for the dying and their families. In cases in which the dying person wishes to die at home, hospice volunteers work in that setting. The primary functions of hospice services are two fold: to provide relief from pain and to allow the person to die with dignity. No attempt is made to prolong life through technology if doing so would diminish the self-respect of the dying person and their family. To die with dignity is perhaps the best death possible – for, together, the dying and their loved ones are able to experience, for the last time together, reverence for the experience of life.

Chapter review

Prenatal development

- The three stages of prenatal development span the time between conception and birth. In just nine months, the zygote grows from a single cell, void of human resemblance, into a fully developed foetus, complete with physical features that look much like yours and mine, except in miniature.
- Sex is determined by the sex chromosomes. Male sex organs are produced by the action of a gene on the Y chromosome that causes the gonads to develop into testes.
- The testes secrete androgens, a class of hormones that stimulates the development of male sex organs. If testes are not present, the foetus develops as a female.
- The most important factor in normal foetal development is the mother's nutrition; malnutrition leads to abnormal development and impaired cognition.
- Normal foetal development can be disrupted by the presence of teratogens, chemicals which can cause mental retardation and physical deformities; one teratogen is alcohol – when consumed by a pregnant woman, this may lead to foetal alcohol syndrome.
- There is evidence that the human foetus is capable of discriminating between sensory stimuli while in the womb, suggesting that it is capable of a rudimentary form of cognition.

Physical and perceptual development in infancy and childhood

- A newborn infant's first movements are reflexes that are crucial to its survival. For example, the rooting, sucking and swallowing reflexes are important in finding and consuming food.
- Sophisticated movements, such as crawling and standing, develop and are refined through natural maturation and practice.
- A newborn's senses appear to be at least partially functional at birth. However, normal development of the senses, like that of motor abilities, depends on experience.
- The brain appears to develop throughout infancy and adolescence, with myelination being the key characteristic of maturation.
- Because the infant lacks language, most studies of motor and perceptual development examine the child's non-verbal response to stimulation. These responses include movements involving the head, mouth and eyes.
- If an infant is deprived of the opportunity to practise them during a critical period, these skills may fail to develop, which will affect the child's performance as an adult.
- Before the age of 2 years, infants seem to be more concerned with the contours of visual stimuli – a phenomenon called the externality effect.

Cognitive development in infancy and childhood

- The first step in a child's cognitive development is learning that many events are contingent on its own behaviour. This understanding occurs gradually and is controlled by the development of the nervous system and by increasingly complex interactions with the environment.
- By around 3 months, the infant shows awareness of changes in its environment; by 6 months, it is able to remember temporal order of stimuli. At 8 months, it is able to recognise words spoken in a story that it heard a while before.
- Over the course of development from 1 to 2 years the number of sequences of actions that the child can remember increases.
- Three factors seem to account for the child's ability to recall information better with age: the formation of memory-related structures, the development of language, and the development of metamemory – the realisation that using memory strategies will help the child to think and behave.
- According to Piaget, as children develop they acquire cognitive structures – mental representations or rules that are used for understanding and dealing with the world and for thinking about and solving problems. The two principal types of cognitive structure are schemata (mental representations or sets of rules that define a particular category of behaviour) and concepts (rules that describe properties of environmental events and their relations to other concepts).
- According to Piaget, two processes help a child to adapt to its environment: assimilation, the process by which new information is modified to fit existing schemata, and accommodation, the process by which old schemata are changed by new experiences.
- Piaget divided a child's cognitive development into four periods – a system that is widely, if not universally, accepted. These periods are determined by the child's experiences and the maturation of its nervous system.
- An infant's earliest cognitive abilities are closely tied to the external stimuli in the immediate environment; objects exist for the infant only when they are present (the sensorimotor period).
- Gradually, infants learn that objects exist even when hidden. The development of object permanence leads to the ability to represent things symbolically, which is a prerequisite for the use of language (the preoperational period).
- Next, the ability to perform logical analysis and to understand more complex cause-and-effect relations develops (the period of concrete operations).
- Around the age of 11 years, a child develops more adult-like cognitive abilities – abilities that may allow the child to solve difficult problems by means of abstract reasoning (the period of formal operations).

- Piaget's critics point out that, in some cases, his tests of cognitive development underestimate children's abilities. For example, if tested appropriately, it is evident that they conserve various properties earlier than he thought, and that their egocentrism is less pronounced than his tests indicated.
- Vygotsky's writings and the research they have stimulated have showed that the sociocultural context in which children are raised has a significant impact on their cognitive development.
- In particular, language appears to influence how children learn to think, solve problems, formulate plans, make decisions and contemplate ideas.
- Two information processing accounts of cognitive development have been developed recently. Case's M-space model argues that cognitive development proceeds according to expansion of mental space, or the brain's information processing capacity. M-space expands due to three causes: brain maturation, practice using schemata, and the integration of schemata for different objects and events.
- Fischer's skill model focuses on the relation between brain maturation and a child's ability to learn new cognitive skills specific to particular tasks, such as conservation. Maturation of the brain permits the child to acquire new cognitive skills necessary to solve increasingly complex tasks. Both of these models in essence reinterpret Piaget's theory in the language of information processing.
- Children rate people who speak their own 'national' language and in their own accent more positively than they do ethnically different groups.
- Autism is a childhood disorder in which the child shows abnormal patterns of social interaction (indifference and unwillingness to make eye or physical contact), delayed and/or idiosyncratic language, and stereotypical and repetitive behaviour.
- An influential theory of autism suggests that autistic children lack a theory of mind: they are unable to imagine the thoughts, actions or feelings of others.
- Others theories suggest that autistic children have an impairment of executive function or that they are unable to see wholes (instead of features); these theories are based on the finding that not all autistic children experience theory of mind difficulties.
- There seems to be a reduction in dopamine in the frontal regions of autistic children which may suggest an impairment in executive function and some studies have suggested that theory of mind tasks are mediated by the frontal lobe.
- Asperger's syndrome describes impaired interpersonal communication and social functioning but seems to differ from autism in also being characterised by individuals having a narrow and obsessional range of interests.
- Attention deficit hyperactivity disorder (ADHD) describes a failure of the child to inhibit its own antisocial and deviant behaviour; these children are impulsive, hyperactive and have a poor attention span.
- Evidence suggests that maternal depression is associated with poor social interaction with the child and poor sensitivity to the infant's behaviour; infants of depressed mothers are more expressive with caregivers than with the mother.
- Emotional distress may be predicted by decreased left frontal EEG activation and increased right frontal activation.

Social development in infancy and childhood

- Because babies are totally dependent on their parents, the development of attachment between parent and infant is crucial to the infant's survival.
- Some of the behaviours that babies possess innately are sucking, cuddling, looking, smiling and crying. These behaviours promote parental responses and are instrumental in satisfying physiological needs.
- Play is a social and cognitive behaviour – children interact with each other or with objects in the environment in an enjoyable and positive way and learn about these objects and the objects' relationship to the environment. At around 12–18 months, infants begin to play with objects symbolically – they pretend that the object is something else. At the age of 4 years, children use play to find out more about their environment and its social values as well as its customs and traditions.
- Ainsworth's Strange Situation theory allows a researcher to determine the nature of the attachment between infant and caregiver. By using this test, several investigators have identified some of the variables – some involving infants and some involving mothers – that influence attachment.
- Maternal sensitivity (as measured by the mother's ability to respond positively to the baby's signals) appears to be the best predictor of secure attachment.
- Interaction with peers is probably the most important factor in social development among children and adolescents. However, a caregiver's style of parenting can also have strong effects on the social development of children and adolescents.

Development of sex roles in childhood

- A person's sexual identity refers to one's private sense of being a male or female and consists primarily of the recognition of membership in a particular group of people: males or females.
- According to Kohlberg, the ability of children to identify with their sex is determined in large part by their ability to classify objects as being boys' objects or girls' objects.
- Gender schema theory argues that children construct a 'schema' – a mental representation – of male and female and pay special attention to features of their own sex. Children's perception of sex is matched with information about others' sex that the child has already processed and understood.
- The ability to identify others' and the child's own sex emerges between the ages of 1 and 3 years.
- Research has shown that both parents and peers tend to encourage children to behave in sex-appropriate ways, especially with regard to play activities and toys.

Moral development

- Piaget suggested that moral development consists of three principal stages: the premoral stage, characterised by little

understanding of rules or principles; the moral realism stage, characterised by egocentrism and blind adherence to rules; and the moral relativism stage, characterised by empathy and a realisation that behaviour is judged by the effects it has on others.

- Kohlberg suggested that moral development consists of three levels, with seven stages.
- During the preconventional level, morality is based on the personal consequences of an act.
- During the conventional level, morality is based on the need to be well regarded and on sharing a common interest in social order. During the postconventional level, which is achieved by only a few people, morality becomes an abstract, philosophical virtue.
- Critics of Piaget and Kohlberg point out that the stages of moral development are, to a certain degree, products of the measuring instruments. Although it does not appear, as Gilligan originally suggested, that females follow different moral rules from males, her work has sensitised researchers to the importance of including both sexes in studies of human development. Subtle changes in the way that moral dilemmas are posed can produce very different answers.
- Damon's model of redistributive justice argues that the child begins the process of moral development by making decisions about sharing based on egocentric consideration.
- Eventually, the child makes moral decisions based on concepts of fairness and merit.

Adolescence

- Adolescence is the transitional stage between childhood and adulthood. Puberty is initiated by the hypothalamus, which causes the pituitary gland to secrete hormones that stimulate maturation of the reproductive system.
- Puberty marks a significant transition, both physically and socially. Early maturity appears to be socially beneficial to boys, because early maturers are more likely to be perceived as leaders. The effects of early maturity in girls is mixed; although their advanced physical development may help them acquire some prestige, early-maturing girls are more likely to engage in norm-breaking behaviour.
- Whereas boys seem to look forward to the increasing strength, freedom and social status that puberty brings, girls regard the period as one in which they need to conform to society's view of women and as one that restricts freedom.
- The nature of friendship changes during adolescence. Girls seek out confidantes rather than playmates, and boys join groups that provide mutual support in their quests to assert their independence. Insecure friendships at this time can lead to increased psychopathology later in life.
- Bullying can be physical (actual bodily violence), verbal or psychological (such as social exclusion) and increases during the transition from primary to secondary school; contrary to received wisdom, the bully is not socially inept but very aware of the power of manipulation.
- Although adolescence brings conflicts between parents and children, these conflicts tend to be centred on relatively minor issues. Most adolescents hold the same values and attitudes concerning important issues as their parents do. Mood swings during adolescence can be dramatic but, on the whole, teenagers report that they are generally happy and self-confident.

Adulthood: beyond adolescence

- Up to the time of young adulthood, human development can reasonably be described as a series of stages: a regular sequence of changes that occurs in most members of our species. But development in adulthood is much more variable and few generalisations apply.
- Older people are more likely to exhibit gradual changes, especially in abilities that require flexibility and in learning new behaviours.
- Intellectual abilities that depend heavily on crystallised intelligence – an accumulated body of knowledge – are much less likely to decline than are those based on fluid intelligence – the capacity for abstract reasoning.
- Erikson and Levinson have both proposed that people encounter a series of crises that serve as turning points in development. Erikson's stages span the entire life cycle, from infancy to old age, whereas Levinson's stages concentrate on mid-life development.
- By the time people reach middle adulthood, they have achieved or have chosen to achieve, almost all of the major life decisions available to them such as marriage or cohabitation, having children, setting up a home or establishing a career. People during this period in life generally feel comfortable and contented, and a conventional way of life becomes the norm. People feel at their most confident, most in control and most productive. Depression declines during this period in life.
- There appears to be no scientific evidence to support the idea that people experience a mid-life crisis.
- Marriages seem to be happiest just after the birth of children and after the children have left home. It appears to be unhappiest just before the children leave home – possibly owing to the emotional and time demands that adolescents place on their parents.
- Men and women seem to respond to unemployment differently. Men appear to engage in activities that give structure to their lives such as claiming state benefits, attending benefit interviews or job hunting, whereas women will engage in more domestic chores.
- At late adulthood, the body undergoes a shift, especially in women. Alternation in the endocrine system leads to the pituitary gland and the hypothalamus releasing hormones that prevent the ovaries from controlling menstruation. This physical change is called the menopause and is sometimes accompanied by 'hot flushes', sweating during sleep, fatigue and irritability.
- Having a partner, good family and social support and high self-esteem can lead to better coping with chronic illness in old age.

- With old age and retirement, people feel less independent and more of a burden than they did when working. The dependence on others and on state benefits has led to this period in life being described as a second childhood.
- Kübler-Ross's interviews with terminally ill people have revealed that many of them seem to experience a five-stage process in facing the reality that they are going to die.

- Liben, L.S. (2009). *Current Directions in Developmental Psychology*. Boston: Allyn & Bacon.
- Schaffer, H.R. (2003) *Introducing Child Development*. Oxford: Blackwell.
- Schaffer, H.R. (2006) *Key Concepts in Developmental Psychology*. London: Sage.

There are dozens of books available on all aspects of development which makes choosing the best text to recommend a little troublesome. The titles above are recommended as good introductory texts to general development.

Infancy

- Berk, L.E. (2008) *Infants and Children: Prenatal through middle childhood*. (6th edn). Boston: Prentice Hall.
- Muir, D. and Slater, I. (2000) *Infant Development: The essential readings*. Oxford: Blackwell.
- Slater, A. and Lewis, M. (2002) *Introduction to Infant Development*. Oxford: Oxford University Press.
- Special section on 'face processing' in *Journal of Child Psychology and Psychiatry*, 2004, 45, 7.
- These books provide well-researched introductions to infant development, with the issue of JCCP providing some recent research on the development of face processing.

Cognitive development

- Oates, J. and Grayson, A. (2004) *Cognitive and Language Development in Children*. Oxford: Blackwell.
- This excellent book provides an in-depth and fairly up-to-date account of what we know about the development of thinking and remembering in childhood.

Social cognition

- Kraft, U. (2006) Detecting autism early. *Scientific American Mind*, 17, 5, 68–73.
- Treffert, D.A. and Christensen, D.D. (2005) Inside the mind of a savant. *Scientific American*, December, 108–13.
- Special issue of *Clinical Neuroscience Research on advances in autism research*, 2006, 6, 3–4, 111–24.
- Interesting items giving a good background to theory of mind (and autism).

Moral reasoning

- Gibbs, J.C. (2010) *Moral Development and Reality: Beyond the theories of Kohlberg and Hoffman*. (2nd edn). Boston: Allyn & Bacon.
- Langford, P.E. (1995) *Approaches to the Development of Moral Reasoning*. Hove: Psychology Press.
- These texts will give you more detailed information about the child's moral reasoning ability.

Piaget and Vygotsky

- Smith, L. (1996) *Critical Readings on Piaget*. London: Routledge.
- Smith, L., Dockrell, J. and Tomlinson, P. (1997) *Piaget, Vygotsky and Beyond*. London: Routledge.
- Piaget and Vygotsky are very much alive in developmental thinking and these two books critically assess the contributions of these thinkers to developmental psychology.

Social development

- Brody, G.H. (2004) Siblings' direct and indirect contributions to child development. *Current Directions in Psychological Science*, 13, 1, 124–6.
- Schafer, M. (2005) Stopping the bullies. *Scientific American Mind*, 16, 2, 76–81.
- Smith, P.K. (2004) *Bullying in Schools*. Cambridge: Cambridge University Press.
- The child's relationships with others are examined in these books and papers.

Adolescence and adulthood

- Adams, G. and Berzonsky, M. (2005) *The Blackwell Handbook of Adolescence*. Oxford: Blackwell.
- Bee, H.L. and Boyd, D. (2005) *Lifespan Development* (4th edn). New York: Addison Wesley Longman.
- Berk, L.E. (2003) *Development Through the Lifespan* (3rd edn). Boston: Allyn & Bacon.
- Blakemore, S.-J. and Choudhury, S. (2006) Development of the adolescent brain: Implications for executive function and social cognition. *Journal of Child Psychology and Psychiatry*, 47, 3/4, 296–312.
- Burke, D.M. and Shafto, M.A. (2004) Aging and language production. *Current Directions in Psychological Science*, 13, 1, 21–4.
- Lakeman, M.E. (2004) Development in midlife. *Annual Review of Psychology*, 55, 305–32.
- Papalia, D.E., Sterns, H., Feldman, R.D. and Camp, C. (2006) *Adult Development and Aging*. Maidenhead: McGraw-Hill.
- Reyna, V.F. and Farley, F. (2007) Is the teen brain too rational? *Scientific American Mind*, 17, 6, 58–65.
- Willis, S.L. and Martin, M. (2005) *Middle Adulthood*. London: Sage.
- Very readable accounts of the main phases of development after childhood.

Ageing

- Burke, D.M. and Shafto, M.A. (2004) Aging and language production. *Current Directions in Psychological Science*, 13, 1, 21–4.
- Charles, S.T. (2009) *Current Directions in Adulthood and Ageing*. Boston: Allyn & Bacon.
- Craik, F.I.M. and Salthouse, T.A. (2000) *The Handbook of Aging and Cognition*. London: Lawrence Erlbaum Associates.
- Morris, R.G. (2004) Neuropsychology of older adults. In L.H. Goldstein and J.E. McNeil (eds) *Clinical Neuropsychology: A practical guide to assessment and management for clinicians*. Chichester: John Wiley & Sons.
- Naveh-Benjamin, M., Moscovitch, M. and Roediger, H.L. (2002) *Perspectives on Human Memory and Cognitive Aging*. Hove: Psychology Press.
- Rabbitt, P. (2005) Cognitive gerontology: Cognitive change in old age. *Special issue of Quarterly Journal of Experimental Psychology Section A*. Hove: Psychology Press.
- Sachdev, P.S. (2003) *The Ageing Brain*. Hove: Psychology Press.
- Special issue of *The American Journal of Geriatric Psychiatry* on 'Successful ageing', 2006, 14, 1.
- A good selection of books, chapters and articles on ageing

Motivation and emotion

How happiness can be catching

Sarah Boseley, Health editor

Happiness is catching, new research has confirmed, and depends on how cheerful about life your friends feel.

Happiness is spread through social networks and exists in clusters of close friends and neighbours, according to a study published in the *British Medical Journal*. Being around happy people at work does not help, the research found – happiness is most contagious in your street. Living next door to somebody who becomes happy can increase your own chances of happiness by 34%.

WHAT YOU SHOULD BE ABLE TO DO AFTER READING CHAPTER 13

- Define motivation.
- Describe and understand the processes involved in starting and stopping a meal.
- Outline the basic psychology and physiology of thirst.
- Describe the major eating disorders, anorexia nervosa, bulimia nervosa and obesity, and outline their possible causes.
- Describe and understand the process of sexual development and orientation.
- Evaluate the theories explaining aggression and describe the factors which lead to aggressive behaviour.
- Describe the ways in which psychologists have defined and studied emotion.
- Evaluate the 'fundamental emotion' debate.
- Outline the major theories of emotion.
- Describe current understanding of the biological basis of emotion.

QUESTIONS TO THINK ABOUT

- What motivates us to eat, drink, be aggressive and have sex?
- What influences sexual preference and orientation?
- What causes eating disorders?
- What strategies can an overweight person adopt to lose weight and, more importantly, maintain this loss?
- How does aggressive behaviour manifest itself and what theories could account for it?
- How would you define emotion?
- Are there basic emotions? If so, how many and what distinguishes one from the other?
- What role do physiology and the brain play in the expression and recognition of emotions of different types?

Motivation

Why do people behave differently? Why do some individuals eat particular foods whereas others eat different foods? Why do we eat in the first place? What makes us attracted to different sexual partners, or any sexual partner? Why do we become aggressive?

Most of these questions can probably be answered by motivation. When commonly used, **motivation** refers to a driving force that moves us to a particular action. More formally, motivation is a general term for a group of phenomena that affect the nature of an individual's behaviour, the strength of the behaviour and the persistence of the behaviour.

Motivation includes two types of phenomenon. First, stimuli that were previously associated with pleasant or unpleasant events motivate approach or avoidance behaviours. For example, if something reminds you of an interesting person you met recently, you may try to meet that person again by consulting your mobile and sending a message. Secondly, being deprived of a particular reinforcer increases an organism's preference for a particular behaviour. Besides obvious reinforcers such as food or water, this category includes more subtle ones. For example, after spending a lot of time performing routine tasks, we become motivated to go for a walk or meet with friends.

Motivation affects all categories of behaviour. This chapter considers three important categories of motivated behaviour: eating, sexual behaviour and aggression. Other types of motivation such as intention and being influenced by real or imaginary others will be discussed in Chapters 15 and 16.

Biological needs

Biological needs can be potent motivators. To survive, we need air, food, water, various vitamins and minerals, and protection from extremes in temperature. Complex organisms possess physiological mechanisms that detect deficits or imbalances associated with these needs and **regulatory behaviours** that bring physiological conditions back to normal. Examples of regulatory behaviours include eating, drinking, hunting, shivering, building a fire and putting on a warm coat. This process of detection and correction, which maintains physiological systems at their optimum value, is called **homeostasis** ('stable state'). Deficits or imbalances motivate us because they cause us to perform the appropriate regulatory behaviours.

A regulatory system has four essential features: the **system variable** (the characteristic to be regulated), a **set point** (the optimum value of the system variable), a **detector** that monitors the value of the system variable,

and a **correctional mechanism** that restores the system variable to the set point. A simple example of such a regulatory system is a room where temperature is regulated by a thermostatically controlled heater. The system variable is the air temperature of the room, and the detector for this variable is a thermostat. The thermostat can be adjusted so that contacts of a switch will close when the temperature falls below a pre-set value (the set point). Closure of the contacts turns on the correctional mechanism – the coils of the heater. You can see this process illustrated in Figure 13.1.

If the room cools below the set point, the thermostat turns the heater on, which warms the room. The rise in room temperature causes the thermostat to turn the heater off. Because the activity of the correctional mechanism (heat production) feeds back to the thermostat and causes it to turn the heater off, this process is called **negative feedback**. Negative feedback is an essential characteristic of all regulatory systems.

The **drive reduction hypothesis** was the earliest attempt to explain the nature of motivation and reinforcement. This theory stated that biological needs, caused by deprivation of the necessities of life, are unpleasant. The physiological changes associated with, say, going without food for several hours produce an unpleasant state called hunger. Hunger serves as a drive, energising an organism's behaviour. The organism then engages in behaviours that in the past have obtained food. The act of eating reduces hunger, and this drive reduction is reinforcing, as seen in Figure 13.2.

Not all drives are based on homeostasis, on biological needs like the ones for food and water. The most obvious example is the drive associated with sexual behaviour. An individual can survive without sexual behaviour; but the sex drive is certainly motivating, and sexual contact is certainly reinforcing. Similarly, most organisms placed in a featureless environment will soon become motivated to seek something new; they will work at a task that gives them a view of the world outside.

The drive reduction hypothesis of reinforcement has fallen out of favour for two primary reasons. The first is that drive is almost always impossible to measure. For example, suppose you obtain pleasure from watching a set of colour slides taken by a friend while on holiday. According to the drive reduction hypothesis, your 'exploratory drive' or 'curiosity drive' is high, and looking at holiday slides reduces it, providing reinforcement. Or consider a woman who enjoys listening to music. What drive induces her to turn on her iPod? What drive is reduced by this activity? There is no way to measure 'drive' in either of these examples and confirm that it actually exists; thus, the hypothesis cannot be tested experimentally.

The second problem is that if we examine our own behaviour we find that most events we experience as rein-

Figure 13.1 An example of a regulatory system.

forcing are also exciting, or drive-increasing. The reason a roller-coaster ride is fun is certainly not because it reduces drive. The same is true for skiing, surfing or viewing a horror film. Likewise, an interesting, reinforcing conversation is one that is exciting, not one that puts you to sleep. And people who engage in prolonged foreplay and sexual intercourse do not view these activities as unpleasant because they are accompanied by such a high level of drive. In general, the experiences we really want to repeat (that is, the ones we find reinforcing) are those that increase, rather than decrease, our level of arousal.

Physiology of reinforcement

To understand the nature of reinforcement we must understand something about its physiological basis. Olds and Milner (1954) discovered quite by accident that electrical stimulation of parts of the brain can reinforce an animal's behaviour. For example, rats will repeatedly press a lever when the brain is electrically stimulated.

The neural circuits stimulated by this electricity are also responsible for the motivating effects of natural reinforcers such as food, water or sexual contact, and of

drugs such as heroin, alcohol and cocaine. Almost all investigators believe that the electrical stimulation of the brain is reinforcing because it activates the same system that is activated by natural reinforcers and by drugs that people commonly abuse. The normal function of this system is to strengthen the connections between the neurons that detect the discriminative stimulus (such as the sight of a lever) and the neurons that produce the operant response (such as a lever press). The electrical brain stimulation activates this system directly.

Researchers have discovered that an essential component of the reinforcement system consists of neurons that release dopamine as their transmitter substance. Thus, all reinforcing stimuli appear to trigger the release of dopamine in the brain.

Optimum-level theory

Although events that increase our level of arousal are often reinforcing, there are times when a person wants nothing more than some peace and quiet. In this case, avoidance of exciting stimuli motivates our behaviour. As you saw in Chapter 7, the removal (or avoidance) of an aversive stimulus produces negative reinforcement. In an attempt to find a common explanation for both positive and negative reinforcement, some psychologists have proposed the **optimum-level hypothesis** of reinforcement and punishment: when an individual's arousal level is too high, less stimulation is reinforcing; when it is too low, more stimulation is desired (Hebb, 1955; Berlyne, 1966). Berlyne hypothesised two forms of exploration: diversive exploration is a response to understimulation (boredom) that increases the diversity of the stimuli the organism tries to come in contact with; specific exploration is a response to overstimulation (usually because of a specific need, such as lack of food or water) that leads to the needed item, thereby decreasing the organism's drive level.

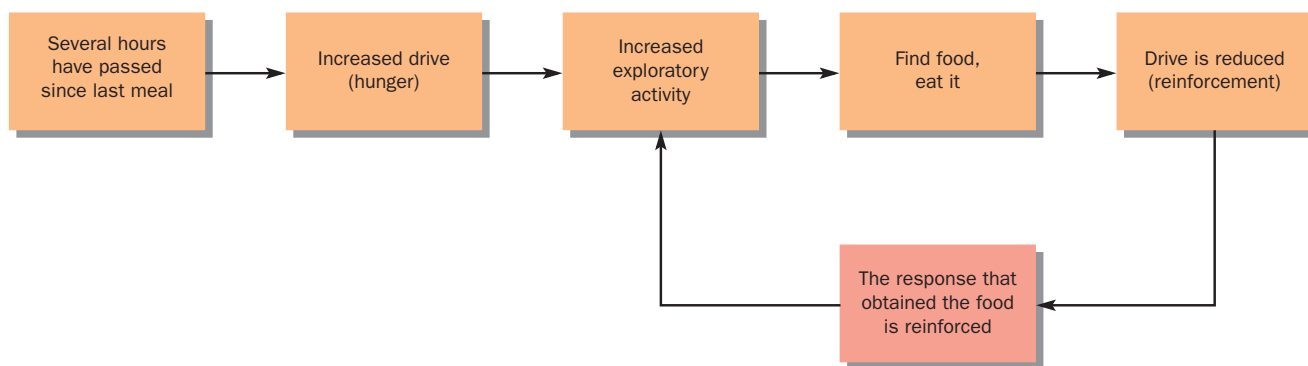

Figure 13.2 The drive reduction hypothesis of motivation and reinforcement.

The hypothesis that organisms seek an optimum level of arousal is certainly plausible. Any kind of activity, even the most interesting and exciting one, eventually produces satiety; something that was once reinforcing becomes bothersome. Presumably, participation in an exciting behaviour gradually raises an organism's arousal above its optimum level. However, the logical problem that plagues the drive reduction hypothesis also applies to the optimum-level hypothesis. Because we cannot measure an organism's drive or arousal, we cannot say what its optimum level should be. Thus, the optimum-level hypothesis remains without much empirical support.

Effects of intermittent reinforcement

You saw in Chapter 7 that when an organism's behaviour is no longer reinforced, the behaviour eventually ceases, or extinguishes. If the behaviour was previously reinforced every time it occurred, extinction is very rapid. However, if it was previously reinforced only intermittently, the behaviour persists for a long time. Intermittent reinforcement leads to **perseverance**, even when the behaviour is no longer reinforced.

Many human behaviours are reinforced on intermittent schedules that require the performance of long sequences of behaviours over long intervals of time. A person's previous experience with various schedules of reinforcement probably affects how long and how hard the person will work between occasions of reinforcement. If all attempts at a particular endeavour are reinforced (or if none are), the person is unlikely to pursue a long and difficult project that includes the endeavour. If we knew more about a person's history with various schedules of reinforcement, we would probably know more about their ability to persevere when the going gets difficult (that is, when reinforcements become variable).

The role of conditioned reinforcement

Another phenomenon that affects the tendency to persevere is conditioned reinforcement. When stimuli are associated with reinforcers, they eventually acquire reinforcing properties of their own. For example, the sound of the food dispenser reinforces the behaviour of a rat being trained to press a lever.

Motivation is not merely a matter of wanting to do well and to work hard. It also involves the ability to be reinforced by the immediate products of the work being done. If a person has regularly been exposed to particular stimuli in association with reinforcers, that person's behaviour can be reinforced by those stimuli. In addition, if the person has learned how to recognise self-produced stimuli as conditioned reinforcers, the performance of the behaviours that produce them will be 'self-reinforcing'.

Failure to persist: learned helplessness

A large body of evidence suggests that organisms can learn that they are powerless to affect their own destinies. Two social psychologists, Maier and Seligman (1976), reported a series of experiments demonstrating that animals can learn that their own behaviour has no effect on an environmental event. This result is exactly the opposite of what has been assumed to be the basis of learning. All the examples of learning and conditioning cited so far have been instances in which one event predicts the occurrence of another. **Learned helplessness** involves learning that an aversive event cannot be avoided or escaped.

Overmeier and Seligman (1967) conducted the basic experiment. They placed a dog in an apparatus in which it received electrical shocks that could not be avoided; nothing the animal did would prevent the shocks. Next, they placed the dog in another apparatus in which the animal received a series of trials in which a warning stimulus was followed by an electrical shock. In this case the animal could avoid the shocks simply by stepping over a small barrier to the other side of the apparatus. Dogs in the control group learned to step over the barrier and avoid the shock, but dogs that had previously received inescapable shocks in the other apparatus failed to learn. They just squatted in the corner and took the shock as if they had learned that it made no difference what they did. They had learned to be helpless.

Seligman (1975) has suggested that the phenomenon of learned helplessness has important implications for behaviour. When people have experiences that lead to learned helplessness, they become depressed and their motivational level decreases. The change in motivation occurs because the helplessness training lowers their expectation that trying to perform a task will bring success. Seligman also suggested that learned helplessness has the characteristics of a personality trait; that is, people who have had major experiences with insoluble tasks will not try hard to succeed in other types of task, including ones they could otherwise have solved.

Seligman's theory of learned helplessness has been challenged by other investigators, who have explained the phenomenon in other ways. The issue is whether learning to be helpless in a particular situation generalises only to similar situations or to a wide variety of them. For example, McReynolds (1980) observed that when people experience a situation in which reinforcements are not contingent on their responding, their responding extinguishes. If the situation then changes to one in which responding will be reinforced, the people will continue not to respond unless they perceive that the schedule of reinforcement has changed. The more similar the second situation is to the first, the more likely it is that the person will act helpless. This explanation describes the phenomenon of learned helplessness as a failure to discriminate between the condi-

tion under which responding is reinforced and the condition under which it is not. Further research will have to determine whether learned helplessness is, as Seligman asserts, a stable personality trait or whether it can be explained by the principles of instrumental conditioning. We will return to learned helplessness in the depression section of Chapter 18 (see p. 821).

Ingestion: drinking and eating

Much of what an animal learns to do is motivated by the constant struggle to obtain food and drink. The need to eat certainly shaped the evolutionary development of our own species. Simply put, motivation to eat is aroused when there is a deficit in the body's supply of stored nutrients, and it is satisfied by a meal that replenishes this supply. A person who exercises vigorously uses up the stored nutrients more rapidly, and loses water, and consequently must eat more food and ingest more fluid. Thus, the amount of food and drink a person normally ingests is regulated by physiological need. But what, exactly, causes a person to start eating and drinking, and what stops these behaviours? These are simple questions, yet the answers are complex. There is no single physiological measure that can tell us reliably whether a person should be hungry or thirsty; hunger and thirst are determined by a variety of conditions. So, instead of asking 'What is the cause of hunger or thirst?' we should ask, 'What are the causes?'

Thirst

A popular theory at the turn of the twentieth century argued that thirst was caused by a dry mouth and that it was this dryness that regulated how much water we ingested. When the salivary glands reduced the amount of fluid they secreted, this made the mouth dry and was the cue for drinking. While plausible, the theory was not supported by evidence because even if water was made available to the mouth but was prevented from reaching the stomach, drinking would continue: the mouth was being kept wet, not dry, and yet drinking continued because the fluid did not reach the stomach. Why?

Osmometric thirst

A later theory suggested that thirst was caused by dehydration within cells (Gilman, 1937). The fluid in cells is called intracellular fluid and contains a little sodium but large amounts of potassium and other metabolites. The other source of fluid in the body is extracellular fluid and this is found in two places. Interstitial fluid surrounds the cell body and is salty; blood plasma is found in the capillaries, arteries and veins and allows living cells and blood to be

suspended within it. Extracellular fluid comprises about 20 per cent of the body's weight; intracellular fluid comprises about 40 per cent of body weight. Gilman administered solutions of sodium chloride to animals. The membranes surrounding cells are not very permeable to sodium and so water is drawn from the intracellular fluid to the extracellular fluid by a process called osmosis, whereby water moves through a semi-permeable membrane from a region where there is a low concentration of solutes to one where there is a high concentration. This reduces the concentration of sodium available across the membrane and the movement of water by osmosis dehydrates and shrinks the body's cells. This is what Gilman found and the type of thirst is called **osmometric thirst**. Because the organism needs to be aware of this thirst, there must be cells in the body which serve to inform the central nervous system that dehydration is occurring. These cells are called osmoreceptors and are located in the brain. When salt solutions are injected into the brain, drinking increases, but if sodium chloride is injected into the general blood supply, no such increase is observed (Wood *et al.*, 1977).

The precise locus of the osmoreceptors seems to be a part of the brain called the lateral preoptic area. If even small lesions are made to this region, the typical increase in drinking seen in response to dehydration is reduced (Mason, 1980). When neurons are exposed to urea, salt and sucrose – neurons are impermeable to salt and sucrose but not to urea – those neurons stimulated by salt and sucrose and which caused increased drinking were located in the lateral preoptic area (Peck and Novin, 1971).

Volumetric thirst

Osmometric thirst is caused by dehydration within cells. There is another type of thirst that results from dehydration outside cells, that is, a reduction in the level of blood plasma. This is called **volumetric thirst** because the thirst is provoked by a reduction in the volume of blood plasma. One obvious way in which volumetric thirst can occur is through bleeding – a loss of blood leads to a great loss of extracellular fluid with all the substances that the fluid contains. People who suffer from haemophilia experience thirst during a bleeding episode and this is alleviated by an infusion of blood.

Volumetric thirst can also result from low levels of salt in the diet. The loss of extracellular fluid produces the movement of water from the extracellular fluid and into cell bodies, by the process of osmosis described earlier. This process leads to drinking.

Given that blood plasma is lost as a result of extracellular/volumetric thirst, you might hypothesise that receptors detecting this loss are located in the vascular or circulatory system. One important structure in this system is the kidney. If blood flow to the kidney is inhibited, the total volume of blood in the body does not change, but there is

an increase in thirst and drinking (often excessive). The kidney responds to this inhibition (in effect, a decrease in blood pressure) by releasing an enzyme, renin, which produces two hormones called angiotensin I and II. Rolls *et al.* (1972) found that when animals were injected with angiotensin II, they strove to complete a task which gave them water. The animals even gave priority to searching for water and stopped eating, even when they had previously been deprived of food. The kidney's secretions, therefore, appear to play an important part in regulating the body's awareness of volumetric thirst.

One further way in which the body experiences volumetric thirst is via baroreceptors. Baroreceptors are receptors on the walls of blood vessels which detect changes in the blood pressure of the cardiovascular system. If blood pressure drops, these baroreceptors can detect this drop and initiate volumetric thirst via the brain.

What starts a meal?

Cultural and social factors

Like the ingestion of fluid, the ingestion of food often follows cultural or social conventions, rather than physiological demands. Most of us do not exhibit a need for alcohol, but we might drink if we are at a party, a dinner engagement or have friends around. Most of us eat three times a day. When the time for a meal comes, we get hungry and eat, consuming a relatively constant amount of food. The regular pattern of eating is not determined solely by biological need; it is at least partially determined by habit. If we miss a meal, we notice that our hunger does not continue to grow indefinitely. Instead, it subsides some time after the meal would normally have been eaten only to grow again just before the scheduled time of the next one. Hunger, then, can wax and wane according to a learned schedule.

Besides learning when to eat, we learn what to eat. Most of us would refuse to eat fresh clotted seal blood, but many Inuit consider it a delicacy. What we accept as food depends on our culture. Our tastes are also shaped by habits acquired early in life.

Physiological factors

Cultural and social factors influence when and how much we eat. But the 'real' reason for eating must be related to the fact that the body needs nourishment: if all other factors were eliminated, eating would be determined by some internal physiological state. What are the internal factors that cause us to eat?

Many years ago, Cannon and Washburn (1912) suggested that hunger resulted from an empty stomach. The walls of an empty stomach rubbed against each other, producing what we commonly identify as hunger pangs.

Cannon also suggested that thirst was produced by a dry mouth, because a loss of body fluid resulted in a decreased flow of saliva. Some sceptics called Cannon's explanation of hunger and thirst the 'spit and rumble theory'. However, removal of the stomach does not abolish hunger pangs. Inglefinger (1944) interviewed patients whose stomachs had been removed because of cancer or large ulcers; their oesophagi had been attached directly to their small intestines. Because they had no stomachs to catch and hold food, they had to eat small, frequent meals. Despite their lack of a stomach, these people reported the same feelings of hunger and satiety that they had experienced before the operation.

A more likely cause of hunger is depletion of the body's store of nutrients. The primary fuels for the cells of our body are glucose (a simple sugar) and fatty acids (chemicals produced when fat is broken down). If our digestive system contains food, these nutrients are absorbed into the blood and nourish our cells. But the digestive tract is sometimes empty; in fact, most of us wake up in the morning in that condition. So there has to be a reservoir that stores nutrients to keep the cells of the body nourished when the gut is empty. Indeed, there are two reservoirs, one short term and the other long-term. The short term reservoir stores carbohydrates, and the long-term reservoir stores fats.

The short term reservoir is located in the cells of the muscles and the liver, and it is filled with a carbohydrate – a form of animal starch – called **glycogen**. When glucose is received from a meal, some of it is used for fuel and some is converted into glycogen and stored in the liver. Our long-term reservoir consists of adipose tissue (fat tissue), which is found beneath the skin and in various locations in the abdomen. Adipose tissue consists of cells capable of absorbing nutrients from the blood, converting them to triglycerides (fats), and storing them. The cells can expand in size enormously; in fact, the primary physical difference between an obese person and a person of normal weight is the size of their fat cells, which is determined by the amount of triglycerides that these cells contain.

The long-term fat reservoir is obviously what keeps us alive during a prolonged fast. Once the level of glycogen in our short term carbohydrate reservoir gets low, fat cells start breaking down fats and releasing fatty acids and a carbohydrate called glycerol. The brain lives primarily on glucose, and the rest of the body lives on fatty acids. Glycerol is converted into glucose, so the brain continues to be nourished even after the short term reservoir is depleted, as Figure 13.3 shows.

Because glucose is such an important fuel, Mayer (1955) proposed the glucostatic hypothesis of hunger. According to the **glucostatic hypothesis**, hunger occurs when the level of glucose in the blood becomes low, presumably after the glycogen in the body's short-term reservoir has

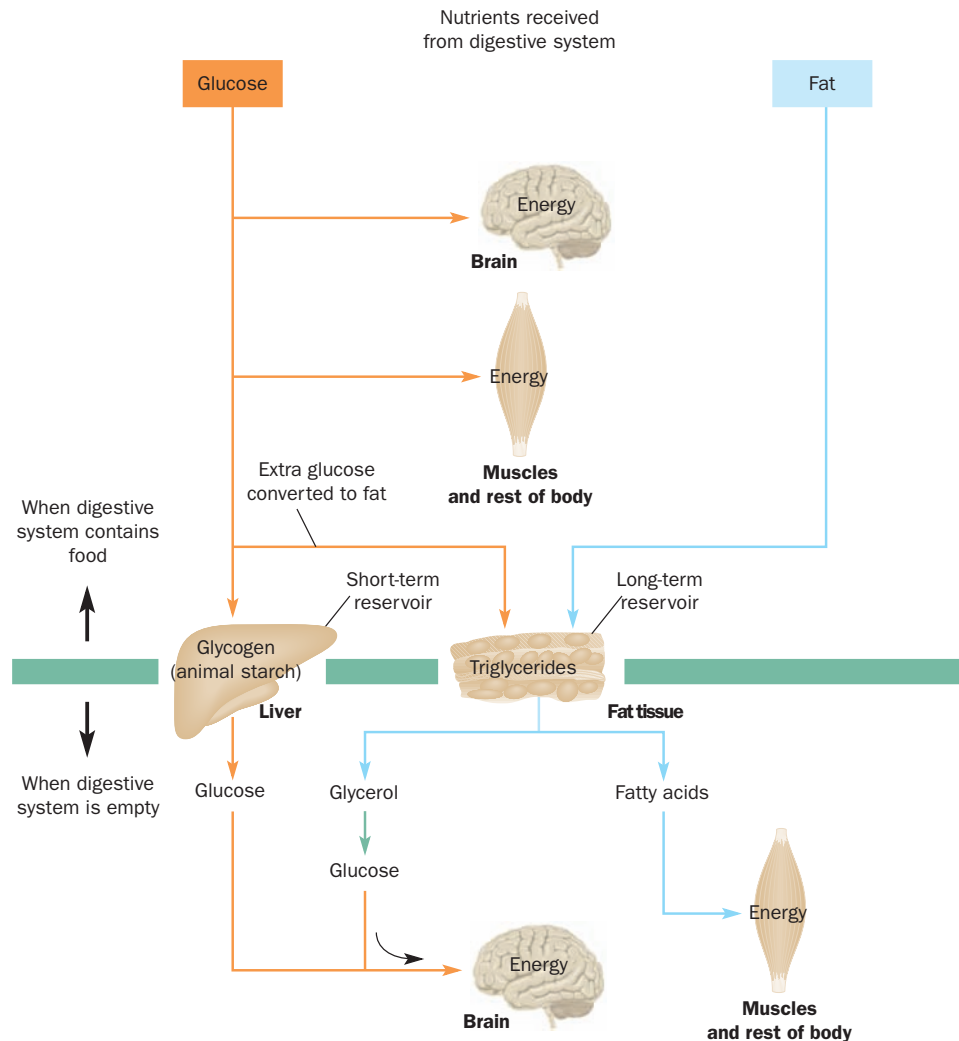

Figure 13.3 Overview of food metabolism. When the digestive system contains food, glucose nourishes the brain and muscles. Extra glucose is stored in the liver and converted to fat. When the digestive system is empty, glucose obtained from glycogen stored in the liver nourishes the brain until this short-term reservoir is used up. Fatty acids from fat tissue nourish the muscles, and glycerol is converted to glucose to nourish the brain.

been used up. Mayer theorised that this decrease in blood sugar is detected by glucose-sensitive neurons in the brain called **glucostats** (the term ‘glucostat’ is analogous to thermostat, but it refers to the measurement of glucose rather than temperature). Mayer suggested that these detectors activate neural circuits that make a person hungry, thus stimulating the correctional mechanism, eating.

Subsequent evidence suggests that there are two different types of nutrient detectors, which measure the blood level of the two primary nutrients, glucose and fatty acids (Friedman *et al.*, 1986, 1991). The glucose detectors appear to be located in the liver, but the location of the fatty acid detectors is not yet known (Ritter and Taylor, 1989; Ritter

et al., 1992). Both sets of detectors send information to the brain, and activity of neural circuits there stimulates hunger.

What stops a meal?

Nutrient detectors sense the fact that the body’s supplies of stored energy are getting low by measuring glucose and fatty acids in the blood. Through their connection with the brain these detectors are able to stimulate hunger. But what ends hunger? What brings a meal to its finish? Consider what happens when you eat. Your stomach fills with food, and the digestive process begins. However, about an hour passes before significant amounts

of nutrients are absorbed from the intestines into the bloodstream. Therefore, the body's supply of fuel is not replenished until quite some time after the meal begins. If you were to continue to eat until the nutrients actually entered the bloodstream, your stomach would burst. Therefore, some other detectors must be responsible for stopping the meal.

Although evidence suggests that the primary cause of hunger is not an empty stomach, the primary cause of satiety (that is, the cessation of hunger caused by eating) seems to be a full stomach. Many studies have shown that satiety is caused by entry of a sufficient quantity of nourishing food into the stomach. Therefore, the stomach must contain detectors that sense the presence of food. We have known for a long time that hunger can be abolished by injecting food into an animal's stomach by means of a flexible tube. Even though the animal does not get to taste and smell the food, it will not subsequently eat. Davis and Campbell (1973) showed how precisely the stomach can measure its contents. The investigators allowed hungry rats to eat their fill and then removed some food from their stomachs. When they let the rats eat again, they ate almost exactly as much as had been taken out.

The stomach appears to contain detectors that inform the brain about the chemical nature of its contents as well as the quantity. The ability to detect the chemical nature of food that has entered the stomach is important, because eating should stop relatively soon if the food is very nutritious but should continue for a longer time if it is not. Deutsch *et al.* (1978) injected either milk or a dilute salt solution into hungry rats' stomachs and 30 minutes later allowed them to eat. The rats that had received injections of milk ate less than the ones that had received the salt solution. Because the rats could not taste what was put in their stomachs, the effect had to come from detectors there. The nature of these detectors is not known, but they must respond to some chemicals present in food. You can try an experiment of your own: drink two glasses of water when you are very hungry and see whether they satisfy your appetite.

Detectors that measure the amount and nutritive value of food in the stomach contribute only to short-term control of eating – the termination of a single meal. Long-term factors also control food intake. For example, when people eat especially nutritious food, they soon learn to eat less. When they begin to exercise more, and hence burn up their store of nutrients faster, they soon start eating more.

There may also be characteristics of food that may make us eat more or less of it. Some psychologists have argued that the variety and sensory properties of food can reduce or increase our intake; these reductions are associated with a reduction in ratings of the food's pleasantness. The section below reviews some of this evidence.

Sensory-specific satiety

Have you ever experienced the feeling when, after eating a big savoury meal, you could still manage to eat dessert? Or that you have had enough of eating peanuts but could quite happily contemplate eating a packet of crisps?

These experiences reflect **sensory-specific satiety (SSS)** – the decrease in the pleasantness and consumption of specific food after eating it to satiety. The satiety is sensory-specific because individuals may become satiated eating foods of specific tastes, shapes, sizes and textures but not foods of different taste, shape, size and texture (Rolls *et al.*, 1986). This phenomenon explains why, if we eat a meal composed of a variety of foods, we eat more because there is greater sensory stimulation available from a varied meal (we would consume a greater quantity of a meal consisting of a bowl of soup, sausages, egg and bacon, and chocolate mousse than we would a meal comprising solely of sausages). SSS also has survival value because if we become bored with eating one food but not another, this increases the likelihood of a variety of foods being eaten.

If a food is eaten to satiety, a second course of the same food will result in a reduction in intake of around 50 per cent (Rolls *et al.*, 1981). In Rolls's early experiment, all foods, with the exception of roast beef, produced sensory-specific satiety. In one study, participants ate either a four-course meal of sausages, bread and butter, chocolate dessert and bananas or ate only one of these foods to satiety. The researchers found that consumption was 60 per cent higher when foods were presented together than when presented separately (Rolls *et al.*, 1986). At a post-satiety tasting session, those foods presented alone were also rated as less pleasant than those eaten as part of a four-course meal (Rolls *et al.*, 1984). Even colour and shape influence the amount of food eaten. When a variety of pasta shapes is presented for consumption, more is eaten than when only one pasta shape is presented; people also eat more food if it is made up of different colours than one colour (Rolls *et al.*, 1982). The effect of varying the shape and variety of food can be seen in Figures 13.4(a), (b).

SSS is also seen in the sense of smell. In an experiment where participants were asked to rate the pleasantness of the odours of banana, satsuma, fish paste, chicken and rose water before and after consuming bananas and chicken to satiety, the pleasantness of chicken and banana odours (but not other foods) significantly declined after satiety (Rolls and Rolls, 1997).

Why should this be? SSS allows us to enjoy and consume a greater variety of food and, therefore, represents a mechanism that enables us to consume a variety of nutrients. There is also evidence that certain regions of the brain may be responsible for our feeling of satiety. The hypothalamus, as you have seen, is important to feeding.

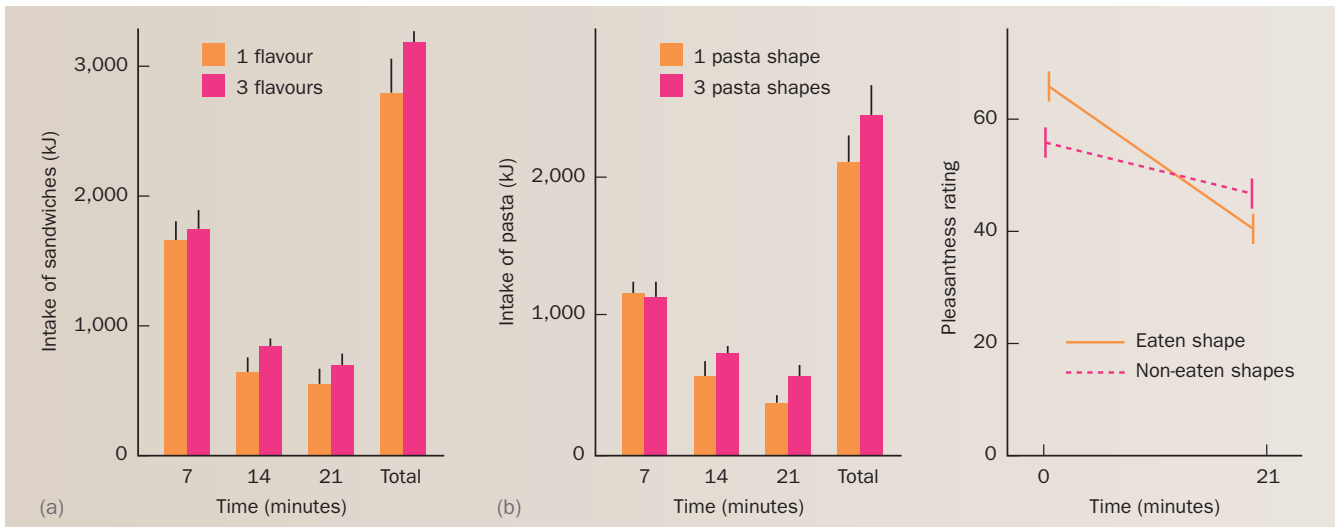

Figure 13.4 (a) The amount eaten of a one-flavoured and a three-flavoured meal. **(b)** The effect of varying the type of pasta shape on food intake and pleasantness ratings of the taste of the shapes. In both these examples, the sensory properties of the food influence intake and ratings of pleasantness.

Source: Reprinted from Rolls, B.J., Rolls E.T. and Rowe E.A., How sensory properties of foods affect human feeding behaviour, *Psychology and Behaviour*, 1982, 29, 409–417. © 1982, with permission from Elsevier Science; and Rolls and Rolls (1997).

Neurons in this region in monkeys stop responding to the sight and taste of food when the food has been eaten to satiety (Rolls *et al.*, 1986). Small *et al.* (2001b) and others, however, suggest that a key region involved in satiety is the orbitofrontal cortex (OFC).

An fMRI study in which the odour of banana was presented before and after people had eaten bananas to satiety found that activation in the OFC decreased when people sniffed the odour of banana after satiety (O'Doherty *et al.*, 2000). No such decrease was observed when people sniffed the odour of vanilla, suggesting that the OFC response was a specific response to a specific property of the food eaten to satiety. One role for the prefrontal cortex in this process may be that of responding to reward. When we have eaten to satiety, the OFC will not respond because the brain does not feel rewarded. Rolls *et al.* have reported that OFC taste cells in monkeys reduce their firing to food stimuli when these monkeys have eaten to satiety.

In another study, volunteers ate chocolate to satiety as a PET scanner measured brain activation (Small *et al.*, 2001a). Participants first ate a chunk of chocolate, rated it for pleasantness and were then asked if they would like another. If they did, they were given another piece and asked to rate its pleasantness again. This continued until the participants felt that they had consumed enough chocolate.

The researchers found that when participants ate chocolate they found pleasant, there was increased blood flow in a collection of regions including areas beneath the corpus callosum, a part of the OFC called the caudomedial OFC, the insula, striatum and midbrain. When participants were sated, blood flow increased in the parahippocampal gyrus and a different part of the OFC (the caudolateral OFC)

than was activated during initial eating. What could this activation represent?

Small *et al.* suggest that the activity with chocolate reflects two different systems which mediate two aspects of behaviour: approach and withdrawal. That is, when the brain responds to reward, it activates the insula and part of the OFC. This reflects an 'approach' behaviour because we tend to approach things we like and this generates a positive emotion. When the brain responds to non-reward or stimuli that do not provide an opportunity for reward (such as food we no longer want to eat) brain regions involved in 'withdrawal' are recruited. These are involved in withdrawal because we tend to withdraw from stimuli we do not like and we find such stimuli unpleasant (or at the very least, do not find them pleasant).

This is an interesting hypothesis because it is in keeping with a model of emotion which argues that the frontal cortex is the region that becomes active during the experience of positive and negative emotion. We will describe and evaluate this model in the emotion section of the chapter (see p. 589).

The region is also activated while looking at food-related stimuli after fasting (Porubsky *et al.*, 2006). Twelve lean participants were asked look at food- and non-food-related stimuli after five hours of fasting. Functional MRI measured brain activation as they did this. The left side of the OFC was significantly more active when participants viewed the food slides (the insula on both sides of the brain was also more active). As self-reported appetite increased, so did activation in the insula bilaterally, the left operculum and the right putamen. The data suggest that all of these regions are involved in the motivation to eat.

Obesity

The mechanisms that control eating generally do an efficient job. However, some people do not control their eating habits and become too fat or too thin. Does what we have learned about the normal regulation of food intake help us to understand these disorders?

Obesity is extremely difficult to treat, but attempts have been made to design intervention programmes for clinically obese people. The evidence for the success of these treatments, as well as a description of obesity and its consequences, can be found in the Psychology in Action section.

Psychology in action – The problem of obesity and its treatment

Obesity: some figures

In Western countries, obesity is defined as having body fat that exceeds 25 per cent of body weight in women and 18 per cent in men (Bray, 1998). The amount of fat is estimated using a measure called body mass index (BMI). This takes a person's weight in kilograms and divides it by their height in metres squared. This figure is expressed as $X \text{ kg/m}^2$. To be diagnosed as clinically obese, a person must have a BMI that is equal to or greater than 30 kg/m^2 (World Health Organization, 1998). Figure 13.5 shows you how to calculate BMI.

The prevalence of being overweight in 6–11-year-old children had increased from 6 per cent in 1980 to 10.65 per cent in 1994 (Troiano and Flegal, 1998). Only a minority of adults have the desired BMI of 18.5 to 24.9 kg/m^2 and this shift towards being overweight is thought to carry severe health risks. The risk of mortality increases by around 30 per cent in people with a BMI of 30 kg/m^2 ; this percentage continues upward to 40 per cent when BMI exceeds 40 kg/m^2 (Manson *et al.*, 1995). A study of 14,403 Norwegian men aged between 40 and 49 and initially free of coronary heart disease (CHD) has shown that body mass index was a risk factor for the subsequent development of the disease later in life (Haheim *et al.*, 2007). The causes of death in obese people include stroke, diabetes and cancer (these correlate with obesity). Obese people also suffer social and physical complications (Wadden *et al.*, 2002). Obese girls complete fewer years in school, despite having just as good grades as those who remain, are less likely to marry, and earn less than their non-obese counterparts. Obese people also elicit negative aesthetic judgements from others (as you saw in Chapter 3): people tend to prefer partners with a specific shape and size (and it is not obese).

Consequences of obesity and rationale for intervention

Interventions are recommended when a person has a serious BMI statistic and a risk of developing ill health. For people with a BMI of below 27 kg/m^2 , clinicians recommend an increase in physical activity and a decrease in fat and sugar intake, coupled with self-directed efforts to maintain weight loss and the taking of a doctor's advice (Wadden *et al.*, 2002). For people with higher BMIs, the same intervention may be implemented but if

this does not work more drastic measures may be adopted such as drugs or, for those with a BMI in excess of 40 kg/m^2 , surgery (this is called **bariatric surgery**). The side effects of surgery are considerable, but weight loss is produced more efficiently (Yanovski and Yanovski, 2002). It is expensive, costing around £17,000 per operation (Bauchowitz *et al.*, 2005).

Initial success at weight loss depends on the goals of the person losing the weight. First, people need to be motivated to lose weight. Secondly, they need to realise that weight reduction programmes are designed for health rather than aesthetic reasons. For example, until recently interventions were guided towards helping people achieve their ideal weight (rather than a weight which would reduce the risk of ill health). Current emphasis, however, is on reducing health complications and so a loss of 5–15 per cent can be effective in producing this reduction, even though the patient/client may not be happy with having lost so little weight and expect a weight loss of 20–35 per cent (Blackburn, 1995; O'Neil *et al.*, 2000). Wadden *et al.* cite one study which reported that weight reduction of 7 kg/m^2 combined with 150 minutes of exercise a week reduced the likelihood of developing diabetes by 58 per cent (Diabetes Prevention Program Research Group, 2002, cited in Wadden *et al.*, 2002). A meta-analysis of obesity prevention programmes for children has found that only 21 per cent of 64 programmes showed evidence of weight gain prevention in children (Stice *et al.*, 2006). The effect was greater for children and adolescents (rather than pre-adolescents) and for girls.

Psychological interventions

Difficulty in restricting food intake is increased during holiday periods which the overweight regard as high-risk periods because of family celebrations or national holiday celebrations. One way in which this difficulty could be reduced is by self-monitoring, the act of closely observing what is eaten and when and in which contexts. Boutelle *et al.* (1999) examined the effect of self-monitoring during this high-risk holiday period in a group of overweight individuals on a weight-loss programme. Forty-nine obese people who had been on the programme for at least a month, were known to self-monitor rarely and who were willing to be contacted in a two-week holiday period (Christmas–New Year), took part in the study.

Figure 13.5 How to determine BMI in adults.

Here is a shortcut method for calculating BMI (if you are too short or too tall for the table: Step 1, multiply weight (in pounds) by 703; Step 2, multiply height (in inches) by height (in inches); Step 3, divide the answer in Step 1 by the answer in Step 2 to get your BMI. Example: for a person who is 5 feet 5 inches tall weighing 149 lbs. Step 1, $149 \times 703 = 104747$; Step 2, $65 \times 65 = 4225$; Step 3, $104747 \text{ divided by } 4225 = 24.8$.

Self-monitoring took the form of examining food intake and taking weight measurements daily. Two groups – an intervention group and a non-intervention group – were observed and both groups were encouraged to do this basic level of self-monitoring. However, the intervention group also received daily mailings (comics and literature about self-monitoring and weight loss) from the researchers as well as one or two

phone calls in each week in the two-week period reminding them to self-monitor.

Those in the intervention group self-monitored more frequently but also managed their weight more effectively than did those in the non-intervention group. Both groups had difficulty in managing their weight, however (the comparison group putting on a pound, on average). Those in the self-monitoring

Psychology in action – *Continued*

In 2008, chef Jamie Oliver launched a campaign called 'Pass It On' to get the people of Rotherham in the North of England eating well and healthily. One resident, Julie Critchlow (pictured here), was so unimpressed she took take-away orders from disgruntled schoolchildren outside the school railings. She was eventually won over.

Source: Corbis: Peter Dench (l), Ross Parry Agency: (r);

group lost more weight and there was a strong association between self-monitoring and weight loss.

The difficulty in maintaining weight loss is one of the most serious problems obese people face. Studies of 20-week intervention programmes, such as the one described, have found that people can lose up to 9 kg (around 9 per cent of body weight) but when the intervention programme stops, people can regain as much as one-third of their weight in the following 12 months (Foreyt and Goodrick, 1993; Wing, 2002). Clinicians, therefore, have focused their attention on how to achieve the maintenance of weight loss.

This can be done by creating detailed behavioural plans for the client to follow, as well as by controlling the portions of food the client eats. Replacing normal meals and snacks with portion-controlled meals, for example, can lead to an 8 per cent reduction in weight over a sustained period of dietary regime control. The longer the intervention, the greater the weight loss, but most of the loss is seen in the first six months (Perri *et al.*, 1989; Flechtner-Mors *et al.*, 2000). The greatest predictor of whether people maintain their loss is their ability to engage in physical activity. Those who do, tend to maintain their weight-loss programmes, as Figure 13.6 shows. Those who exercise at home are more successful at maintenance than are those who attend gyms or leisure centres (Perri *et al.*, 1997).

Surgical interventions

If psychological interventions do not succeed in producing weight loss, more aggressive interventions such as surgery are sometimes implemented if the person is morbidly obese, i.e. the person has a BMI of over 40 kg/m². There are two methods of surgically effecting weight loss in the obese. The first, called an intestinal bypass, worked by bypassing a part of the digestive system called the jejunum (Mason and Ito, 1969). The effect of this was to produce dramatic weight loss – in the order of 45 kg – but also very serious side effects such as liver failure. The second, and the one that is most commonly adopted, is also a form of gastric bypass. A 50 ml pouch is attached to the gullet which restricts food intake. The pouch is connected to the jejunum, bypassing the stomach and part of the intestine called

[illegible]

Every overweight person's dream: a pill that reduces fat. Pharmaceutical companies are working on such products constantly but no pill is currently totally effective.

the duodenum. The effect of this is to reduce weight by around 30 per cent in the first-year-and-a-half after surgery (Albrecht and Pories, 1999) and a sustained loss over a decade later.

Pharmacological interventions

Surgery is not the only physical intervention for obesity. Another possibility might be drugs and, in recent years, several companies have sought to deliver the perfect anti-obesity drug or ‘fat-buster’. Historically, such drugs have been used for other purposes – for depression (fenfluramine, sibutramine) or to combat smoking (rimonabant). Customised drugs have focused on the substances in the body which regulate hunger and satiety, such as the hormone, cholecystikinin (CCK), amylin, insulin and glucagons. All of these are released when we eat and help limit meal size (Woods *et al*, 2006; Naslund and Hellstrom, 2007). One, ghrelin, is released in the stomach and affects the vagus nerve and hypothalamus and increases food intake. Drugs which mimic the effects of these hormones produce an increase in the feeling of satiety. Drugs that antagonise ghrelin receptors decrease the feelings of hunger (Moran, 2006). There are also chemicals, melanocortins, which are released by

Psychology in action – Continued

leptin's action on a group of neurons in the arcuate nucleus. When melanocortin receptors are activated, there is a decrease in feeding and an increase in energy expenditure. Drugs are being developed which act as agonists for melanocortin receptors (Nargund *et al.*, 2006). Other drugs being developed include histamine 3 antagonists which may help to reduce weight gain (Ebenshade *et al.*, 2006). None of these drugs have met with long-term success, as yet, but the quest to develop the perfect weight-loss drug continues.

Policy for the future

Wadden *et al.* (2002) suggest five ways in which the obesity problem might be tackled. These are:

- Regulating the food advertising aimed at children, especially the advertising of sugary and fatty food.
- Prohibiting fast foods and drinks from schools.
- Subsidising the sale of healthy foods.
- Taxing unhealthy foods.
- Providing resources for physical activity.

Some of these steps may probably never happen, because they are quite stark and potentially expensive, especially for the manufacturer who will see its goods taxed and the advertising of these goods reduced. The authors do acknowledge that these steps may not even achieve the aims they set out to achieve. Of course, there is also the important issue of choice and freedom of choice: people can decide not to consume

sugary or fatty food and some people enjoy eating such foods in moderation. For those who consume sensibly to reduce or impede access to such foods, by reducing their advertising or taxing them heavily, would it be psychologically (perhaps morally) beneficial?

What causes obesity?

Various psychological variables may be a cause of obesity, including lack of impulse control, poor ability to delay gratification, and maladaptive eating styles (primarily eating too fast). However, in a review of the literature, Rodin *et al.* (1989) found that none of these suggestions has received empirical support. Rodin and her colleagues also found that unhappiness and depression seem to be the effects of obesity, not its causes, and that dieting behaviour seems to make the problem worse.

There is no single, all-inclusive explanation for obesity, but there are many partial ones. Habit plays an important role in the control of food intake. Early in life, when we are most active, we form our ideas about how much food constitutes a meal. Later in life, we become less active, but we do not always reduce our food intake accordingly. We fill our plates according to what we think is a proper-sized meal (or perhaps the plate is filled for us), and we eat everything, ignoring the satiety signals that might tell us to stop before the plate is empty.

One reason why many people have so much difficulty losing weight is that metabolic factors appear to play an

important role in obesity. In fact, a good case can be made that obesity is most often not an eating disorder but rather a metabolic disorder. Metabolism refers to the physiological processes, including the production of energy from nutrients, that take place within an organism. Just as cars differ in their fuel efficiency, so do people. Rose and Williams (1961) studied pairs of people who were matched for weight, height, age and activity. Some of these matched pairs differed by a factor of two in the number of calories they ate each day. People with an efficient metabolism have calories left over to deposit in the long-term nutrient reservoir; thus, they have difficulty keeping this reservoir from growing. In contrast, people with an inefficient metabolism can eat large meals without getting fat. Thus, whereas a fuel-efficient automobile is desirable, a fuel-efficient body runs the risk of becoming obese.

Genetic influences

Are people who suffer from excessive weight gain genetically different from those with normal weight or is it true that, as Bray (1998) suggests, ‘genes load the gun, the

environment pulls the trigger? Differences in metabolism appear to have a hereditary basis. Griffiths and Payne (1976) found that the children of obese parents weighed more than other children even though they ate less. Stunkard *et al.* (1986) found that the body weight of a sample of people who had been adopted as infants was highly correlated with their biological parents but not with their adoptive parents. Thus, a person's weight (presumably closely related to their metabolic efficiency) is influenced by genetic factors.

Why are there genetic differences in metabolic efficiency? James and Trayhurn (1981) suggest that under some environmental conditions metabolic efficiency is advantageous. That is, in places where food is only intermittently available in sufficient quantities, being able to stay alive on small amounts of food and to store up extra nutrients in the form of fat when food becomes available for a while is a highly adaptive trait. Therefore, the variability in people's metabolisms may reflect the nature of the environment experienced by their ancestors. For example, physically active lactating women in Gambia manage to maintain their weight on only 1,500 calories per day (Whitehead *et al.*, 1978). This high level of efficiency, which allows people to survive in environments in which food is scarce, can be a disadvantage when food is readily available because it promotes obesity.

Another factor – this one non-hereditary – can influence people's metabolism. Many obese people diet and then relapse, thus undergoing large changes in body weight. Some investigators have suggested that starvation causes the body's metabolism to become more efficient. For example, Brownell *et al.* (1986) fed rats a diet that made them become obese and then restricted their food intake until their body weights returned to normal. Then they made the rats fat again and reduced their food intake again. The second time, the rats became fat much faster and lost their weight much more slowly. Clearly, the experience of gaining and losing large amounts of body weight altered the animals' metabolic efficiency.

Steen *et al.* (1988) obtained evidence that the same phenomenon (called the yo-yo effect) takes place in humans. They measured the resting metabolic rate in two groups of adolescent wrestlers: those who fasted just before a competition and binged afterwards and those who did not. The investigators found that wrestlers who fasted and binged developed more efficient metabolisms. Possibly, these people will have difficulty maintaining a normal body weight as they get older.

The role of leptin

For a long time, investigators believed that fat tissue provided some chemical signal that could be detected by the brain. When too much fat began accumulating, more of this chemical was secreted, and the person began eating

less. If the amount of body fat began to decrease, the level of the chemical fell and the person began eating more.

After many years of searching for such a chemical signal, researchers have finally succeeded in finding one. The discovery came after years of study with a strain of genetically obese mice. The ob mouse (as this strain is called) has a low metabolism, overeats and gets monstrously fat. It also develops diabetes in adulthood, just as many obese people do. Recently, researchers in several laboratories have discovered the cause of the obesity (Campfield *et al.*, 1995; Halaas *et al.*, 1995; Pelleymounter *et al.*, 1995). A particular gene, called *OB*, normally produces a protein known as **leptin** (from the Greek word *leptos*, 'thin'). Leptin is normally secreted by fat cells that have absorbed a large amount of triglyceride. Because of a genetic mutation, the fat cells of ob mice are unable to secrete leptin.

Leptin has profound effects on metabolism and eating, acting as an anti-obesity hormone. If ob mice are given daily injections of leptin, their metabolic rate increases, their body temperature rises, they become more active and they eat less. As a result, their weight returns to normal. The treatment works even when the leptin is injected directly into the brain, indicating that the chemical acts directly on the neural circuits that control eating and metabolism. Figure 13.7 shows a photograph of an untreated ob mouse and an ob mouse that has received injections of leptin.

Maffei *et al.* (1995) discovered that leptin is found in humans and that the level of leptin in the blood is correlated with obesity; thus, this chemical signal appears to be present in our species as well as in mice. But if leptin is produced by human fat cells, why do some people nevertheless overeat and become obese?

As you saw in Chapter 4, hormones act on their target cells by stimulating receptor molecules located on these cells. Using the techniques of molecular genetics, Tartaglia *et al.* (1995) discovered the leptin receptor. In order for leptin to reduce weight, the brain must contain function-

Controversies in Psychological Science – Can the bitter gene cause obesity?

The issue

If the media are to be believed, we in the well-resourced West are turning into lumpen couch potatoes, gorging on criminally inedible food and staring gormlessly at *Big Brother* while mentally eyeing up the next kebab. This pattern of unhealthy eating seems to be particularly prominent in adults and children from poorer backgrounds. For example, the Head Start programme in the US, a pre-school programme for children from low-income families, found that obesity was greater in these children than in the general population – 15 per cent were obese compared to 10 per cent for the general population (Feese *et al.*, 2003). Various reasons have been suggested for this, but one possible factor may be surprising: obesity may be caused by the gene that allows us to perceive bitter tastes.

The evidence

Around 30 per cent of Europeans are thought to be unable to taste the bitter substances, 6-n-propylthiouracil (PROP) and phenylthiocarbamide, an ability thought to be mediated by a specific gene called *TAS2R38*. People who are able to taste PROP have been found to have a lower BMI than do non-tasters (Tepper and Ullrich, 2002) but evidence is mixed. One study found no difference and another reported that the effect was found for boys but that girl tasters had higher BMIs than girl non-tasters (Keller *et al.*, 2002; Keller and Tepper, 2004).

Being able to taste or not taste bitter substances has evolutionary advantages. As you saw in Chapter 5, most poisons are bitter and so it is to our advantage to have a gene that codes for this taste because it can prevent harm and assist survival. Those who cannot taste bitterness, however, can ensure that they ingest a wider range of (non-poisonous) foods, thereby ensuring a healthy diet and a healthy life. The ability to taste PROP is associated with several quirky behavioural features: PROP-tasters have more food aversions, dislike (and eat fewer) vegetables, think that vegetables taste bitter (especially broc-

coli, orange/grapefruit juice and spinach), and prefer sweeter foods (Keller *et al.*, 2002; Dinehart *et al.*, 2006). When child PROP-tasters are allowed to eat what they like, they eat fewer bitter-tasting vegetables and fewer vegetables in general than do non-tasters (Bell and Tepper, 2006). This selective diet may be related to the obesity seen in PROP-tasting children.

To test this explicitly, a recent study asked 81 children attending a Head Start pre-school to taste a solution of PROP and indicate whether it tasted of water or 'like something else' (Lumeng *et al.*, 2008). Because the children were around 3–3½ years-old, facial expression was used as a measure of bitterness perception (children would exhibit the 'yuck' response if they tasted bitter). The children's BMI was measured, along with their diet, their neophobia (whether they were afraid or spurned new or unfamiliar foods) and the mother's race, BMI, weight, height, etc.

There were 18 non-tasters and 63 tasters in the sample. The tasters had a significantly higher BMI than did the non-tasters and were more overweight. The mother's BMI and tasting status were the two strongest predictors of the child's obesity.

Conclusion

The researchers note that the study has limitations – such as using facial expression to index response and that children from high-income homes were not included. The research raises an important question, however: why do children from low-income families and who are tasters have a higher BMI? The researchers point to studies showing that feeding is less restrictive in low-income families and meal times are less structured. Their consumption of fruit and vegetables is lower, they eat more fatty and sugary foods, and consume more fast food. Given that PROP tasters find vegetables less palatable and prefer sweet foods, this characteristic, combined with the vegetable-light/fat and sugar-heavy diet of low-income family children, could lead to the increased BMI in this group.

ing leptin receptors. Perhaps, researchers speculate, some people have leptin receptors that do not respond normally to the presence of leptin in the blood. The overgrown fat cells of these people secrete high levels of leptin, but the effect the hormone produces in the brain is less intense than normal. Hence, people overeat.

How emotion affects food intake

One reason for why they do so given by people who eat excessively is that it makes them feel better. Some researchers have linked this increased positive mood to the

dopamine release caused by carbohydrate and fat (which the foods people crave tend to be full of – crisps, sweets, biscuits and so on). A new study of healthy men, however, suggests that the relationship can be quite complex: if a man is exposed to a stimulus that creates happiness, his appetite for chocolate increases; if he is exposed to one that causes sadness it decreases (Macht *et al.*, 2002).

Macht *et al.* asked men to abstain from eating for either two or eight hours before watching film clips designed to elicit anger, fear, sadness and happiness (e.g. a sequence from the film *Cry Freedom* was used to generate anger). After this, participants were given up to four

pieces (5 g) of their preferred chocolate to eat and were asked to rate their appetite for chocolate and how much they liked what they ate.

Men in the happiness condition ate more chocolate and rated it as more pleasant than did men in the sadness condition. The findings suggest that emotion can affect eating in two ways: one involves people eating nice food when in a good mood and rating the food in a way that is congruent with their mood. The other involves people regulating their emotion through eating: people may, like binge eaters, eat tasty food to feel better.

Some research, however, suggests that when it comes to mood, ingesting chocolate does not necessarily improve positive mood but instead reduces negative mood. Macht and Mueller (2007) asked 48 men and women of normal weight to eat a 5 g piece of chocolate or drink some water after watching film clips designed to elicit positive, negative or neutral mood states. Mood was measured after seeing the clips and before and after ingesting the chocolate.

The chocolate eaters reported less negative mood compared to the water drinkers but the food had no effect on the other mood states. The authors suggest that this reduction in bad mood was attributable to the chocolate's palatability. In a second study, therefore, participants ate either palatable or unpalatable chocolate – one that was not rated as particularly pleasant – just after watching mood-inducing films. The palatable chocolate reduced negative mood, but the unpalatable chocolate did not. The benefit disappeared after three minutes.

The results suggest that emotional eating may arise from palatable food's ability to reduce negative mood, such as that experienced during periods of stress.

A study by researchers from Wales and Germany has found that the taste of sweet but not bitter foods can be affected by the taster's mood. Greimel *et al.* (2006) induced joy or sadness in participants by presenting them with video clips designed to elicit these emotions. Participants then rated the pleasantness and sweetness of a sweet chocolate drink, a bitter quinine solution and a bitter-sweet drink. Emotion significantly influenced pleasantness and sweetness ratings of the sweet drink: those who had been made sad rated the drink as less pleasant and sweet; those who had been made happy, rated it as more pleasant and sweeter. There was no effect of emotion on the ratings of the bitter and bitter-sweet drinks. 'The results fit the motivational and cognitive properties of the two emotions', the authors conclude. 'Whereas joy is associated with an increased readiness to savour the world, sadness is associated with a focus on inner experiences' (p. 267).

Anorexia nervosa

Anorexia nervosa is an eating disorder characterised by a severe restriction of eating. The literal meaning of the word 'anorexia' suggests a loss of appetite, but people with this disorder generally do not lose their appetite (DSM-IV TR, 2001). Their limited intake of food – especially fats and carbohydrates – occurs despite intense preoccupation with food, its preparation

Cutting edge – Mood food

Go into any restaurant or café and you'll invariably hear the sound of music coming through the PA system. It is designed to create an ambiance, a feeling of relaxation (or excitement) befitting the establishment. A study from the US has also shown that this music can affect not only how long you eat for, but also how much (Stroebele and de Castro, 2006).

In a diary study, 78 college students made a note of what they ate and for how long for seven consecutive days. They also noted where and when they ate, whether there was music present, how loud and fast/slow this music was, and how many people were present.

The researchers found that listening to music was significantly associated with higher food intake and meals of longer duration, regardless of whether the food was a proper meal or a snack. The speed and volume of music was not significantly associated with either of these variables. People ate more and longer when more people were present but the effect of music

on meal duration was eliminated when the number of people present was taken into account. This number, rather than the music, was the better predictor of meal length.

On a related note, research shows that we eat less in the presence of a stranger of the opposite sex than one of the same sex. We often adjust our eating depending on what the other person is doing. To explore this further, researchers from the US and Canada paired participants either with friends, partners or strangers and then asked them to eat as many biscuits and crackers as they wanted (Salvy *et al.*, 2007).

Men and women ate more in the presence of those they knew than when with strangers. But certain men and women were likely to eat more. Women in couples ate more than any of the other female samples; and men who ate with friends ate more than men in any other pairing. Eating is facilitated by social interaction, especially, it seems, in men.

and with their own disorder (Hermans *et al.*, 1998). Their average intake is around 100 calories a day; for healthy adult women, the recommended calorie intake is between 1,500 and 2,000. They may enjoy preparing meals for others to consume, collect recipes, and even hoard food that they do not eat. They have an intense fear of becoming obese, and this fear continues even if they become dangerously thin. There is a significant disturbance in the perception of body shape and size, with anorexics consistently overestimating body size and shape (Smeets *et al.*, 1997). Many exercise excessively by cycling, running, or almost constant walking and pacing. The prevalence of the disorder is between 0.5 and 1 per cent.

Bulimia nervosa

A different eating disorder, **bulimia nervosa**, is characterised by a loss of control of food intake. The term bulimia comes from the Greek *bous*, 'ox', and *limos*, 'hunger'. People with bulimia nervosa periodically gorge themselves with food, especially dessert or snack food, and especially in the afternoon or evening. These behaviours must occur at least twice a week for three months for a diagnosis of bulimia nervosa to be made (DSM-IV TVR, 2001). These binges are usually followed by self-induced vomiting or the use of laxatives, along with feelings of depression and guilt (Mawson, 1974; Halmi, 1978). This behaviour is called purging, although not all bulimics use this behaviour as a means of compensating for the binge eating. With this combination of bingeing and purging, the net nutrient intake (and consequently, the body weight) of bulimics can vary; Weltzin *et al.* (1991) report that 44 per cent of bulimics undereat, 37 per cent eat a normal amount, and 44 per cent overeat. Episodes of bulimia are seen in some patients with anorexia nervosa. Bulimics seem to be less concerned with food but are excessively preoccupied with body shape (Lovell *et al.*, 1997). The prevalence rate is a little higher than that for anorexia and ranges between 1 and 3 per cent. Despite a reported increase in the prevalence of the disorder over many decades, some recent research suggests that it is declining, with data from the UK, the USA and The Netherlands showing reduced prevalence of bulimia (Keel *et al.*, 2005; Currin *et al.*, 2005; Hoek and van Hoeken, 2003).

Aetiology of anorexia and bulimia nervosa

Because anorexia is characterised by constraint, reduced affect and emotion, and an ascetic way of life, and bulimia is characterised by impulsivity and sensation-seeking, the causes of each might be different. Some researchers have suggested that bulimia might be attribut-

able to some neurophysiological problem, such as an imbalance of serotonin (a neurotransmitter involved in mood, eating and impulsive behaviour). Serotonin disturbances are seen in the disorder during and after the illness (Kaye, 2008) and one mechanism for the process might be that gonadal steroids affect the regulation of 5HT during puberty. Bulimics, like anorexics, might discover that reducing intake also affects serotonin and mood because the lack of food reduces blood levels of a chemical called tryptophan. In the short term, they might experience an improvement in mood but with continued calorie restriction, the effect on serotonin is to make their mood worse (Kaye, 2008).

The fact that anorexia nervosa is seen primarily in young women has prompted a number of biological, cognitive and sociocultural explanations. There is good evidence, primarily from twin studies, that hereditary factors play a role in the development of anorexia (Russell and Treasure, 1989). The existence of hereditary factors suggests that abnormalities in physiological mechanisms may be involved. However, most psychologists believe that the emphasis our society places on slimness, especially in women, is largely responsible for this disorder. Others suggest that the excessive need to control eating (which is, in turn, caused by Western societies' preoccupation with shape and weight) is the characteristic feature (Fairburn *et al.*, 1999).

Body dissatisfaction in healthy and eating-disordered women

Around 50 per cent of girls and undergraduate women report being dissatisfied with their bodies (Bearman *et al.*, 1986), and this can occur as early as 7 years of age and across cultures (Dohnt and Tiggemann, 2006). This dissatisfaction with one's body is seen as a significant risk factor for the development of eating disorders (Grabe *et al.*, 2007). A number of studies has shown that such body dissatisfaction is significantly higher in young women than it is in middle-aged women. One theory that could account for this dissatisfaction is Frederickson and Roberts's self-objectification theory (1997). This argues that most Western cultures regard the female body as something to be viewed and evaluated. In such cultures, there is a tendency in women to monitor their appearance, judging it as others (mostly, men) would view it. Noting that the body does not meet the ideal – or the perceived notion of an ideal – the woman becomes dissatisfied about her appearance. One consequence of such monitoring is increased anxiety and shame about the body. Ultimately, it could be argued, such monitoring leads to eating disorder, anxiety and sexual dysfunction.

Strahan *et al.* (2006) found that women rated their appearance more negatively than did men and also com-

pared their bodies with very attractive women, especially unrealistic ones such as models, more often than they did less attractive ones. This bias was eliminated by removing the salience of ‘cultural norms’, i.e. the emphasis on what people find attractive in women and what magazines and television portray as being the ideal of womanly pulchritude and physical perfection. When cultural norms are minimised, women compare themselves with their (more realistic and relevant) peers. However, when cultural norms are made salient, women are more likely to compare themselves with models (and consequently feel worse about themselves when they make such comparisons).

The widespread portrayal of such norms, and women’s susceptibility to their psychologically pernicious effects, might explain their insecurity with their bodies. A recent television advertisement for a well-known UK pharmacist showed a woman nervously standing amongst a beach of sunbathers, as the voice-over conveyed her inner thoughts about whether she was slim enough to expose herself in the summer sun. ‘The most dreaded moment of the year’, the voice-over intoned. A newspaper commentator takes up the story: ‘Her fellow baskers turn en masse to judge her. She nervously reveals smooth, caramel limbs, thus enabling the meerkats to return to their sunbathing, safe in the knowledge that they won’t have to look at her bingo wings and stubble for the rest of the day’ (Raeside, 2007).

This manipulation has some basis in fact. Frederick *et al.* (2006) found that more women than men felt too heavy, unattractive and avoided wearing a swimsuit in public (16 per cent of men versus 31 per cent of women). Men felt better about their bodies than did women but underweight women were most happy with their bodies, alarmingly. Slender women were more satisfied than those with higher BMIs. Various studies have shown that women, particularly young women, are overly concerned with their appearance and with how others view them; self-objectification seems to occur when the women have the maximum potential for reproduction.

To investigate the relationship between weight, age and self-objectification, Tiggemann and Lynch (2001) asked 322 Australian women aged between 20 and 84 to rate how they viewed their physical appearance. The researchers found that although body dissatisfaction was consistent across all ages, self-objectification, habitual body monitoring, appearance anxiety and symptoms of eating disorders was greatest in the younger sample and decreased with age. Previous studies – and the self-objectification theory – would predict this change over time. Although women become dissatisfied with their bodies, they attach less importance to physical appearance as they get older. Such responses may be affected by culture and class. For example, young Australian female undergraduates express greater body dissatisfaction and lower body esteem than

their Pakistani equivalents. However, when the Pakistani group is divided into Urdu-medium (middle social class) or English-medium (upper social class) groups, the latter group express more concern with body shape than the former (Mahmud and Crittenden, 2007). Although the BMI of the Australians was higher, the findings remained even when physical weight was taken into consideration. The researchers suggest that ‘Pakistani women, by virtue of belonging to a collectivist society, where identities are based more on one’s group membership rather than on one’s personal attributes, may be less likely to face pressures and shape-related criticism’ (p. 194).

One source of women’s body dissatisfaction is the media. Thin women are portrayed as paragons of their kind: they are healthy, better-looking, attract the most desirable men and so on. Films, magazines and television programmes emphasise the thinness of women (Fouts and Burggraf, 1999), there are fewer fat people portrayed on television and portrayals now are thinner than on television in the past and thinner than is normal in the population (Greenberg *et al.*, 2003; Silverstein *et al.*, 1986; Fouts and Burggraf, 1999). Women who watch thin media images of other women express a significantly greater negative body image than when watching average-sized women, especially if the viewers are under 19 years old and are concerned with their body weight (Groesz *et al.*, 2002; Grabe *et al.*, 2007). Culturation theory argues that increased exposure to material makes this material the norm over time and people come to accept it as real (Gerbner *et al.*, 2002): if this is what women are like, women might think, this is how I need to be, too. If women with a negative body image watch a seven-minute analysis of how the media portrays women, they engage less in social comparison – comparing themselves to an imagined ideal – and are affected less by seeing images of thin, beautiful women (Posavac *et al.*, 1998).

The effects of watching television and fashion magazine images appear to be different: seeing thin women in fashion magazines is associated with a greater activation of what psychologists call ‘internalisation of thin ideals’, the ability to evoke a stereotype of the most desirable (thin) woman (Tiggemann, 2003). Interestingly, women with eating disorders report less anxiety about their body when watching magazine advertisements featuring average-sized models (Halliwell *et al.*, 2005). The advertisements featuring very thin and average-sized women were rated as just as effective as each other, suggesting that advertisements need not recruit the thinnest of stick-thin women so sell their wares.

About one anorexic patient in 30 dies of the disorder. Many anorexics suffer from osteoporosis, and bone fractures are common. When the weight loss becomes severe

In 2004, the company Dove launched its campaign for Real Beauty (top) using models which contrasted with those normally seen in adverts for similar products (bottom). Of course, both types are designed to sell us thing we do not really need.

enough, anorexic women cease menstruating (this is called amenorrhoea). Another possible cause is that changes in a young woman's endocrine status alter her metabolism or the neural mechanisms involved in feeding, but because prolonged fasting and the use of laxatives have many effects, interpreting these differences is difficult (Halmi, 1978). Recent neuroimaging research, however, has shed some light on the neurobiological mechanisms of the disorder. Uher *et al.* (2003) reported that women with anorexia who had been successfully tested showed differences in activation in the anterior cingulate and prefrontal cortex when looking at pictures of food. Wagner *et al.* (2008) went a step further and used fMRI to measure brain activation in 16 women who had recovered from anorexia and 16 controls who tasted sucrose or water. They found reduced activation in the insula, anterior cingulate and striatum in the recovered anorexic group. The pleasantness ratings of the tasters were correlated with brain activation, as Figure 13.8 shows.

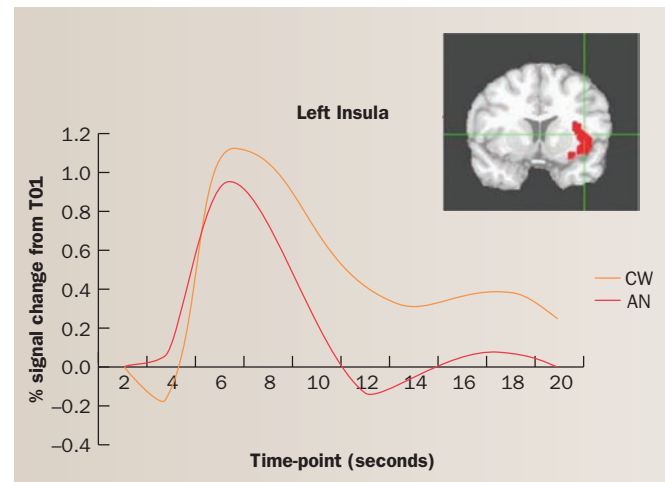

Figure 13.8 Changes in the brain's insula region while recovering anorexic women and healthy women tasted sucrose. Activation was reduced in the recovering group suggesting that this brain region plays a role in the eating disorder.

Cutting edge – Body size, television size and other people's attractive parts

Curiously, women's response to watching other women's bodies on television, as well as their intake of crisps and chocolates, can be affected by the size of the television screen they watch. One study had female students of normal weight eat snacks while watching a 30-minute film of beautiful girls in a frame size that was either in 4:3 ratio (normal) or 16:9 (where the image is stretched) (Anschutz *et al.*, 2008). Restrained eaters felt worse and ate less in the thinner condition.

Furthermore, if women are asked to look at photographs of themselves and other women and identify a part of their own and others' bodies they find unattractive, women with higher BMI judged their bodies to be less attractive (Roefs *et al.*, 2008). Eye-tracking technology showed that they would spend more time looking at their unattractive body parts and more time looking at other women's attractive parts.

Eating disorders – An international perspective

It is almost a cliché to say that eating disorders have increased significantly in the past few decades and that this increase is most obvious in young women raised in 'the West'. Like most clichés, however, it is underpinned by a strong element of truth and evidence. Eating disorders are still more common in Western cultures and more common in girls and women than boys and men. According to Prince (1985), the most well-known eating disorder (after obesity) is anorexia nervosa and there is evidence that this disorder may be culture-bound, that is, one limited to culture 'primarily by reason of certain of their psychosocial features'.

In a review of the extent to which anorexia and bulimia nervosa are culture-bound, Keel and Klump (2003) showed that anorexia has been reported in every non-Western region of the world but that bulimia nervosa appears most frequently in Western cultures. Although suggesting that the former may be culture-bound, the authors caution that anorexia is a more

widely studied and accepted disorder than is bulimia and the lack of extensive evidence on the prevalence of bulimia may explain its greater appearance in studies of Western participants.

If we humour the study's conclusion, however, and try to explain why the discrepancy should arise, one factor that might be important is the availability of high-sugar, fatty, palatable foods. Binge eating involves eating these foods to excess; there must, therefore, be a ready source of them. The great prevalence of bulimia in the West may, therefore, reflect the fact that more of this food is available. It does not explain, however, why the bingeing occurs in the first place. The authors suggest a possible genetic predisposition to bulimia, citing evidence that the disorder may share genetic transmission with other 'neuroses' such as phobia. This idea may be too general to be valid, however. Why should genetic predisposition to bingeing be transmitted along with genetic predisposition to being afraid of a spider?

Sexual behaviour

The motivation to engage in sexual behaviour can be very strong. However, sexual behaviour is not motivated by a physiological need, in the way that eating is. Because we must perform certain behaviours in order to reproduce, the process of natural selection has ensured that our brains are constructed in such a way as to cause enough of us to mate with each other that the species will survive.

Effects of sex hormones on behaviour

Sex hormones – hormones secreted by the testes and ovaries – have effects on cells throughout the body. In general, these effects promote reproduction. For example, they cause the production of sperms, build up the lining of the uterus, trigger ovulation, and stimulate the production of milk. Sex hormones also affect nerve cells in the brain, thereby affecting behaviour, but they do not cause behaviours. Behaviours are responses to particular situations and are affected by people's experiences in the past. Sex hormones affect people's motivation to perform particular classes of reproductive behaviours. We therefore start our exploration of sexual behaviour with the motivational effects of sex hormones.

During prenatal development, the testes of male foetuses secrete testosterone, which causes the male sex organs to develop. This hormone also affects the development of the brain. The prenatal effects of sex hormones are called **organisational effects** because they alter the organisation of the sex organs and the brain. Studies using laboratory animals have shown that if the organisational effects of androgens on brain development are prevented, the animal later fails to exhibit male sexual behaviour. In addition, males cannot have an erection and engage in sexual intercourse unless testosterone is present in adulthood. These effects are called **activational effects** because the hormone activates sex organs and brain circuits that have already developed.

J.M. Davidson *et al.* (1979) performed a carefully controlled double-blind study of the activational effects of testosterone on the sexual behaviour of men whose testes failed to secrete normal amounts of androgens. The men were given monthly injections of a placebo or one of two different dosages of a long-lasting form of testosterone. When the men receiving testosterone were compared with the men in the control group, the effect of testosterone on total number of erections and attempts at intercourse during the month following the injection was found to be large and statistically significant, and the larger dosage produced more of an effect than did the smaller dosage. Thus, we may conclude that testosterone definitely affects male sexual performance.

If a man is castrated (has his testes removed, usually because of injury or disease), his sex drive will inevitably decline. Usually, he first loses the ability to ejaculate, and then he loses the ability to achieve an erection (Bermant

Effects of androgens

As you saw in Chapter 12, androgens such as testosterone are necessary for male sexual development.

and Davidson, 1974). But studies have shown that some men lose these abilities soon after castration, whereas others retain at least some level of sexual potency for many months. Injections or pills of testosterone quickly restore potency. Possibly, the amount of sexual experience prior to castration affects performance afterwards. Rosenblatt and Aronson (1958) found that male cats who had copulated frequently before castration were able to perform sexually for much longer periods of time after the surgery. Perhaps the same is true for men.

Testosterone affects sex drive, but it does not determine the object of sexual desire. A homosexual man who receives injections of testosterone will not suddenly become interested in women. If testosterone has any effect, it will be to increase his interest in sexual contact with other men.

Although evidence shows clearly that testosterone affects men's sexual performance, humans are uniquely emancipated from the biological effects of hormones in a special way. Not all human sexual activity requires an erect penis. A man does not need testosterone to be able to kiss and caress his partner or to engage in other non-coital activities. Men who have had to be castrated and who cannot receive injections of testosterone for medical reasons report continued sexual activity with their partners. For humans, sexual activity is not limited to coitus.

Androgens appear to activate sex drive in women as well as in men. Persky *et al.* (1978) studied the sexual activity of 11 married couples ranging in age from 21 to 31. The subjects kept daily records of their sexual feelings and behaviour, and the experimenters measured their blood levels of testosterone twice a week. Couples were more likely to engage in intercourse when the woman's testosterone level was at a peak. In addition, the women reported finding intercourse more gratifying during these times.

Effects of progesterone and oestrogen

In most species of mammals, the hormones oestradiol and progesterone have strong effects on female sexual behaviour. The levels of these two sex hormones fluctuate during the menstrual cycle of primates and the **oestrus cycle** of other female mammals. The difference between these two cycles is primarily that the lining of the primate uterus – but not that of other mammals – builds up during the first part of the cycle and sloughs off at the end. A female mammal of a non-primate species – for example, a laboratory rat – will receive the advances of a male only when the levels of oestradiol and progesterone in her blood are high. This condition occurs around the time of ovulation, when copulation is likely to make her become pregnant. During this time, the female will stand still while the male approaches her. If he attempts to mount her, she will arch her back and move her tail to the side, giving him access to her genitalia. In fact, an oestrus

female rat often does not wait for the male to take the initiative; she engages in seductive behaviours such as hopping around and wiggling her ears. These behaviours usually induce sexual activity by the male (McClintock and Adler, 1978).

A female rat whose ovaries have been removed is normally non-receptive, even hostile, to the advances of an eager male. However, if she is given injections of oestradiol and progesterone to duplicate the hormonal condition of the receptive part of her oestrus cycle, she will receive the male or even pursue him. In contrast, women and other female primates are unique among mammals in their sexual activity: they are potentially willing to engage in sexual behaviour at any time during their reproductive cycles. Some investigators have suggested that this phenomenon made monogamous relationships possible: because the male can look forward to his mate's receptivity at any time during her menstrual cycle, he is less likely to look for other partners.

In higher primates (including our own species), the ability to mate is not controlled by oestradiol and progesterone. Most studies have reported that changes in the level of oestradiol and progesterone have only a minor effect on women's sexual interest (Adams *et al.*, 1978; Morris *et al.*, 1987). However, as Wallen (1990) points out, these studies have almost all involved married women who live with their husbands. In stable, monogamous relationships in which the partners are together on a daily basis, sexual activity can be instigated by either of them. Normally, a husband does not force his wife to have intercourse with him, but even if the woman is not physically interested in engaging in sexual activity at a particular moment, she may find that she wants to do so because of her affection for him. This fact poses an interesting question. If all of a woman's sexual encounters were initiated by her, without regard to her partner's desires, would we find that variations in oestradiol and progesterone across the menstrual cycle affect her behaviour? Studies using monkeys suggest that this may be the case (Wallen *et al.*, 1986). And as Alexander *et al.* (1990) showed, women taking oral contraceptives (which prevent the normal cycles in secretion of ovarian hormones) were less likely to show fluctuations in sexual interest during the menstrual cycle.

Sexual orientation

When people reach puberty, the effects of sex hormones on their maturing bodies and on their brains increase their interest in sexual activity. As sexual interest increases, most people develop a special interest in members of the opposite sex – they develop a heterosexual orientation. Why does opposite-sex attraction occur? And why does same-sex attraction sometimes

occur? Research has not yet provided definite answers to these questions, but it has provided some hints.

Homosexual behaviour (engaging in sexual activity with members of the same sex; from the Greek *homos*, meaning ‘the same’) is seen in male and female animals of many species. The widespread occurrence of homosexual behaviour means that we should not refer to it as unnatural. However, humans are apparently the only species in which some members regularly exhibit exclusive homosexuality. Other animals, if they are not exclusively heterosexual, are likely to be bisexual, engaging in sexual activity with members of both sexes. In contrast, the number of men and women who describe themselves as exclusively homosexual exceeds the number who describe themselves as bisexual.

Traditional theories of sexual orientation have stressed the importance of a person’s early environment. In the early twentieth century, most mental health professionals regarded homosexuality as a disorder, caused by a faulty home environment, for example as the result of having been raised by an overprotective mother and an indifferent father. More recent research has refuted these conclusions. First, there is no evidence that homosexuality is a disorder. The adjustment problems that some homosexuals have occur because others may treat them differently. Therefore, even if we observe more neuroses in homosexuals than in heterosexuals, we cannot conclude that their maladjustment is directly related to their sexual orientation. In a society that was absolutely indifferent to a person’s sexual orientation, homosexuals might be as well adjusted as heterosexuals. In fact, a large number of homosexuals are well adjusted and happy with themselves (Bell and Weinberg, 1978), suggesting that homosexuality is not necessarily associated with emotional difficulties.

Sexual orientation appears to be determined prior to adolescence and prior to homosexual or heterosexual activity and most homosexual men and women have engaged in some heterosexual experiences during childhood and adolescence (Bell *et al.*, 1981). But unlike heterosexuals, they found these experiences unrewarding. The most important single predictor of adult homosexuality was a self-report of homosexual feelings, which usually occurred three years before first genital homosexual activity. This finding suggests that homosexuality is a deep-seated tendency. It also tends to rule out the suggestion that seduction by an older person of the same sex plays an important role in the development of homosexuality.

As the researchers admit, the results of the study are consistent with the hypothesis that homosexuality is at least partly determined by biological factors. That is, biological variables may predispose a child to behaviour that is more typical of the other sex and eventually to sexual arousal by members of their own sex.

What might be the biological causes of homosexuality? We can immediately rule out the suggestion that male homosexuals have insufficient levels of testosterone in

their blood; well-adjusted male homosexuals have normal levels of testosterone (Tourney, 1980).

A more likely cause of male homosexuality is the pattern of exposure of the developing brain to sex hormones. Some experiments suggest that if a female rat is subjected to stress during pregnancy, the pattern of secretion of sex hormones is altered, and the sexual development of the male offspring is affected (Ward, 1972; Anderson *et al.*, 1986). Various laboratories have studied the brains of deceased heterosexual and homosexual men and have found differences in the size of two different subregions of the hypothalamus and in a bundle of axons that connects the right and left temporal lobes (Swaab and Hofman, 1990; LeVay, 1991; Allen and Gorski, 1992). We cannot necessarily conclude that any of these regions is directly involved in people’s sexual orientation, but the results do suggest that the brains may have been exposed to different patterns of hormones prenatally.

When the organisational effects of androgens are blocked in male laboratory animals, the animals fail to develop normal male sex behaviour. Nature has performed the equivalent experiment in humans (Money and Ehrhardt, 1972; Ris-Stalpers *et al.*, 1990). Some people are insensitive to androgens. They have **androgen insensitivity syndrome**, caused by a genetic mutation that prevents the formation of androgen receptors. Because the cells of the body cannot respond to the androgens, a genetic male with this syndrome develops female external genitalia instead of a penis and scrotum. The person does not develop ovaries or a uterus.

If an individual with this syndrome is raised as a girl, all is well. Normally, the testes (which remain in the abdomen) are removed because they often become cancerous. At the appropriate time, the person is given oestrogen pills to induce puberty. Subsequently, the individual will function sexually as a woman. Women with this syndrome report average sex drives, including normal frequency of orgasm in intercourse. Most marry and lead normal sex lives. Of course, lacking a uterus and ovaries, they cannot have children.

Although little research has been done on the origins of female homosexuality, Money *et al.* (1984) found that the incidence of homosexuality was several times higher than the national average in women who had been exposed to high levels of androgens prenatally. The cause of the exposure was an abnormality of the adrenal glands, which usually secrete very low levels of these hormones. Thus, sexual orientation in females may indeed be affected by biological factors.

There is also some evidence that genetics may play a role in sexual orientation. Twin studies take advantage of the fact that identical twins have identical genes, whereas the genetic similarity between fraternal twins is, on average, 50 per cent. Bailey and Pillard (1991) studied pairs of male

twins in which at least one member identified himself as homosexual. If both twins are homosexual, they are said to be concordant for this trait. If only one is homosexual, the twins are said to be discordant. Thus, if homosexuality has a genetic basis, the percentage of identical twins concordant for homosexuality should be higher than that for fraternal twins. And this is exactly what Bailey and Pillard found; the concordance rate was 52 per cent for identical twins and 22 per cent for fraternal twins. In a subsequent study, Bailey *et al.* (1993) found evidence that heredity plays a role in female homosexuality, too. The concordance rates for female identical and fraternal twins were 48 per cent and 16 per cent, respectively.

A study by Canadian and American academics has found a significant relationship between handedness, homosexuality and the number of older brothers (Blanchard *et al.*, 2006). A previous meta-analysis had found a significant positive association between the number of older brothers (but not sisters) and homosexuality in men (Blanchard, 2004). Blanchard *et al.* (2006) combined five samples of participants to give 1,774 right-handed heterosexuals, 287 non-right-handed heterosexuals, 928 right-handed homosexuals and 157

non-right-handed homosexuals. They found that homosexuality was greater in those who had older brothers, but only if participants were right-handed. In participants who had no older brothers, homosexuals were more likely to be non-right-handed than were heterosexuals.

The data suggest that fraternal birth order and handedness interact to influence sexual orientation. The authors speculate that some factor (such as higher levels of foetal testosterone) associated with non-right-handedness 'increases the odds of homosexuality in first male births'. Of course, these data are correlational and do not suggest that one factor causes the other.

Neurobiological correlates of sexual behaviour

Arnow *et al.* (2002) have used fMRI to determine which regions of the brain were recruited when heterosexual young men watched 'explicitly erotic' video material, or relaxing or sports-related material. During viewing, penile turgidity was measured using a custom-built device. Figure 13.9 identifies regions of activation during arousal.

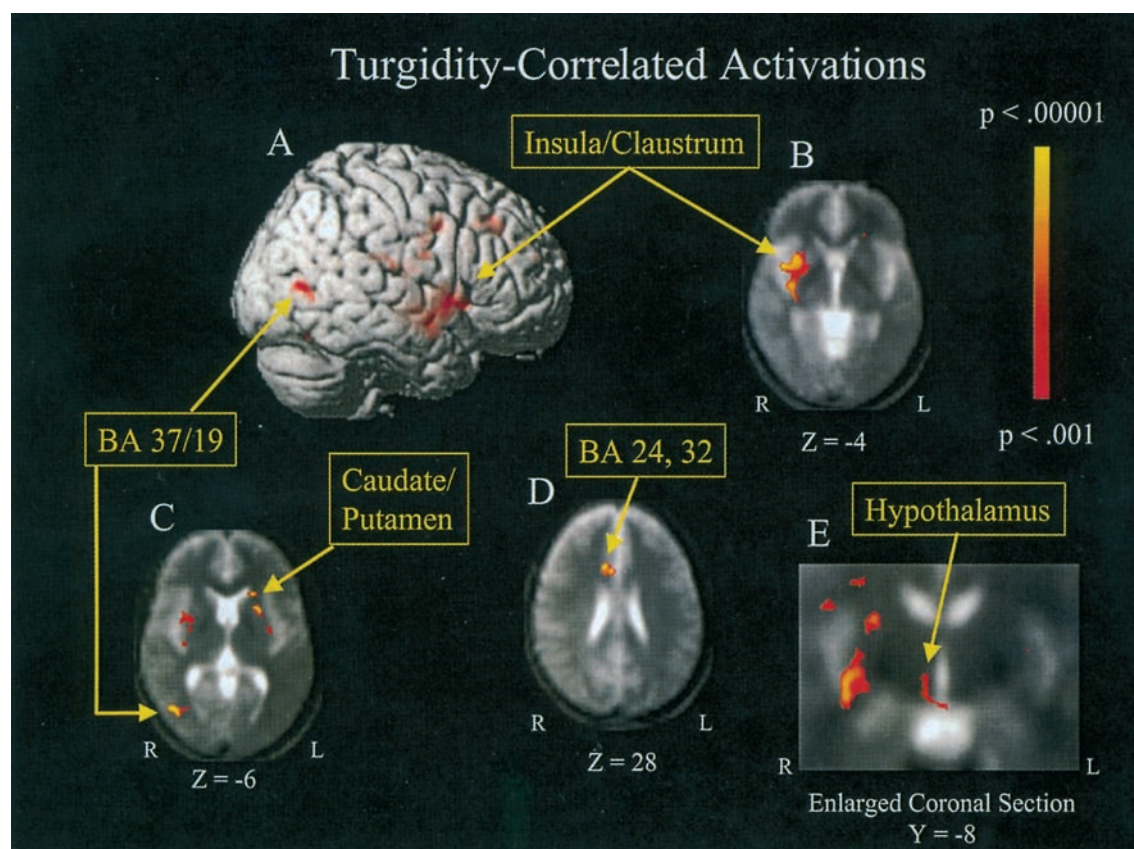

Figure 13.9 Activation in the male brain, measured during fMRI, during penile erection.

Source: From Arnow, B.A. *et al.*, Brain activation and sexual arousal in healthy, heterosexual males, *Brain*, 2002, Vol. 125, 1014–23. Reprinted by permission of Oxford University Press and Bruce Arnow.

The right hemisphere showed the most consistent activation during arousal. Various regions, including the premotor region, subcortical parts of the motor system and the occipital and temporal cortex, were activated during tumescence (much more so than during non-tumescence). The authors suggest that the results are consistent with other, differently designed studies. However, they cite a study showing that there is little overlap between the areas activated in men and those in women. 'Further studies will be needed', the authors say, 'to determine if such discrepancies reflect gender or paradigm differences in sexual arousal related brain activation.'

Aggressive behaviour

Aggression is a serious problem for humans: every day, we hear or read about incidents involving violence and cruelty and, undoubtedly, thousands more go unreported. Many factors probably influence a person's tendency to commit acts of aggression, including childhood experiences, peer group pressures, hormones and drugs, and malfunctions of the brain. Various aspects of aggressive behaviour have been studied by zoologists, physiological psychologists, sociologists, social psychologists, political scientists and psychologists who specialise in the learning process.

Ethological studies of aggression

The utility of species-typical behaviours such as sexual activity, parental behaviour, food gathering and nest construction is obvious; we can easily understand their value to survival. But violence and aggression are also seen in many species, including our own. If aggression is harmful, one would not expect it to be so prevalent in nature. Ethologists – zoologists who study the behaviour of animals in their natural environments – have analysed the causes of aggression and have shown that it, too, often has value for the survival of a species.

Intraspecific aggression

Intraspecific aggression involves an attack by one animal upon another member of its species. Ethologists have shown that intraspecific aggression has several biological advantages. First, it tends to disperse a population of animals, forcing some into new territories, where necessary environmental adaptations may increase the flexibility of the species. Secondly, when accompanied by rivalry among males for mating opportunities, intraspecific aggression tends to perpetuate the genes of the healthier, more vigorous animals.

Human cultures, however, are very different even from those of other species of primates. Perhaps intraspecific aggression has outlived its usefulness for humans and we would benefit by its elimination. Whatever the case may be, we must understand the causes of human aggression in order to eliminate it or direct it to more useful purposes.

Threat and appeasement

Ethologists have discovered a related set of behaviours in many species: ritualised **threat gestures** and **appeasement gestures**. Threat gestures enable an animal to communicate aggressive intent to another before engaging in actual violence. For example, if one dog intrudes on another's territory, the defender will growl and bare its teeth, raise the fur on its back (making it look larger to its opponent), and stare at the intruder. Almost always, the dog defending its territory will drive the intruder away. Threat gestures are particularly important in species whose members are able to kill each other (Lorenz, 1966; Eibl-Eibesfeldt, 1989). For example, wolves often threaten each other with growls and bared teeth but rarely bite each other. Because an all-out battle between two wolves would probably end in the death of one and the serious wounding of the other, the tendency to perform ritualised displays rather than engage in overt aggression has an obvious advantage to the survival of the species.

Aggression shows distinct sex differences. During play, young boys often display more aggression than do young girls (Fabes and Eisenberg, 1992). In an American longitudinal study of elementary and high school students, males were shown to be more aggressive than were females and patterns of aggression were found to be less stable for males than for females (Woodall and Matthews, 1993).

However, sex differences in aggression may vary in different cultures. In some cultures and subcultures, girls may join gangs that are involved in aggressive activities. For example, in Chihuahua, Mexico, a girl being initiated into a gang must fist-fight a gang member. Girl gangs often join their 'brother' gangs in defending their turf against other male gangs. Girl gangs also fight other girl gangs, and such fights may involve knife-fighting and rock-throwing as well as fist-fighting.

Hormones and aggression

In birds and most mammals, androgens appear to exert a strong effect on aggressiveness. Do hormones also influence aggressive behaviour in humans? Men are generally more aggressive than women (Knight *et al.*, 1996) although such differences are attenuated when factors such as provocation are considered (Bettencourt and Miller, 1996). The fact that a man's sexual behaviour depends on the presence

of testosterone suggests that this hormone may also influence aggressive behaviour. Some cases of aggressiveness – especially sexual assault – have been treated with drugs that block androgen receptors and thus prevent androgens from exerting their normal effects (Heim and Hirsch, 1979; Brain, 1984, 1994). The rationale is based on animal research that indicates that androgens promote both sexual behaviour and aggression in males. However, the efficacy of treatment with anti-androgens has yet to be established conclusively (Mazur and Booth, 1998).

Another way to determine whether androgens affect aggressiveness in humans is to examine the testosterone levels of people who exhibit varying levels of aggressive behaviour in the laboratory and outside the laboratory. Testosterone is secreted into the bloodstream sporadically and so changes in levels can be measured easily. Levels are greatest in the morning and lower in the afternoon (Dabbs, 1990). Clearly, in the laboratory it is unethical (and probably undesirable) to encourage aggression. Psychologists, therefore, have used measures that increase feelings of hostility rather than generate hostility itself and have reported a significant correlation between these measures and testosterone levels: increased testosterone levels were associated with increased feelings of hostility. Most studies, however, report negative results, that is, no relationship between testosterone level and hostility (Mazur and Booth, 1998).

Outside the laboratory, the findings are slightly different. Dabbs *et al.* (1987), for example, measured the testosterone levels of 89 male prison inmates and found a significant correlation between these levels and (1) the violence of the crime, and (2) their fellow prisoners' ratings of their toughness. These effects were also found in female prison inmates. Dabbs *et al.* (1988) found that women prisoners who showed unprovoked violence and had several prior convictions also showed higher levels of testosterone. It is reported that 17–18-year-old criminals with high testosterone levels were more likely to have committed violent crimes and to have violated prison rules (Dabbs *et al.*, 1991). The picture is not entirely uniform, however. One study found no significant difference between the testosterone levels of those individuals charged with violent offences and those charged with property crime (Bain *et al.*, 1987).

In an experimentally controlled study, researchers have noted that losing a tennis match or a wrestling competition causes a fall in blood levels of testosterone (Mazur and Lamb, 1980; Elias, 1981). In a very elaborate study, Jeffcoate *et al.* (1986) found that the blood levels of a group of five men confined on a boat for 14 days changed as they established a dominance-aggression ranking among themselves: the higher the rank, the higher the testosterone level was. Increases have also been reported in individuals about to play a chess match, with

greater increases found in winners than losers after the match (Mazur *et al.*, 1992), and in Brazilian supporters who saw their team on television win the 1994 World Cup Final against Italy; the (losing) Italian viewers showed relatively lower levels (Fielden *et al.*, 1994, cited in Mazur and Booth, 1998).

Testosterone seems to have masculinising (androgenic) and anabolic (building protein tissue) effects. Some athletes take anabolic steroids in order to increase their muscle mass and strength and, supposedly, to increase their competitiveness. Anabolic steroids include natural androgens and synthetic hormones having androgenic effects. Several studies have found that anabolic steroids increase aggression. For example, Yates *et al.* (1992) found that male weightlifters who were taking anabolic steroids were more aggressive and hostile than those who were not. But, as the authors note, we cannot be certain that the steroid is responsible for the increased aggressiveness; it could simply be that the men who were already more competitive and aggressive were the ones who chose to take the steroids.

Testosterone and dominance

What could account for the relationship between testosterone and aggression? Mazur and Booth (1998) have recently proposed that a reciprocal relationship exists between these two factors. Specifically, high levels of testosterone encourage dominant behaviour which maintains high status. The model is reciprocal because testosterone and dominance are seen as reinforcing each other in contrast to the basal model which suggests that the individual has a static, basal level of testosterone which routinely predicts his behaviour. These authors suggest that reciprocal relationships can obviously only be observed across time and at different testing points. They point to a study in which testosterone levels in American Air Force veterans were low during marriage but increased during divorce as evidence for their model (Mazur and Michalek, 1998). The authors interpreted this finding in terms of competition. Divorce is a stressful, but competitive, process. Marriage, on the other hand, is a positive experience, free of competition and – if successful – stress.

The way in which women view themselves is directly related to the degree of testosterone they secrete (Grant and France, 2001). Women with the higher levels of testosterone used more 'dominant' adjectives to describe themselves than did those with lower levels, providing additional evidence for a link between testosterone and dominance. There is also an unusual link between testosterone and communication. Men high in testosterone are less likely to get married, more likely to get divorced and report a lower quality of interaction in marriages they stay in (or leave). Testosterone, it has been argued, promotes simple thinking

and not abstract, subtle or complex thought. This, of course, is highly controversial and is based on indirect evidence. Pennebaker *et al.* (2004) correlated testosterone level with natural written language in two people who were undergoing testosterone therapy for the development of upper body strength (male) or as part of a transgender procedure (female). The longer the time since the last testosterone injection, the fewer words describing social relations were used in the participants' text.

Testosterone: status, relationships and empathy

People showing comparatively high and low levels of testosterone tend to react differently in simple social settings, suggesting that the hormone plays some part in assertiveness (Dabbs *et al.*, 2001). Dabbs *et al.* found that participants with low testosterone looked around a room more when entering (to the left and the exit) and focused less frequently on a camera present than did high-testosterone participants.

There is evidence that when high testosterone-level persons feel that their status is threatened, they try to regain this quickly – usually through physical challenge. Researchers have also begun to examine the mismatch effect – where people normally low in testosterone are placed in positions of great status.

In one experiment, researchers placed high and low testosterone students in high and low status positions – making sure they completed a short or long version of a spatial intelligence test accurately (Josephs *et al.*, 2006). Those who completed the task first would put their hand up and say 'done' thus signalling status: they were intellectually superior.

Low testosterone individuals were more emotionally aroused, focused more on their status and performed worse on the test if they were in the high status position. The same pattern was seen in the high testosterone individuals only when they were in the low status position, thus demonstrating the mismatch effect. The same effect for emotional arousal and poor cognition was replicated in a separate experiment with a different type of cognitive test (mathematics) and when heart rate was measured. In a final experiment, the researchers found that levels of testosterone were better predictors of dominance than were self-report measures such as questionnaires.

What are the implications of these findings? 'It is possible that after an increase in status', say Josephs *et al.*, 'a person's physiology will gradually change in concert to the new position. . . . When testosterone increases, this informs the individual that the environment is safe for further attempts at maintaining or enhancing status. When testosterone decreases, the individual is being flashed a sell signal and should flee the situation to avoid further loss of status' (p. 1011).

Does being with a partner increase or decrease a person's testosterone level? A study by Canadian researchers measured testosterone in men and women who were single, in long-distance relationships or in relationships with people living in the same city. Testosterone was higher in single men than those in relationships (whether long-distance or same-city). Testosterone was lower in women with same-city partners than single women or those with long-distance relationships. The results suggest that hormone levels can increase or decrease depending on a person's relationship status. A cross-sectional and longitudinal study of heterosexual and 'non-heterosexual' men and women has reported that testosterone was lower in heterosexual men and non-heterosexual women (but not non-heterosexual men and heterosexual women) (van Anders and Watson, 2006). The longitudinal study found that having a partner was associated with low testosterone: those with low testosterone were more likely to be partnered at follow-up.

Having a high level of testosterone has also been associated with lack of empathy, although whether it causes this lack of empathy or whether it is only correlated with it is open to question. To test this hypothesis, Hermans *et al.* (2006) administered testosterone to 20 healthy women whose facial muscles were recorded while they observed happy and angry faces. Empathy was measured by participants' mimicry of others' facial expression of emotions. Testosterone was found to be associated with a decrease in facial mimicry, suggesting that the hormone has a role in empathy.

Imitation and aggression

A large percentage of non-violent people may have been hit or punished at least once when they were children, with no obvious harm. But when parents habitually resort to aggression, their children are likely to do the same. In the extreme case of child abuse, parents who beat their children usually turn out to have been victims of child abuse themselves; this unfortunate trait seems to be passed along like an unwanted family heirloom (Parke and Collmer, 1975).

Another factor which is thought to influence aggression in children is exposure to violence on television, in films, video games and in comics. Does the continued observation of violence in the mass media lead children to choose aggressive means to solve their problems? Or are the television companies' representatives correct when they argue that children have no trouble separating fact from fantasy and that the mass media only give us what we want anyway?

Field studies suggest that long-term viewing of violence on television is associated with an increase in children's violent behaviour. For example, Lefkowitz *et al.* (1977) observed a correlation of 0.31 between boys' viewing of

Psychology in action – Aggression at work

Sometimes, work isn't as pleasant as it should be. You turn up to work in a bad mood: it's raining, you overslept, you had too many bill reminders in the post, your train was half an hour late (for which you are told off), the ticket assistant was rude to you, your boss appears to be irritated with you and all morning you've had the most annoying customers in the world on the phone or at your cash desk. These slings and arrows may make you wonder why you're doing the job you're doing. These quotidian irritations pale into insignificance, however, compared to real workplace troubles – assault and murder.

Aggression in the workplace has been studied for some years, and was pioneered in Europe by research in Scandinavia, but we still know too little about how to prevent it. Or, perhaps more pertinently, employers still do too little to put what we know about it into practice.

Workplace aggression refers to psychological acts (such as shouting) and physical assault that can harm another or cause offence in the workplace (Dupre and Barling, 2003). One researcher has specifically characterised workplace aggression as involving either expressions of hostility (which can be verbal or non-verbal, such as giving someone the 'silent treatment'); acts of obstruction (deliberately hampering a person's ability to do their job); and overt physical aggression (Baron *et al.*, 1999).

The chances of your being verbally or physically assaulted by a work colleague, however, are comparatively rare. In fact, most aggression in the workplace is committed by members of the public (customers) or people outside the company. In 1997, 866 Americans were murdered at work; 85 per cent of these murders were committed by outsiders (US Bureau of Labor Statistics, 1998). A study of eight Californian cities found that 90 per cent of non-fatal assaults were caused by non-workmates (Peek-Asa *et al.*, 2001).

In a review, LeBlanc and Barling (2004) highlighted some of the causes of workplace aggression (and, therefore, how aggression could be reduced)

LeBlanc and Barling have identified four types of aggression. Type I aggression involves an assailant that is not remotely related to the victim (those most at risk are people who handle money with members of the public). Type II aggression involves an assailant who has a legitimate relationship with the organisation (e.g. a customer). Type III aggression involves an offence where the aggressor is a current or former employee of the

company or organisation. The fourth type involves aggression by a current employee against another.

Psychologically, the last two types may be the more interesting and important to explore because whereas you might expect a degree of irritation and anger from customers (as you might have felt when listening to your rude ticket assistant), you can take physical steps to protect yourself against them. It is more difficult to protect yourself physically from work colleagues – largely because there should be no need to because you are working together.

So, what predicts workplace aggression? Several factors appear to be involved. Being under surveillance, for example, increases aggression towards an employee's supervisor but not colleagues (Greenberg and Barling, 1999).

The two most important predictors, however, are alcohol consumption and perceived organisational injustice. Organisational injustice refers to perceived wrongdoing or unfairness by the company and/or supervisors. These two factors have been found to predict aggression against colleagues and subordinates. Excessive drinking can also interact with job insecurity to produce aggression towards colleagues: those who don't feel secure in their job and drink excessively are more likely to be aggressive than heavy drinking people who are more secure in their job. These feelings of insecurity and aggression increase if people feel they are being mistreated (Jockin *et al.*, 2001).

A sense of justice is important to every employee. We expect to be treated with politeness, dignity and respect. Supervisors who are perceived as abusive were likely to see their employees quit. But those who remain, and still felt that they were being abused, were likely to be less satisfied with life and would experience more psychological distress and conflicts between work and family (Tepper, 2000). These are the people likely to show less job commitment and satisfaction. Those who felt they could find other jobs felt better.

The conclusion from the studies reviewed by LeBlanc and Barling (2004) seems clear. A happy workforce is one where supervisors are not over-controlling, where decision-making is transparent, where employees' views are respected and addressed (not simply acknowledged and disregarded), where people are not prevented from doing their job properly and where individuals are appropriately rewarded for their efforts. It all seems quite simple, doesn't it?

violence and their later behaviour. They reported that the greater the boys' preference for violent television at age 8, the greater their aggressiveness was both at that age and ten years later, at age 18. Girls were found to be much less aggressive, and no relation was observed between television viewing and violence.

Feshbach and Singer (1971) carried out a bold and interesting field study in an attempt to manipulate directly the amount of violence seen by boys on television, and thus to determine whether the viewing would affect their later aggressiveness. With the cooperation of directors of various private boarding schools and homes

for neglected children, half the teenage boys were permitted to watch only violent television programmes, the other half only non-violent ones. Six months later, no effect was seen on the behaviour of the boys in the private schools. The boys in the homes for neglected children who had watched violent programmes tended to be slightly less aggressive than subjects who had watched the non-violent ones.

Two factors prevent us from concluding from this study that violent television programmes promote pacifism or at least have no effect. First, by the time people reach their teens, they may be too old to be affected by six months of television viewing; the critical period may come earlier. Secondly, some of the boys resented not being allowed to watch their favourite (in this case, violent) television programmes, and this resentment may have made them more aggressive. As with many other complex social issues, we lack definitive evidence that television violence makes people more aggressive.

Emotion

Most psychologists who have studied emotion have focused on one or more of the following questions: What kinds of situations produce emotions? What kinds of feelings do people say they experience? What kinds of behaviours do people engage in? What physiological changes do people undergo in situations that produce strong emotions? What exactly is an emotion?

The word ‘emotion’ comes from Latin and means ‘to move’ or ‘to stir up’. In general terms, **emotion** is used by psychologists to refer to a display of feelings that are evoked when important things happen to us. Emotions are relatively brief and occur in response to events having motivational relevance (or to their mental re-creation, as when we remember something embarrassing that we did in the past and experience the feelings of embarrassment again). Emotions are the consequence of events that motivate us. When we encounter reinforcing or punishing stimuli, stimuli that motivate us to act, we express and experience positive or negative emotions. The nature of the emotions depends on the nature of the stimuli and on our prior experience with them.

There are problems, however, associated with defining emotions. We have a multitude of ways of expressing what we think are emotional behaviours. Davitz (1970), for example, found 556 words and phrases that were emotion-related.

Some psychologists view emotion as being produced by reinforcing stimuli or by a set of interacting brain regions or by our awareness of bodily feelings. Given the disparate nature of these definitions, LeDoux (1995b) was right

when he concluded that emotion had ‘proved to be a slippery concept for both psychologists and neuroscientists’.

If the definition is unclear, then perhaps we can agree on examples of emotions and can describe a core set of basic, fundamental emotions. Yet, even here, the evidence is ambiguous. There are psychologists who have argued that a set of basic emotions exists (Ekman, 1973; Izard, 1977, 1992; Plutchik, 1980). The number of basic emotions has ranged from six or seven (Ekman, 1984, 1992) to eight (Plutchik, 1980), to ten (Izard, 1992). To Ekman, the basic emotions are sadness, joy (happiness), surprise, fear, anger, disgust and contempt (or fear), and these can be universally seen in facial expression (see Figure 13.10).

To Plutchik, the basic emotions are fear/terror, anger/rage, joy/ecstasy, sadness/grief, acceptance/trust, disgust/loathing, expectancy/anticipation and surprise/astonishment. There are other psychologists who have argued that because we have no satisfactory criteria on which to base any concept of ‘basic-ness’ then we cannot conclude that any emotions we care to list are basic ones (Ortony and Turner, 1990). Yet others argue that the methods used to determine basic emotions are flawed and that the findings are not wholly conclusive (Russell, 1994; cf. Ekman, 1994). What, therefore, is the evidence for basic emotions?

Basic emotions

Charles Darwin (1872) suggested that human expressions of emotion have evolved from similar expressions in other animals. He said that emotional expressions are innate, unlearned responses consisting of a complex set of movements, principally of the facial muscles. Thus, a man’s sneer and a wolf’s snarl are biologically determined response patterns, both controlled by innate brain mechanisms, just as coughing and sneezing are. Some of these movements resemble the behaviours themselves and may have evolved from them. For example, a snarl shows one’s teeth and can be seen as an anticipation of biting.

Darwin performed what was probably the first cross-cultural study of behaviour. He obtained evidence for his conclusion that emotional expressions were innate by observing his own children and by corresponding with people living in various isolated cultures around the world. He reasoned that if people all over the world, no matter how isolated, show the same facial expressions of emotion, these expressions must be inherited instead of learned. The logical argument goes like this. When groups of people are isolated for many years, they develop different languages. Thus, we can say that the words that people use are arbitrary; there is no biological basis for using particular words to represent particular concepts. However, if facial

Figure 13.10 The six basic emotions shown in facial expression, and a combination of two, as suggested by Ekman.

Source: From Pinel, John P.J., *Biospsychology*, 3rd edn © 1997. Published by Allyn and Bacon, Boston, MA. Copyright © by Pearson Education. By permission of the publisher.

expressions are inherited, they should take approximately the same form in people from all cultures, despite their isolation from one another. And Darwin did, indeed, find that people in different cultures used the same patterns of movement of facial muscles to express a particular emotional state. Of the basic emotions that we experience most often, it has been argued that sadness and happiness are the two most common. Recent research, however, suggests that we may experience happiness more often than was

originally thought. Studies also suggest that the degree of positive mood that we exhibit in our facial expression may correlate with other expressions of positive behaviours in our lives. The Controversies in Psychological Science section below reviews this research.

The biology of emotion

Perhaps one way of determining whether an emotion is basic or not is by observing the neural machinery activated by these so-called basic emotions. If these emotions are distinct then it follows that different brain regions or pathways might mediate them. In animal research, much of the work on understanding the neural correlates of emotion has focused on fear because this emotion is easy to condition in the laboratory. Evidence from animal work and from studies of brain-damaged humans suggests that the amygdala is an important structure for the recognition and expression of fear. Other neuropsychological evidence suggests that other brain regions may also be involved in different types of emotion.

All emotional responses contain three components: behavioural, autonomic and hormonal. The behavioural component consists of muscular movements that are appropriate to the situation that elicits them. For example, a dog defending its territory against an intruder first adopts an aggressive posture, growls and shows its teeth. If the intruder does not leave, the defender runs towards it and attacks. Autonomic responses – that is, changes in the activity of the autonomic nervous system – facilitate these behaviours and provide quick mobilisation of energy for vigorous movement. As a consequence, the dog's heart rate increases, and changes in the size of blood vessels shunt the circulation of blood away from the digestive organs towards the muscles. Hormonal responses reinforce the autonomic responses. The hormones secreted by the adrenal glands further increase heart rate and blood flow to the muscles and also make more glucose available to them.

One of the more important neurotransmitters for emotion is dopamine. When we experience even a slight lift in our mood – or positive affect – the increase is accompanied by an increase in dopamine in two of the major pathways that send dopamine projections to the brain. This does not mean to say that no dopamine was being carried along these pathways in the first place – there are levels of dopamine in the brain, even at rest – but it does mean that a change in behaviour resulted in an increase in these levels.

Emotional responses, like all other responses, can be modified by experience. For example, we can learn that a particular situation is dangerous or threatening. Once the learning has taken place, we will become frightened when we encounter that situation. This type of response,

acquired through the process of classical conditioning, is called a conditioned emotional response. A **conditioned emotional response** is produced by a neutral stimulus that has been paired with an emotion-producing stimulus. If an organism learns to make a specific response that avoids contact with the aversive stimulus (or at least minimises its

painful effect), most of the non-specific ‘emotional’ responses will eventually disappear. That is, if the organism learns a successful coping response – a response that terminates, avoids or minimises an aversive stimulus – the emotional responses will no longer occur.

Controversies in Psychological Science – What is the key to enduring happiness?

The issue

Freud, in one of his more perspicacious moments, once remarked that our common mental state is unhappiness. This we punctuate with attempts, of varying success, at relieving it. The American Declaration of Independence accords the right to all American citizens the ‘pursuit of happiness’. The intuitive psychology behind this right seems to be the belief that we all deserve happiness and should pursue it without hindrance. This, however, is easier said than done. Research shows that lottery winners have a short-term boost in well-being but no significant long-term increase in happiness. That said, the famous North American Nun study (a longitudinal study of ageing and Alzheimer’s disease in nuns from the School Sisters of Notre Dame) found an association between positive thoughts expressed in handwritten diaries and longer living (Danner *et al.*, 2001).

The evidence

A recent study by Zelenski and Larsen (2000) reported that, contrary to the view that we make sporadic attempts at happiness injections, positive emotions are the ones we experience most frequently during the day. For three times a day over the course of a month, their 82 undergraduates reported the degree of various emotions that they experienced. The researchers found that positive emotions dominated the participants’ self-reports, as Table 13.1 shows.

The intensity and frequency of positive emotions far outnumbered negative emotions. The researchers also found that some emotions were frequently experienced together. Examples included fear and sadness, sadness and anger, and anger and disgust. Jealousy was the most commonly experienced secondary emotion.

Would people who outwardly express positive emotions also show high degrees of positive affect in their ‘inner’ life? To try to answer this question, Harker and Keltner (2001) took the unusual step of taking photographs of women printed in their college yearbook and relating the degree of affect expressed in their faces to personality later in life. Ratings of the women’s disposition was also obtained from independent observers.

Table 13.1 The frequency of types of emotion experienced in everyday life by 5,642 respondents. 0 = experienced not at all; 7 = experienced very much

Emotion	Mean frequency
Excited	1.73
Interested	1.80
Enthusiastic	1.84

Frustrated	1.13
Anxious	1.21
Disgusted	0.35
Angry	0.47
Afraid	0.30

Source: Adapted from Zelenski, J.M. and Larsen, R.J., The distribution of basic emotions in everyday life: A state and trait perspective from experience sampling data. *Journal of Research in Personality*, 2000, 34, 178–197.

High degrees of positive affect expressed in the photographs correlated with self-reported traits of affiliation, competence and low negative affect. Positive facial expression was also positively correlated with having a good marriage and enhanced well-being, up to 30 years after the photograph was taken. When observers rated the personalities of the women based only on information provided by the yearbook photographs, women showing positive affect were judged more positively. These were the women with whom observers expected to have more rewarding exchanges.

The researchers admit that the measure of positive emotional expression was very limited. They say that ‘it is hard to think of a thinner slice of behaviour’. They also concede that the study focused on women exclusively.

Controversies in Psychological Science – *Continued*

The results of the study, however, are consistent with another showing that very happy people are likely to have stronger social and romantic relations than their less happy counterparts. Diener and Seligman (2002) screened 222 undergraduates for self-reported happiness and compared the 10 per cent who scored most highly on happiness and well-being measures ($N=22$) with a sample of those who scored in the average range ($N=60$) or below-average ($N=24$). Comparison measures included personality, social relations, romantic relations, exercise and psychopathology.

Very happy people were found to have a rich social life and to spend less time alone than did the moderately happy people. They had stronger romantic and social relationships than did the less happy groups and were more extraverted, agreeable and less neurotic. Unhappy people's social relations were worse than moderately happy people's. The very happy people did not experience a greater number of objectively defined good events in their lives than did the other groups but no one factor was sufficient for happiness, that is, there was no one factor which was common to all very happy people. Even the very happy people were not consistently happy – they occasionally experienced negative moods.

Sheldon and Houser-Marko (2001) sought to see whether people who pursued and attained happiness, actually sustained this sense of happiness. The authors referred to the 'self-concordance model' to underpin their research. This model suggests that the intrinsically motivated personal goals we set ourselves will lead to greater happiness and a sense of fulfilment than will goals that seem to be determined by context or environment.

North American undergraduates were contacted at the beginning of their university course and asked to rate their adjustment to college life and to generate eight personal goals. Parents were also contacted at this point and asked how well they thought their children would adjust to college life. Halfway through the semester, the students were con-

tacted again and asked how well they had pursued their goals. The adjustment measure was taken later in the semester. In the January following this exercise, participants generated goals again for the second semester (they were allowed to keep the goals set in semester 1). Two months later, the students were asked to rate how well they had achieved their goals. They were also asked to give their peers questionnaires which evaluated the students' ability to adjust and students' success in achieving adjustment.

Students who were self-concordant, that is, set goals that were personally meaningful, were more likely to achieve their goals. Greater attainment in semester 1 predicted increased feelings of self-concordance in semester 2. Those most likely to achieve their goals in semester 2 showed best adjustment and sense of growth at the end of the study. They were also likely to have a higher average mark across all courses, even though the goals may not have been specifically class-related.

The experimenters suggest that the new level of well-being brought about by goal attainment may extend to further semesters, and studies are needed to answer this question and to see whether older students show the same pattern of achievement as their younger counterparts.

More recently, the Framingham study (which is the study described in the vignette in the chapter opening) has found that people who surround themselves with happy people who are central to their social network are more likely to be happy in future (Fowler and Christakis, 2009). In the study, 4,739 individuals were studied from 1983 to 2003.

Conclusion

The secret to generating happiness, however, remains elusive. As Diener and Seligman conclude: 'There appears to be no single key to high happiness that automatically produces this state . . . High happiness seems to be like beautiful symphonic music – necessitating many instruments, without any one being sufficient for the beautiful quality.'

Emotion – An international perspective

In the late 1960s, Ekman and Friesen undertook a series of cross-cultural observations that validated those of Darwin (Ekman *et al.*, 1972). They visited an isolated tribe in a remote area of New Guinea – the South Fore tribe, a group of 319 adults and children who had never been exposed to Western culture. If they were able to identify accurately the emotional expressions of Westerners as well as they could identify those of members of their own tribe, and if their own facial expressions were the

same as those of Westerners, then the researchers could conclude that these expressions were not culturally determined.

Because translations of single words from one language to another are not always accurate, Ekman and Friesen told little stories to describe an emotion instead of presenting a single word. They told the story to a subject, presented three photographs of Westerners depicting three different emotions, and asked the subject to choose the appropriate one. This they

were able to do. In a second study, Ekman and Friesen asked Fore tribespeople to imagine how they would feel in situations that would produce various emotions, and the researchers videotaped their facial expressions. They showed photographs of the videotapes to American college students, who had no trouble identifying the emotions. Four of them are shown in Figure 13.11. The caption describes the story that was used to elicit each expression. Table 13.2 shows the degree of accuracy of various cultures at recognising facial expressions of emotion.

However, not all psychologists have agreed with Ekman's conclusions. While the finding that facial expressions can be identified cross-culturally is robust, there is little agreement on what these findings mean. Zajonc (1985), for example, has suggested that facial expressions are epiphenomena – not important of themselves and, in fact, serving another purpose, such as conveying social information. Critics such as Fridlund (1992, 1994) have argued that all facial expressions are commu-

nicative and that to single out a group of emotional facial expressions ignores the fundamental social nature of facial expression. Expressions may not be emotional signals but social tools used for communications: we can communicate happiness or approval via a smile but this smile may not be generated by genuine emotion but by social cues or needs. This objection is difficult, in part, to counter because expressions may sometimes be used for non-emotional purposes. Smiling may indeed be an expression of joy, but it can also be an expression of sarcasm or even, in sinister contexts, threat. What critics suggest is that facial expressions do not reflect the emotion but the social signalling of the emotion; the two are different.

Other critics, such as Russell (1991, 1994), have even questioned whether the cross-cultural findings are robust. Russell has argued in some detail that the faults in the methodology in these experiments, particularly the method of presenting each emotion sequentially and asking respondents to choose from a list of alternative descriptions the expression they have seen, make the conclusions of these studies uninterpretable.

Two large-scale explorations of emotion recognition and experience across cultures, suggest that there is great consistency between cultures but there are also specific differences between them. Members of individual cultures, for example, may be more accurate in judging emotions in the faces of people from their own culture (or 'in-group').

European American, Asian American, Japanese, Indian and Hispanic students were asked to report their emotional experiences over a one-week period and indicate how many pleasant and unpleasant emotions they generally experienced (Scollon *et al.*, 2004). Individuals from Asian cultures reported less life satisfaction and fewer pleasant emotions than did North Americans, a finding also evident within a nation – Asian Americans showed this pattern more than did European Americans, for example (Diener *et al.*, 1995; Okazaki, 2000).

Emotion – Continued

The group also found other significant differences between cultures. Hispanic Americans reported greatest levels of pride, whereas the three Asian samples reported the least, with the Indian sample reporting the least within these (suggesting that pride is not greatly valued in these cultures and may be a negative emotion rather than a positive one). No cultural differences emerged for sadness but did for guilt. Japanese and Asian Americans reported greater levels of guilt than did the European Americans and Hispanics. The Indian sample reported the least guilt. The three Asian cultures reported significantly fewer pleasant emotions (and more negative emotions) than did the other cultures.

The notion that there is an in-group advantage for recognising emotions has been challenged (Beaupre and Hess, 2005). These Canadian researchers measured emotional recognition in a sample of French-Canadian, sub-Saharan Africans and Chinese participants living in Canada. All samples performed similarly when asked to recognise expressions of emotion in the in-group and out-group faces but some groups were better at this task in general (regardless of the nationality of the face). The French-Canadians recognised sadness more accurately than did the other two cultures and recognised shame more accurately than did the Chinese. The authors argue that

because the stimuli used in the experiment derive from North American investigations, this benefited the French-Canadians and might explain their accuracy.

A study of native Japanese and American Japanese people's facial expression suggests that aspects of facial expression can be a clue to cultural background and can be used a bit like phonetic accents: subtle communication cues that reveal a person's background (Marsh *et al.*, 2003). Around 80 American and Canadian undergraduates, largely native white participants, were asked to determine the cultural background of American Japanese and native Japanese people based on facial expressions of emotion. If culture/background produced differences in facial expression, these might be seen as non-verbal 'accents'.

While participants could distinguish between cultures when the faces expressed an emotion, they were poor at doing so when the facial expressions were neutral. This, the authors suggest, indicates that people can judge the cultural background of people based on their facial expression of emotion just as they would do so based on a person's accent. It would be interesting to examine how important such a cue can be – would it predict our ability to distinguish between English-speaking Scots, Welsh, Irish or English people, for example?

The amygdala

The amygdala, located in the temporal lobe, just in front of the hippocampus, plays an important role in the expression of conditioned emotional responses. According to Aggleton and Mishkin (1986), it represents 'the sensory gateway to the emotions'. It serves as a focal point between sensory systems and the systems responsible for behavioural, autonomic and hormonal components of conditioned emotional responses (Kapp *et al.*, 1982; LeDoux, 1995a). (The location of the amygdala can be seen in Chapter 4, Figure 4.36.)

Many studies have found that damage to the amygdala disrupts the behavioural, autonomic and hormonal components of conditioned emotional responses. After this region has been destroyed, animals no longer show signs of fear when confronted with stimuli that have been paired with aversive events (LeDoux, 1995a, 1996). LeDoux and his group have identified two routes by which conditioning to fear can occur. The first is a direct – fast and dirty – route linking the thalamus to the amygdala and a second, slower route which links the two via the visual or auditory cortex (depending on the type of stimulus). The first carries the emotional content of the conditioning; the second carries the sensory content. Take a look at Figure 13.12 to see how this system would operate when a person sees a snake.

When the amygdala is stimulated by means of electricity or by an injection of an excitatory drug, animals show physiological and behavioural signs of fear and agitation. Long-term stimulation of the amygdala produces gastric ulcers (Henke, 1982). These observations suggest that the autonomic and hormonal components of emotional responses controlled by the amygdala are among those responsible for the harmful effects of long-term stress.

Figure 13.12 What happens in the brain when we fear a snake. LeDoux's model suggests that there are two pathways in the brain which mediate this response. Both are highlighted here.

Source: Science Photo Library Ltd./Claus Lunan/Bonnier Publications

The role of the amygdala in human emotion

The effects seen in animals are mirrored in humans. Individuals with damage to the amygdala are unable to recognise fear in facial expressions, are unable to draw a fearful expression (although they can draw other emotional expressions) and are impaired at recognising fear by sound (Adolphs *et al.*, 1994, 1995, 1999; Calder *et al.*, 1996; Scott *et al.*, 1997; Brooks *et al.*, 1998).

Neuroimaging data suggest that the amygdala is relatively more involved than other brain regions in the perception of fear-related material. Morris *et al.* (1996) reported that not only did activation increase in the left side of the amygdala when individuals were watching fearful facial expressions but they also found that this activation was greater when the facial expression was more intense. Other fMRI and PET studies have confirmed this activation in the amygdala during the perception of fear in facial expression (Morris *et al.*, 1998), and in the perception of sad expressions, but not angry ones (Blair *et al.*, 1999). Adolphs *et al.* (1999) reported a case study of a 31-year-old woman who sustained damage to both sides of her amygdala. They asked her to rate facial expressions, words and sentences along two dimensions: how arousing they were and how pleasant they were. While she was able to distinguish pleasant from unpleasant emotions, she was unable to recognise emotional arousal in those expressions conveying negative emotions, specifically fear and anger. The authors argue that these results support a role for the amygdala in responding to highly negative, threat-related stimuli that require quick responses, although there are results showing that if we keep negative thoughts in mind, this maintenance, and the subsequent bad feeling it generates, is associated with increases in amygdala activity (Schaefer *et al.*, 2002).

Patients with amygdala damage are significantly poor at identifying social (hostility, friendliness) or cognitive (pensiveness) expressions in faces, although they make judgements about the physical appearance of the faces (Shaw *et al.*, 2005). Patients with damage to the right frontal lobe were poor at interpreting social expressions that were negatively hued, regardless of which part of the frontal lobe was damaged.

The amygdala's role in emotion does not appear to be tied to recognising or generating negative emotion. Viewing positive stimuli has also been found to be associated with a significant increase in activation in the left side of the amygdala; this activation also extends to other brain areas known to be involved in drug addiction and reward (Hamann *et al.*, 2002). Watching diseased and mutilated bodies stimulated both sides of the amygdala (but little beyond it). The notion that the amygdala is active when

encoding and retrieving positive memories suggests that its role here may be due to its role in remembering positive events. That said, the amygdala has many parts (and parts that PET may not have been sensitive enough to measure), and Hamann *et al.* suggest that different regions within the structure may play different roles.

The amygdala is not the only region to be involved in mediating human emotional response. Perceiving the meaning of social situations is obviously more complex than perceiving individual stimuli, such as the expression of fear on people's faces; it involves experiences and memories, inferences and judgements. These skills are not localised in any one part of the cerebral cortex, although research does suggest that one region of the brain – the orbitofrontal cortex – appears to play a special role.

The orbitofrontal cortex and emotion

The orbitofrontal cortex (OFC) is located at the tip of the frontal lobes (see Figure 13.13). It covers the part of the brain just above the orbits – the bones that form the eye sockets – hence the term 'orbitofrontal'. The orbitofrontal cortex receives information from the sensory system and from the regions of the frontal lobes that control behaviour. Thus, it knows what is going on in the environment and what plans are being made to respond to these events. It also communicates extensively with the limbic system, which is known to play an important role in emotional reactions. In particular, its connections with the amygdala permit it to affect the activity of the amygdala, which, as we saw, plays a critical role in certain emotional responses.

Neuroimaging studies implicate the orbitofrontal cortex in emotion. One experiment compared those brain regions that were activated during pleasant or neutral touch, smell and taste (Francis *et al.*, 1999). Participants had their hands stroked by either a velvet glove or a piece of wood as their brain activity was monitored. The pleasant touch (velvet) was associated with significantly greater activation in the orbitofrontal cortex than was the neutral touch (wood). The more intense touch (the neutral wood) was associated with activation in the part of the brain that represents touch. When participants tasted the pleasant sensation of glucose and the pleasant aroma of vanillin, similar but different parts of the orbitofrontal cortex were activated, as were other parts of the brain.

The strongest evidence for the involvement of the orbitofrontal cortex in emotion, however, comes from individuals who have suffered injury to the area. The first – and most famous – case was reported in the mid-nineteenth century and you read about him in Chapter 1. Phineas Gage, the railroad worker, was using a steel rod to ram a charge of dynamite into a hole drilled in solid rock. The

Figure 13.13 The orbitofrontal cortex.

Source: Science Photo Library.

charge exploded and shot the rod into his cheek, through his brain and out of the top of his head. He survived, but he was a different man. Before his injury, he was serious, industrious and energetic. Afterwards, he became childish, irresponsible, boorish and thoughtless of others (Harlow, 1848, 1868). He was unable to make or carry out plans, and his actions appeared to be capricious and whimsical. His accident largely destroyed the orbitofrontal cortex (Harlow, 1848;

Table 13.3 Some of the personality changes that can follow frontal lobe injury

Exaltation/depression

Damasio *et al.*, 1994). Figure 13.14 shows the plotted trajectory of the iron rod through Gage's head.

Over the succeeding years, physicians reported several cases similar to that of Phineas Gage. In general, damage to the orbitofrontal cortex reduced people's inhibitions and self-concern; they became indifferent to the consequences of their actions. A list of the behaviours associated with orbitofrontal cortex damage appears in Table 13.3.

Given the large list of impairments in Table 13.3, what exactly is the role of the orbitofrontal cortex in emotion? Eslinger and Damasio (1985) found that their patient, EVR, who sustained bilateral damage of the orbitofrontal cortex displayed excellent abstract social judgement. When he was given hypothetical situations that required him to make decisions about what the people involved should do – situations involving moral, ethical or practical dilemmas – he always gave sensible answers and justified them with carefully reasoned logic. However, his personal life was a disaster.

EVR frittered away his life savings on investments that his family and friends pointed out were bound to fail. He lost one job after another because of his irresponsibility. He became unable to distinguish between trivial decisions and important ones, spending hours trying to decide where to have dinner but failing to use good judgement in situations that concerned his occupation and family life. As the authors noted, 'He had learned and used normal patterns of social behaviour before his brain lesion, and although he could recall such patterns when he was questioned about their applicability, real-life situations failed to evoke them' (p. 1737). Recall from the section on reasoning and the brain in Chapter 11, that Damasio proposed a somatic marker hypothesis of orbitofrontal cortex function. This suggests that our ability to make social and emotional decisions depends on our being able to make sense of somatic information that the body generates in response to specific events. If we are making a risky decision, this risk will be associated with a physiological response which will reflect our uncertainty about the decision we have made. In frontal lobe patients, Damasio argues, these connections between somatic states and an appreciation of them, are missing.

The type of behaviour seen in EVR is also seen in many patients with orbitofrontal cortex damage. Hornak *et al.* (1996) found that their group of patients with frontal lobe damage were impaired at identifying facial and vocal emotional expression. Some of the comments made by orbitofrontal lobe patients on their disorder might help to illuminate the phenomenology of the social impairment – it shows us in very personal terms how the brain damage has affected that person's behaviour. Some of the comments made by Hornak *et al.*'s patients appear in Table 13.4.

<p>Case 2</p> <p>‘If I have something to say, I can’t wait and have to say it straight away.’</p>
<p>Case 4</p> <p>‘Emotion, tears, that’s all gone out of the window. If I saw someone cry I’d just laugh – people look really silly getting upset.’</p> <p>‘I’m much more aggressive and I feel less fear. I go fighting for no reason.’</p> <p>‘Since I’ve taken up body building, I tend to show off a bit.’</p>
<p>Case 5</p> <p>‘Anger and irritability had increased; anxiety had decreased.’</p>
<p>Case 7</p> <p>‘I ain’t scared of nobody. I’m not frightened of opening my mouth and speaking my mind. If I think someone’s in the wrong, I’ll tell them and not give a monkey’s what they think of me.’</p>
<p>Case 8</p> <p>‘I’m not the woman he married; much more outspoken.’</p>

Source: Adapted from Hornak, J., Rolls, E.T. and Wade, D., Face and voice expression identification in patients with emotional and behavioural changes following ventral frontal lobe damage. *Neuropsychologia*, 1996, 34(4), 247–61.

Emotional processing deficits and social conduct problems seen in frontal lobe patients most often accompany damage to the right (ventromedial) prefrontal cortex, rather than the left (Tranel *et al.*, 2002). Patients with damage to the left side show normal skin conductance response when faced with the risky gambling task described in Chapter 11 and show little antisocial behaviour. Those with damage to the right side, however, show reduced skin conductance to the gambling task and meet the criteria for antisocial personality disorder, suggesting that the right prefrontal cortex plays a more involved role than the left in emotional regulation. The idea that the prefrontal cortex responds asymmetrically during the experience of emotion is reviewed, in a slightly different context, below.

Some patients with frontal lobe damage are unable to inhibit making incorrect responses on some cognitive tasks (although others can). Do you think that this lack of inhibition may be related to the emotional changes seen after damage to the orbitofrontal cortex?

Left–right frontal asymmetry and emotion

Other evidence implicates the anterior cortex in emotion but in a different way. It has generally been thought that the right hemisphere was the dominant hemisphere for processing emotion. We now know, however, that this is far too crude a characterisation of a complex behaviour and function. While the right hemisphere is superior to the left at recognising and perceiving emotional stimuli – such as distinguishing neutral from emotional faces and distinguishing sentences that vary according to their emotional tone – the left hemisphere plays a more important role in the experience of emotion. This hypothesis has been suggested and tested

most prolifically by Richard Davidson and his colleagues at the University of Wisconsin (Tomarken *et al.*, 1990; Wheeler *et al.*, 1993; Davidson and Sutton, 1995). In Davidson’s experiments, participants were exposed to film clips designed to elicit specific emotions – positive and negative – as EEG activity was recorded. Participants indicated when they were experiencing these positive and negative emotions during viewing.

Using such a paradigm – but employing only women participants – Davidson has found that left frontal activation in a specific EEG waveband (alpha) is associated with the experience of positive emotion, whereas increased relative right frontal activation and left frontal reduction in activation is associated with the experience of negative emotion (R.J. Davidson *et al.*, 1979; Wheeler *et al.*, 1993). One study measured resting EEG in men and women at two sessions separated by six weeks (Sutton and Davidson, 2000). At the second session, participants were given a word-pair judgement task. Participants were required to indicate which of two word pairs went together the best. The words were manipulated for emotional tone so that some word pairs were pleasant and some were unpleasant (although the associative strength between words in all pairs was the same).

Participants with greater left-sided activation were more likely to select the pleasant word pairs as being the two that went best together. The results, the authors suggest, show an attentional bias towards positive stimuli in healthy individuals who show frontal left-sided baseline EEG. In a variation of these experiments, Ekman *et al.* (1990) investigated whether the type of EEG activity associated with a genuine smile (the so-called **Duchenne smile**) would differ from that generated by false smiles. The Duchenne smile is known as the genuine smile because it spontaneously activates the

Figure 13.15 The Duchenne smile. The face is that of Paul Ekman

Source: The Orion Publishing Group Ltd.

zygomatic muscles around the corners of the mouth and the orbicularis oculi muscles around the corners of the eyes, as you can see from Figure 13.15. It is also associated with better long-term adjustment, that is, people who express Duchenne smiles seem to be those who are better adjusted in the long-term (Papa and Bonanno, 2008).

Ekman *et al.* (1990) found that the Duchenne smiles were associated with greater left-sided activation in temporal and parietal regions. On the basis of these and other studies, Davidson suggested that the frontal asymmetry reflects motivational tendencies to withdraw or approach. That is, pleasant stimuli should be approachable and, therefore, activate the left frontal region whereas unpleasant stimuli would be avoided or withdrawn from and would activate the right frontal region (and decrease activity in the left frontal region). Coupled with this motivational model is the idea that asymmetry predisposes individuals to react in a specific emotional way. Greater baseline right frontal activation, for example, may predict the intensity of response to negative stimuli but this activation is a necessary but not sufficient condition for this response to occur (this is called the **diathesis model**).

A recent study has extended this research to feelings during the menstrual cycle (Hwang *et al.*, 2008). The researchers used MEG to measure changes in frontal brain asymmetry across the menstrual cycle in 16 healthy women. They found that women in their ovulatory period showed higher right frontal activity whereas higher left was found during the menstrual period. The researchers suggest that this change reflects the effects of hormonal changes which themselves modify brain activity.

Two studies highlight the role of the left and right frontal cortex in depression and anxiety. In one longitudinal study, people who showed relatively greater right frontal EEG

activation at the beginning of the study were more likely to report greater trait anxiety one year later (Blackhart *et al.*, 2006). A study of EEG activation to various film clips has also implicated the right hemisphere (Hagemann *et al.*, 2005a). Resting EEG and self-reported emotions after watching film clips on four occasions were analysed. Participants with greater right-sided EEG activation (and smaller left-sided activation) reacted more intensely to the film clips, regardless of the emotion they were designed to elicit. The researchers suggest that this highlights a role for the right hemisphere in automatically generating emotional responses; the left hemisphere they argue, is more involved in the control or modulation of emotion.

Exercise, music and EEG asymmetry

Similar studies have shown that variables such as the type of music you listen to or the degree of exercise you undertake or even the types of words you read, correlate with changes in mood and frontal EEG activity. For example, Petruzzello *et al.* (2001) measured EEG activity from very fit or low to moderately fit adults before and during a 30-minute session on the treadmill. Measures of mood were taken after the exercise.

Their findings were similar to those found in Sutton and Davidson's (2000) experiment: relative left-sided activity at baseline predicted the degree of positive affect experienced after exercise. The greater the left-sided activation, the better the mood of participants post-exercise. However, this prediction held only for the highly fit individuals. This suggests that resting baseline EEG and predisposition to positive affect may be mediated by other variables (such as fitness). Those with greater left-sided activity also expended the greatest energy.

Schmidt and Trainor (2001) found greater relative left frontal EEG activity in participants who listened to pleasant musical excerpts (pleasant–calm: *Spring* by Vivaldi; pleasant–intense: *Brandenburg Concerto No. 5* by Bach) and greater relative right frontal EEG activity in participants who listened to unpleasant excerpts (unpleasant–calm: *Adagio* by Barber; unpleasant–intense: *Peter and the Wolf* by Prokofiev). No asymmetrical pattern of activation was found when the intense and calm excerpts were compared. However, overall frontal cortex activity declined as the pieces became more intense. Activity declined from the unpleasant–intense, pleasant–intense, pleasant–calm and unpleasant–calm.

The results are consistent with the emotional asymmetry model outlined above. While some studies have supported the frontal asymmetry model, however, some recent evidence has suggested that the type of asymmetry seen depends on the methods of analysis and the EEG recording procedures one uses (Hagemann *et al.*, 1998). Hagemann *et al.* (2005b), for example, have found that EEG asymmetry to emotional stimuli can change from one testing session to the next. In one study, they even found that right-sided activation most consistently predicted the strength of people's emotional responses to emotional stimuli (Hagemann *et al.*, 2005a). In a recent study, it was found that right frontal activation was more common in the morning and during the autumn, suggesting that the EEG can be influenced not only by time of day but also season (Petersen and Harmon-Jones, 2009).

What are the limitations of the approach-withdrawal model of emotion? Can you think of a stimulus that is both approachable and repelling? Would this compromise the model?

Emotional experience: anger and disgust

One study examining the response of the cortex during the recognition of anger in facial expressions found that as the intensity of the angry expression increased so did activity in the right orbitofrontal cortex and the anterior cingulate gyrus (ACC) (Blair *et al.*, 1999). Previous studies have linked activation in the ACC with watching intense emotional facial expression. There was no significant increase in amygdala activity when the men saw angry expressions. The authors propose that the results signify a clear model: there is no unitary system that responds to negative stimuli, but two systems. One system mediates responses to negative stimuli involved in social aversive conditioning (sadness, fear); the other mediates responses to negative stimuli (anger and related stimuli) that curtails behaviour (the emotion is thought to suppress behaviour).

Anger is conceivably an approach tendency because there is motivation to engage in competitiveness or physical harm (Carver and Harmon-Jones, 2009). Anger does

not make people walk away, rather it makes them want to engage more in aggression and readies them for combat. But anger, by definition, is not necessarily a positive emotion. This presents the asymmetry model above with a paradox of sorts. If it is genuinely an approach tendency, we should see increased left frontal brain activity when people experience it. If this increase is found, does not then give the left frontal lobe an exclusive role in positive affect – it can also be activated by a negative emotion. Harmon-Jones (2004), however, suggests that there may be an alternative explanation: that people who get angry actually like being angry and, therefore, anger can be seen, via this logic, as a positive emotion.

To test this hypothesis, he took baseline EEG measurements from men and women and correlated this activity with their responses on an Attitudes Towards Anger questionnaire. This questionnaire asked participants to agree or disagree with a series of statements about anger (e.g. 'I like the feeling of power I get from expressing anger'). Measures of aggression were also taken and were used to divide the participants into those who expressed high levels of trait anger. The results showed that the most angry and aggressive of the group showed greater left frontal brain activity than did their milder counterparts. There was no significant relationship between attitudes towards anger and brain asymmetry: those who found anger to be a positive emotion were no more likely than those who did not view it so to produce left frontal EEG. The study is important because it suggests that the role of the frontal cortex in emotion might be more usefully seen as one involving motivational tendencies rather than emotional valence.

Research from Texas A& M University has found that individuals high in trait anger show greater EEG activation in the left frontal area of the brain when they view pictures designed to make them angry (Harmon-Jones, 2007). The same research group examined whether manipulating frontal asymmetry could affect aggressive response. Peterson *et al.* (2008) asked participants to contract their hand to increase activation in the contralateral hemisphere (contracting the right hand leads to left hemisphere activation and contracting the left, the right hemisphere). After being insulted and then being given the opportunity to show to aggression against their tormentor in a game, participants who contracted their right hand showed more aggression than did left-hand contractors. Left-frontal EEG was also associated with greater aggression. This EEG work has been extended to neuroimaging. In an fMRI experiment, participants were insulted and then asked to think about the incident (Denson *et al.*, 2008). The researchers found that feelings of anger induced by the insult were associated with activation in the anterior cingulate cortex. Activation in the hippocampus, insula and cingulate cortex were associated with thinking about the insult.

Another emotion regarded as negative is disgust and there appears to be a curious link between the recognition of this emotion and the degenerative motor disorder, Huntington's disease (HD) described in Chapter 3. Sprengelmeyer *et al.* (1996, 1997b) found that patients who showed symptoms of HD were poor at recognising facial expressions of disgust (but not other emotions), a finding replicated by Gray *et al.* (1997) who tested carriers of the gene for the disease but who had not yet developed the disease's symptoms. Patients with Gilles de LaTourette and obsessive-compulsive disorder also show this selective deficit in recognition (Sprengelmeyer *et al.*, 1997a). People who have just been diagnosed with the illness are also impaired in recognising disgust in facial expressions, although the ability to detect disgust in people's voices and the ability to experience disgust appear unaffected (Sprengelmeyer *et al.*, 2006). However, in an extensive study of 475 individuals with Huntington's disease, Johnson *et al.* (2007) have found that patients are not likely to show an impairment in recognising disgust specifically, as some studies have suggested. Instead, such patients are impaired at recognising negative emotions in general – anger, disgust, fear, sadness, as well as surprise but not happiness. The greater the patients' motor deficit, the greater their emotion recognition impairment.

The region of the brain that is dysfunctional in HD and these disorders is the fronto-striatal area, especially the basal ganglia. Early fMRI research that explored the neuroanatomical basis of disgust recognition in healthy individuals found increased activation in the putamen – a part of the basal ganglia (Phillips *et al.*, 1997; Sprengelmeyer *et al.*, 1998). This region is also implicated in Parkinson's disease (PD) and this finding prompted Sprengelmeyer *et al.* (2003) to hypothesise that recognition of disgust might also be impaired in patients with PD. They reported that medicated and unmedicated PD patients were poorer at recognising disgust than was a control group; the unmedicated group gave the poorest performance.

Neuroimaging data from healthy participants implicate more cortical regions in tasks where individuals recognise emotions. Using fMRI, Schienle *et al.* (2005) asked 63 women to rate how disgusting they considered 40 generally disgusting scenes and 40 neutral scenes to be. They found that activation was greater in the left orbitofrontal cortex, left medial OFC, the occipitotemporal lobe and left and right amygdala when the women viewed the disgusting stimuli. A broadly similar result was reported in a group of men and women who viewed disgust- and fear-inducing pictures (Schienle *et al.*, 2005). This study found increased activation in the left medial and dorsolateral prefrontal PFC cortex in both sexes.

Schienle *et al.* interpret their results in terms of Rolls's theory of emotion. Briefly, Rolls (1999) has proposed that visual affective stimuli are initially processed by the occipital lobe. The ventral visual system then projects to

the amygdala and PFC via the inferior temporal area. The PFC 'decides' on the reward value of the stimuli – do they afford reward or punishment? This 'decision' then leads to a behavioural outcome and the individual either withdraws or approaches.

Using display rules

We all realise that other people can recognise our expressions of emotions. Consequently, we sometimes try to hide our true feelings, attempting to appear impassive or even to display an emotion different from what we feel. At other times, we may exaggerate our emotional response to make sure that others see how we feel. For example, if a friend tells us about a devastating experience, we make sure that our facial expression conveys sadness and sympathy. Researchers have studied all these phenomena.

Attempting to hide an emotion is called **masking**. An attempt to exaggerate or minimise the expression of an emotion is called **modulation**. And an attempt to express an emotion we do not actually feel is called **simulation**. According to Ekman and Friesen (1974), the expression of emotions often follows culturally determined **display rules** – rules that prescribe under what situations we should or should not display signs of particular emotions. Although the patterns of muscular movements that accompany particular feelings are biologically determined, these movements can, to a certain extent, be controlled by display rules. See Figure 13.16.

Each culture has a particular set of display rules. For example, in Western culture, it is impolite for a winner to show too much pleasure and for a loser to show too much disappointment. The expression of these emotions is supposed to be modulated downwards. Also, in many cultures, it is unmanly to cry or to show fear and unfeminine to show anger.

Context is important in encouraging genuine facial expression of emotion. Participants were asked to listen to stories which varied in funniness and were told by a friend or a stranger (Jakobs *et al.*, 1999). The stories were either told on tape recorder, face-to-face or on the telephone. The researchers found that participants who listened to a stranger smiled less than when listening to a friend, as previous research would predict. Motivation to express an emotion was enhanced by face-to-face encounters, but only when listening to a friend. Simply listening to a friend did not affect this motivation, but the interaction between storyteller and channel of communication did. The study shows that the facial expression of emotion in response to listening to a story of varying emotional content can depend not just on the storyteller but the medium through which that storyteller tells the story. The interpersonal distance between a person and a target who smiles is shorter than the distance between them and a target with a neutral smile or a non-enjoyment smile (Miles, 2009).

Figure 13.16 Controlled facial displays. Innate emotional displays can be modified by display rules.

Source: Adapted from Ekman, P. and Friesen, W., *Semiotica*, 1969, 49–98.

Recent neuroimaging research suggests that we remember smiling faces better than ones with neutral expressions (Tsukiura and Cabeza, 2008). In an fMRI study, people were presented with either smiling or non-smiling faces and were asked to associate the face with a name that was also presented with each face. Participants were then presented with the names and asked to retrieve the facial expression associated with that name. People remembered smiling faces better and faster than neutral ones. The OFC and hippocampus were particularly involved in successful encoding, especially when stimuli were smiling faces. The connections between these two regions were also stronger during the retrieval of smiling than neutral faces.

The results suggest that a smiling face can enhance retrieval. Furthermore, the rewarding nature of the smile is reflected in activation in the OFC. This activation, the researchers suggest, strengthens the hippocampal activation (itself a reflection of strengthened encoding).

Ekman and his colleagues (Ekman *et al.*, 1972; Friesen, 1972) attempted to assess a different kind of culturally determined display rule. They showed a distressing film to Japanese and American college students, singly and in the presence of a visitor, who was described to the subjects as a scientist. Because the Japanese culture discourages public display of emotion, the researchers expected that the Japanese students would show fewer facial expressions of emotion when in public than when alone.

The researchers recorded the facial expressions of their participants with hidden cameras while the participants viewed a film showing a gruesome and bloody coming-of-age rite in a pre-literate tribe. The results were as predicted. When the participants were alone, American and Japanese subjects showed the same facial expressions. When they were with another person, the Japanese participants were less likely to express negative emotions and more likely to mask these expressions with polite smiles. Thus, people from both cultures used the same facial expressions of emotion but were subject to different social display rules.

When people attempt to mask the expression of a strongly felt emotion, they are usually unable to do so completely, that is, there is some **leakage**, or subtle sign of the emotion (Ekman and Friesen, 1969). Ekman and Friesen (1974) investigated this phenomenon. They showed an unpleasant film of burns and amputations to female nursing students. After watching the film, the par-

ticipants were interviewed by an experimenter, who asked them about the film. Some of the participants were asked to pretend to the interviewer that they had seen a pleasant film. The experimenters videotaped the participants during the interviews and showed these tapes to a separate group of raters, asking them to try to determine whether the people they were watching were being honest or deceptive. The raters were shown videotapes of the participants' faces or bodies. The results indicated that the raters could detect the deception better when they saw the subjects' bodies than when they saw their faces. Apparently, people are better at masking signs of emotion shown by their facial muscles than those shown by muscles in other parts of their body. Presumably, people recognise the attention paid to the face and learn to control their facial expressions better than they do the movements of the rest of the body.

Facial feedback hypothesis

The use of display rules suggests that we are capable of manipulating our facial expression to influence others. It has also been suggested that our own facial expressions can influence our own feelings. That our awareness of facial expression influences the way in which we feel is at the heart of the **facial feedback hypothesis** (Tourangeau and Ellsworth, 1979; Lanzetta *et al.*, 1976). If this is so, then manipulating a person's facial expression should result in the feeling of the expression-appropriate emotion. You cannot be angry with a smile on your face, for example. This idea has its origin in a remark by Darwin (1872), who had argued that 'the free expression by outward signs of an emotion intensifies it . . . the repression, as far as this is possible, of all outward signs softens our emotions'.

A test of the facial feedback hypothesis was undertaken by Laird (1974), who asked participants to view photographs while electrical activity from the face muscles was ostensibly recorded. The individuals were told that they would feel emotion-related muscle changes and, to counteract these changes, their muscles would be contracted or relaxed. In fact, the facial manipulation resulted in the participants expressing either a happy or angry face. As predicted, participants who then responded to specific photographs were angrier when exhibiting an angry

expression and happier when exhibiting a happy face. However, a study by Tourangeau and Ellsworth (1979) cast doubt on these findings. They asked participants to exhibit either sad, fearful or neutral expressions while watching sad, anger-provoking and neutral films. Although the films themselves elicited the appropriate emotion, the facial expressions did not influence their feelings.

One final source of support for the hypothesis comes from a study by Strack *et al.* (1988). They required participants to watch cartoons while holding a pen either between their lips (thereby preventing them from making any facial expression) or between their teeth (thereby creating the expression of a smile), as you can see from Figure 13.17.

Figure 13.17 Illustrations of the conditions in Strack *et al.*'s experiment. Participants who watched cartoons while holding a pen between their lips in the 'sucking position' regarded the cartoons as less funny than did participants who held the pen between their teeth. In the 'lips' condition, the muscles involved in smiling were inhibited by the position of the pen.

Cutting edge – A slump in mental fortune: how posture affects mood and cognition

One must sit with a sense of dignity and grandeur, like a mountain or a giant pine ... the innate dignity of man is physiologically manifested in his erect back, since he alone of all creatures has this capacity to hold his spinal column vertical.

Dogen, Zen Buddhist Master, 13th Century (Kapleau, 1980).

Buddhist seating preferences aside, we are all aware of the health benefits of adopting good posture, especially when sitting at a desk typing away at a computer. Darwin highlighted the evolutionary advantage of certain types of deportment – bodily movement and posture sent clear signals to members of the same and different species, especially one that posed a threat. He also noted that pride was one of the more obviously signalled complex emotion – the upright posture indicated superiority over others. You can imagine the howls of despair echoing around Notre Dame.

A study has now empirically tested the hypothesis that upright posture leads to feeling of pride (Roberts and Arefi-Afshar, 2007). Undergraduates completed a brief measure of intelligence (Raven's Progressive Matrices) and were then

asked to adopt a slumped or an upright position while the test was apparently scored in another room. All received feedback indicating that they had scored in the top 25 per cent. Finally, they rated their satisfaction with their Raven's performance, completed a maths test and rated their satisfaction with their maths performance.

Posture had a significant effect on satisfaction ratings, but only in men. Men were significantly more satisfied with their performance if they had been in the upright posture condition. In contrast, women in the upright condition performed less well after adopting this position and expressed more negative attitudes about their performance. Why?

Objectification theory suggests that women would feel self-conscious in the upright condition because it emphasises a sexually salient part of their body, namely their breasts. The discomfort that this produces disrupts performance (and satisfaction with this performance). The authors draw on social psychology research, for example, which shows that women who performed a cognitive task in their swimsuit performed less well than those wearing a jumper (they also performed less well than men who completed the task naked from the waist up).

Those who held the pen by their lips rated the cartoons as being less funny than did those who did not have their facial expression inhibited (i.e. held the pen between their teeth). The facial feedback hypothesis, therefore, seems to have garnered more support than not. What is controversial, and what is currently unclear, is why facial feedback provokes the emotions it does.

Facing emotion

Much work in psychophysiology has tried to outline what type of muscle activity in the face is associated with the experience of different emotions. Facial muscle activity can be extremely subtle and can only be measured by a sensitive psychophysiological technique (EMG, described in Chapter 4): EMG recording can reveal that the muscle activity of the face changes when it expresses pleasant and unpleasant emotion whereas normal observation of the person's face cannot reveal such detail.

Pleasant stimuli tend to produce greater muscle activity in the zygomaticus major (the part of the face that allows us to move the corners of our mouth into a smile) and less over the corrugator supercilii muscles (these draw the brow down and allow frowning) than do unpleasant ones. Whether the decrease in muscle activity is due to a decrease in negative emotion or an increase in a positive one is an important question: it is the key to understanding whether these changes occur because negative feelings are decreased or positive ones are increased. Larsen *et al.* (2003) asked 68 women to report positive and negative feelings during exposure to negative, positive and neutral pictures, sounds and words. The group's facial muscle activity (EMG) was recorded. The pictures included those of mutilated bodies, household objects, people and food amongst others and noises included animal noises, alarms, engines and laughter. Words included insults, terms of endearment and neutral expressions.

One important finding was that pictures and sounds had a more significant effect on muscle activity than did the words. A second finding was that the nature of the stimulus had a much greater effect on activity over the corrugator supercilii muscle especially when people viewed pictures (although this effect was seen for all three types of stimuli). The effects on the zygomaticus major muscle were unreliable.

Self-reported negative emotion was associated with significant increases over the corrugator supercilii muscle whereas positive emotion was associated with less activity. For positive emotion specifically, words and pictures did produce increases over the zygomaticus major area but the region was relatively unaffected by people's self-reports of negative emotion.

This suggests that facial reciprocity in emotion (muscle activity going up during one type of emotion but

down during another) does not occur in this region, but does around the corrugator supercilii under the conditions in which the study's participants found themselves in a quiet room, dimly lit where signalling of emotion was not necessary.

A recent study also compared the effect of another person's emotional expression on our facial expression when we either liked, disliked or had no opinion about that person (Likowski *et al.*, 2008). Participants had their attitudes of various people manipulated so that they either found them pleasant, unpleasant or neither. They then saw photographs of these people showing happy, sad or neutral expressions. EMG recorded participants' muscle activity as they did this. When they saw the face they liked, participants mimicked the face they saw (whether the expression was happy or sad); when they saw the person they disliked, however, there was less mimicry. This is an interesting study because these attitudes had been formed in minutes and they moderated participants' automatic, non-verbal, emotional and social responses.

Theories of emotion

Theories of emotion have attempted to explain the nature of emotion from various perspectives. These perspectives can be broadly described as physiological, evolutionary and cognitive.

Physiological theories

The James–Lange theory

William James (1842–1910), an American psychologist, and Carl Lange (1834–1900), a Danish physiologist, independently suggested similar explanations for emotion, which most people refer to collectively as the **James–Lange theory** (James, 1884; Lange, 1887). Basically, the James–Lange theory states that emotion-producing situations elicit an appropriate set of physiological responses, such as trembling, sweating and increased heart rate. The situations also elicit behaviours, such as clenching of the fists or fighting. The brain receives sensory feedback from the muscles and from the organs that produce these responses, and it is this feedback that constitutes our feelings of emotion. As James (1890, p. 449) put it:

The bodily changes follow directly the perception of the exciting fact, and . . . our feelings of the same changes as they occur is the emotion. Common sense says we lose our fortune, are sorry, and weep; we meet a bear, are frightened, and run . . . The hypothesis here to be

defended says that this order of sequence is incorrect . . . The more rational statement is that we feel sorry because we cry, angry because we strike, afraid because we tremble, and not that we cry, strike, or tremble because we are sorry, angry or fearful, as the case may be.

James suggested that our own emotional feelings are based on what we find ourselves doing and on the sensory feedback we receive from the activity of our muscles and internal organs. Where feelings of emotions are concerned, we are self-observers. Thus, patterns of emotional responses and expressions of emotions give rise to feelings of emotion. By this reasoning, feelings of emotions are simply by-products of emotional responses. The James–Lange model is illustrated in Figure 13.18.

James's and Lange's theory was not entirely correct, however. As Cannon (1927, 1931) pointed out:

- 1 Separating the viscera from the central nervous system did not result in changes in emotional behaviour.
- 2 Emotional and non-emotional states can be associated with the same physiological changes.
- 3 Visceral changes are too slow to be able to reflect emotional changes.
- 4 Inducing visceral change that should result in emotional change usually does not produce these changes.

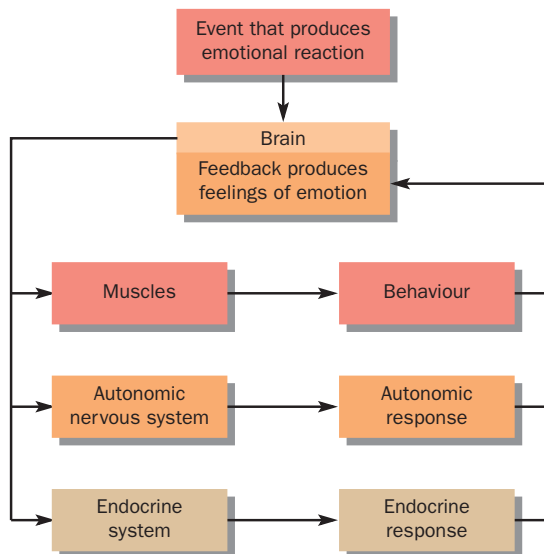

Figure 13.18 A diagrammatic representation of the James–Lange theory of emotion. An event in the environment triggers behavioural, autonomic and endocrine responses. Feedback from these responses produces feelings of emotion.

Schachter and Singer's model

Schachter (1964) proposed that feelings of emotions are determined jointly by perception of physiological responses and by cognitive assessment of a specific situation. Thus, to Schachter, emotion is cognition plus perception of physiological arousal. Both are necessary. Schachter and Singer (1962) tested this hypothesis by inducing physiological arousal in groups of participants placed in various situations. All participants were told that they were part of an investigation on the effects of a vitamin called 'suproxin' on visual perception (no such vitamin exists). The investigators gave some participants injections of adrenalin, a hormone that stimulates a variety of autonomic nervous system effects associated with arousal, such as increased heart rate and blood pressure, irregular breathing, warming of the face and mild trembling. Other participants received a control injection of a salt solution, which has no physiological effects.

Next, the researchers placed some participants in an anger-provoking situation in which they were treated rudely and subjected to obnoxious test questions such as, 'How many men, besides your father, has your mother slept with? (a) one, (b) two, (c) three, (d) four or more.' Others were treated politely and saw the antics of another 'participant' (a confederate who was hired by the experimenters) who acted silly and euphoric. The experimenters hoped that these two situations, together with the physiological reactions produced by the injections of adrenalin, would promote either negative or positive emotional states.

Finally, some participants were correctly informed that the injections they received would produce side effects such as trembling and a pounding heart. Others were told to expect irrelevant side effects or none at all. Schachter and Singer predicted that the participants who knew what side effects to expect would correctly attribute their physiological reactions to the drug and would not experience a change in emotion. Those who were misinformed would note their physiological arousal and conclude that they were feeling especially angry or happy, as the circumstance dictated. All participants reported their emotional states in a questionnaire.

The results were not as clear-cut as the experimenters had hoped. The adrenalin did not increase the intensity of the participants' emotional states. However, participants who expected to experience physiological arousal as a result of the injection reported much less of a change in their emotional states than did those who did not expect it, regardless of whether they had received the adrenalin or the placebo. These results suggest that we interpret the significance of our physiological reactions rather than simply experience them as emotions.

Nisbett and Schachter (1966) provided further evidence that participants could be fooled into attributing their own naturally occurring physiological responses to a drug and thus into feeling less 'emotional'. First, they gave all participants a placebo pill (one having no physiological effects). Half the participants were told that the pill would make their hearts pound, their breathing increase and their hands tremble; the other half (the control subjects) were told nothing about possible side effects. Then, the researchers strapped on electrodes and gave the participants electrical shocks. All participants presumably experienced pain and fear, and, consequently, their heart rates and breathing increased, they trembled, and so on. Yet the participants who perceived their reactions as drug-induced were able to tolerate stronger shocks than were the control subjects, and they reported less pain and fear. Thus, cognition can affect people's judgements about their own emotional states and even their tolerance of pain.

The precise nature of the interaction between cognition and physiological arousal has not been determined. For example, in the Nisbett and Schachter experiment, although the verbal instruction about effects of the placebo affected the participants' reactions to pain, it did not seem to do so through a logical, reasoned process. In fact, Nisbett and Wilson (1977) later reported that participants did not consciously attribute their increased tolerance of pain to the effects of the pill. When participants were asked whether they had thought about the pill while receiving the shocks or whether it had occurred to them that the pill was causing some physical effects, participants typically gave answers such as, 'No, I was too worried about the shock' (Nisbett and Wilson, 1977, p. 237).

Evolutionary theories

Evolutionary theories of emotion view emotions as adaptive traits – they help the organism to adapt to the demands of the environment and thereby survive (Izard, 1977; Plutchik, 1984).

Plutchik's structural, psychoevolutionary theory of emotion

In common with other evolutionary theories of emotion, Plutchik's (1984) psychoevolutionary theory regards emotions as being important to adaptation and survival. However, he argues that in order to understand the nature of emotions, they must be organised in a certain way. He argues, therefore, that emotions can be distinguished on the basis of intensity (anger is less intense than rage, for example), similarity (surprise may engage the same feelings as happiness), polarity (that is, opposites: grief is the opposite of joy), and whether they are primary or secondary (the secondary emotions derive from the primary ones).

Plutchik lists eight behavioural patterns, such as destruction, rejection and reproduction, which can be seen in all organisms; each of his primary emotions (described in an earlier section) is associated with these behavioural patterns.

Shaver's prototype theory

Shaver *et al.*'s (1992) model of emotion also uses the notion that we react to the environment using a limited behavioural repertoire and argues that, like emotional facial expression, these repertoires should be universal. Furthermore, the assumption that emotions are universal suggests that they have a biological basis. Emotions are viewed as 'action tendencies' that arise from an appraisal of the environment. Because the similarities in environmental events are more common than dissimilarities, the theory argues, appraisals will be similar across cultures. Shaver and his colleagues suggest that such a view is supported by evidence from three countries – the USA, Italy and China – in which there was substantial overlap in the words that individuals listed as basic emotions.

Frijda's 'action tendencies'

Shaver adopted the concept of 'action tendencies' from Frijda's (1988) model which also views emotions as adaptive. There is a small number of these tendencies which represents the individual's readiness to respond to the environment in emotional ways. These tendencies mediate the individual's relationship with the environment and Frijda proposed ten of them. Like Plutchik's model, Frijda's argues that emotions are adaptive in that they are used by individuals to solve problems posed by the environment. Unlike Plutchik's, it disagrees that the model can apply to any organism – it is specifically related to human behaviour. However, Frijda also argues that there is little difference between the action tendency and the emotion associated with it, emotion perhaps being the state of awareness of these action tendencies. He also suggests that these emotions (and tendencies) follow on from an individual's appraisal of the environment. That is, the individual first monitors the environment and appraises the threat or problem posed by this environment. Frijda *et al.* (1989) have found that action tendencies and emotions can be predicted from individuals' appraisals of the environment.

This notion of appraisal is important to a number of models and theories of emotion. In general, such theories argue that emotion is dependent on the individual's appraisal of environmental events and situations. Schachter and Singer's model, although described as a physiological model, involved a strong appraisal component. Other models, however, include appraisal as a more explicit feature.

Cognitive theories

Lazarus's model

Lazarus's original model of emotion suggested that emotion arose from the individual's appraisal of the environment (Lazarus, 1966). **Primary appraisal** involved the initial evaluation of the environment – is it positive, negative or neutral; secondary appraisal involved the individual's evaluation of how best to cope with this environment and what options were available to facilitate this coping. **Secondary appraisal** was composed of two types: emotion-focused coping and problem-focused coping. Emotion-focused coping refers to the defence mechanisms that the individual might adopt, such as fleeing the situation or denying negative thoughts and feelings. Problem-centred coping is directed more at finding solutions to the problems posed by the environment when there are changes in the environment.

This original model, however, was devised to explain how people respond to stressors – factors which cause stress (this is discussed in more detail in later chapters). The later reformulation of the model (Lazarus, 1991) was designed to be a general theory of emotion which Lazarus called the 'cognitive-motivational-relational' theory of emotion. Primary appraisal now comprises the components: goal-relevance (Is the environment related to the goal that the individual wants to pursue?), goal congruency/incongruency (Is the goal possible or will it be prevented?) and ego-involvement (Does the environment have consequences for the individual's self-esteem?). Secondary appraisal assesses the environment in terms of how the individual might cope with it and how such coping might affect future relations. Lazarus proposed that the appraisal of situations which might involve harm to the individual were innate; however, secondary appraisal could override the decisions derived from primary appraisal.

Weiner's model

Weiner's model also utilises the concept of appraisal but is based on the notion that individuals make attributions to the environment and behaviour (Weiner, 1985). The environment provides the individual with a range of positive and negative stimuli which produce initial emotional reactions of pleasure and displeasure. These reactions are triggered automatically and are not emotional responses that rely on the individual's attributions, such as experiencing depression because failure is attributed to poor ability and general worthlessness. These emotions are fairly primitive and reflect conditioned emotional reactions.

The individual's account of how events in the environment were caused determines which positive and negative emotions are elicited. This attribution-dependent model suggests that these explanations depend on three factors:

- (1) whether the cause of the emotion is internal to the individual or external and caused by the environment;
- (2) whether the cause is stable or will change over time; and
- (3) whether the cause of the emotion is controllable or uncontrollable. Abramson *et al.* (1978) later added a fourth dimension: whether the environment affected the individual's whole life (global change) or a specific part of it (specific change). According to this model, the attributions for success or failure will determine whether positive or negative emotions are experienced.

The hedonic treadmill theory

In 1971, Brickman and Campbell published a theory of emotion and well-being in which they suggested that we adapt to emotional events in our lives, in the same way that we adapt to a new smell when we enter an unfamiliar house. Studies published in the late 1970s appeared to support this theory. Lottery winners, for example, were no more happy than lottery losers and non-winners and people with paraplegia were similarly not less happy than those who could walk. The theory suggests that experiences inducing happy emotions are transitory; they are transitory because of adaptation.

Recently, however, new research has forced a revision of the theory and Diener *et al.* (2006) describe some of these new developments. For example, the treadmill view suggests that after we experience a highly emotional event, we return to a neutral state soon after. Once you've got your fantastic exam result, for example, or received that promotion, there is a period in which you are elated. The elation then subsides. Research has shown, however, that (exceptional events aside – such as getting that promotion) people are generally happy most of the time, according to self-reports. The European Values Study Group and World Values Survey Association (2005) data indicate that 80 per cent of respondents reported being quite or very happy, suggesting that the baseline is 'happy' rather than 'neutral'. Of course, there is variability in these 'set points'; different people have different set points. You also saw earlier in the book how positive affect declines with age but that negative affect also decreases.

The theory also states that people cannot do very much to change the long-term degree of happiness they experience – because of the return to a neutral state. However, studies of widows and widowers, as well as of people who have been laid off from work, show initially very low levels of happiness but this happiness is restored (but usually, only after a very long period – years, for example). The early data from people with severe disability has also been challenged, with Diener *et al.* (2006) citing evidence from patients with disabilities showing that they experienced a drop in life satisfaction after the disability, a drop that did not recover significantly.

Other models

Other models of emotion assume that thoughts and feelings represent nodes in a network. Thus a node for a specific emotion triggers off activation of other related nodes. Joy, for example, might trigger nodes that recall past achievement or motivate the individual to achieve even greater success by generating creative plans for the future. Failure might trigger nodes related to failure (such as negative feelings of self-worth and thoughts that previous successes may not have been deserved). This outline describes one model devised by Bower (1981; Bower and Cohen, 1982) which explained how mood-dependent memory occurred, that is, why we are more likely to recall happy events if we were happy at encoding and unhappy events if we were unhappy at encoding.

However, as you saw in Chapter 8, mood-dependent memory is not a particularly robust phenomenon and appears to be influenced by factors other than the encoding and retrieval conditions. Another problem is that in mood-dependent memory experiments it is unclear whether positive conditions increase accessibility to positive thoughts and feelings or reduce accessibility to negative ones. Bower (1987) later took account of this by arguing that the individual must realise that the material they learn is usefully related to the mood they are in. How this fits in with the network model, however, is unclear.

Other models such as those of Lang (1979, 1984) suggest that emotions may not be unitary phenomena but comprise three systems: verbal report, behaviour and physiology. This theory suggests that we can express emotion in one of these systems without experiencing it in another. For example, a depressed individual may show a positive disposition to those close around them (by verbal report) but their behaviour (withdrawal, quietness) and physiology suggest another emotion.

Two other models are also worthy of note. Leventhal and Scherer's model (1987) suggests that the emotion system is made up of three components. At the sensory motor level, individuals may respond to situations and

events automatically. This automatic reaction is present from birth onwards. The schematic level is also an automatic level of processing but the automatic behaviour derives from learned associations. Finally, the conceptual level represents reactions that are not automatic but depend on the individual's memories about emotion, expectations, goals, plans and so on. The conceptual level places the event that causes the emotion in a long-term context, that is, how would it affect the individual's future behaviour? In addition to these levels, the model proposes that the stimuli giving rise to emotional reactions are evaluated along various dimensions including novelty, pleasantness, their relevance to goals and plans, the potential to cope with them and their compatibility with social norms and the individual's self-concept.

Finally, Oatley and Johnson-Laird's model (1987; Oatley, 1992) argues that because we often encounter environments in which multiple goals are possible one of these goals must receive priority over the others. Emotion, according to the model, provides the means by which goals are prioritised. This is achieved by two mechanisms: one is primitive and has no symbolic significance (it is almost hormonal); the other is prepositional and symbolic (it has an internal structure and is more 'conscious' than the other mechanism). The model proposes five basic emotions: happiness, sadness, fear, anger and disgust, with other emotions derived from these.

Complex emotions, the theory argues, are likely to involve only one of these emotions although others have suggested that one or two may be necessary (Jones and Martin, 1992). All five of these emotions are related to the achievement of goals so that one type of emotion leads to the achievement of a goal whereas others are related to failure to achieve goals. However, it is difficult to reconcile these goals with certain emotions. Disgust, for example, as Power and Dalgleish (1997) have pointed out, is unlikely to violate only a 'gustatory goal' because disgust can be elicited by smells, sights and even sounds. In addition, why should the emotional reaction to a malodour be part of a goal – what would be the purpose?

Cutting edge – Keeping your emotional distance

Your understanding of psychology so far should tell you that a small change in the environment can have a large effect on behaviour. The section on EMG and emotion is a good example. The beauty of the best psychology is that it reveals something about our behaviour that is astonishing and unexpected. That even placing dots wide apart on a sheet of paper makes you emotionally distant, for example. This is what Williams and Bargh (2008) found.

They reviewed a theory suggesting that when we think about distant events we think about them in the abstract, but when we think about recent events we think and talk about them in more concrete terms (Trope and Liberman, 2003). This even extends to social and physical distance (we think more concretely about people and places near us (Fujita *et al.*, 2006). Think about where you live now and describe it to yourself. You probably used concrete

Cutting edge – Continued

language – it's a first floor flat, it's in a certain part of town, it has two bedrooms and so on.

Williams and Bargh (2008) reasoned that this relationship could be inverted. That is, priming the thought of distance could make people think more distantly. They asked participants to plot a pre-assigned series of points on a graph paper – see Figure 13.19. Some participants had to plot the points far apart from each other; other participants had to plot them near to each other. They were then asked to rate and judge various objects, scenarios and film clips.

Those who had been primed by plotting distal points derived greater enjoyment in film clips depicting embarrassing events, showed less emotional distress when watching violent material, gave lower estimates for the calorie content in unhealthy food and reported weaker ties to family members and the place where they grew up.

And all this from two points placed in graph paper.

Figure 13.19 The graph paper on which Williams and Bargh's participants placed pre-determined dots

Is a good mood good for cognition?

Brewer's model of emotion is based in part on evidence which showed that individuals in a negative or a positive mood would recall material better if the material matched their mood. For example, individuals exposed to a mal-odour would recall more negative memories than they would if exposed to a pleasant odour. Similarly, they would recall more pleasant memories in the pleasant condition (Ehrlichman and Bastone, 1992). You saw in Chapter 8 that individuals who encode information in a pleasant environment will recall better if retrieval also occurs in the pleasant environment. What effects, therefore, does a person's emotional state have on that person's ability to perform cognitive operations?

In a famous series of experiments, Isen and colleagues have demonstrated that being in a positive mood can have positive and negative consequences for behaviour. For example, in a laboratory-based study, Isen and Patrick (1983) reported that while positive mood led to undergraduates betting larger amounts in a gambling game than did controls, these bets were only large when the probability of winning was high. Isen *et al.* (1988) reasoned that either the positive mood predisposed people to believe that losing was likely or that thinking about negative events made them think that their positive mood might be lost. Isen and Geva (1987) found that those in a positive mood did indeed think about loss more than the controls did.

Positive mood has also been found to affect decisions made in more real-life risk situations (although these were

still laboratory-based). Individuals in a positive mood are more likely to choose a risky treatment for back pain than are those in a control group (Deldin and Levin, 1986).

In an investigation of the effect of induced positive mood on creative and executive thinking, Oaksford *et al.* (1996) tested two hypotheses. The facilitation hypothesis suggests that positive mood benefits creative thinking by facilitating it; the suppression hypothesis suggests that positive and negative moods take up resources that would normally be available for performing the cognitive task that the individual is presented with. Ellis *et al.* (1997), for example, found that negative mood was associated with impaired performance on a test in which participants looked for contradictions in a passage of text. The authors suggested that impairment occurred because intrusive and irrelevant thoughts impaired comprehension. Positive and negative mood should, therefore, also impair performance on reasoning and planning tasks, if a change in mood results in a reallocation of resources.

In an earlier experiment, Isen *et al.* (1987) had reported a beneficial effect of positive mood on a creative problem-solving task. The task was to support a lighted candle on a door using tacks, some matches in a matchbox and the candle (the solution, just in case you are not in a positive mood, is to tack the box to the door and place the candle lit with the matches, on top of the box). Those individuals who had watched some comedy were better at solving this problem than those exposed to a neutral or negative film or those exposed to no film.

Oaksford extended this study by having participants complete creative and reasoning tasks after watching

either a comedy programme, a neutral, wildlife programme or a negative documentary about stress. The researchers found that although positive and negative mood impaired performance on a deductive reasoning task, the positive mood only was associated with poor performance on the Tower of London Task which involves forward planning and reasoning. Some examples from the task can be seen in Figure 13.20.

The results of Oaksford's study provide some support for the suppression hypothesis in that a test requiring executive function (forward planning and sequencing of events) was disrupted by a positive mood. It also suggests that a positive mood may not always be beneficial to the performance of some cognitive tasks. The results of this and other research suggest that being in a good mood may not necessarily lead to better cognitive performance.

A study from the University of New South Wales in Australia has found that people in a *negative* mood were much more successful than those in a *positive* mood at convincing others to agree with statements such as 'Student fees should be increased/decreased' or 'Aboriginal land rights should be preserved/restricted in Australia' (Forgas, 2007). People in a negative mood were more likely to persuade others to believe an unpopular view than were people in a positive mood. Why did this effect occur? When the researcher examined the content of the arguments adopted, people in a negative mood were more likely to use concrete messages in their persuasion. This, in turn, led to more effective persuasion. Mood had influenced participants' processing style.

Figure 13.20 The Tower of London task. In (a) the participant is required to move the balls from the initial position to the target position in five moves; (b) shows how this is done.

Controversies in Psychological Science – Dark clouds gathering, sunny spells later . . .

The issue

Is there a relationship between the weather and a person's mood? Many people long for summer months when they can jet off to sunny climes, soak in the sun and lounge on the beach while creatively avoiding skin cancer. People in countries where natural sunlight is restricted appear to have a higher incidence of unhappiness or depression. We know that the mood of the general population appears to decline in the winter months (Harmatz *et al.*, 2000) and that one treatment for **seasonal affective disorder** – the appearance of depression in the dark, winter months (see Chapter 18) – is exposure to artificial light. This seems to improve mood in depressed and non-depressed people (Leppamaki *et al.*, 2002; 2003). Serotonin increases or decreases as naturally occurring sunlight increases or decreases, respectively (Lambert *et al.*, 2002). But, treatment for SAD aside, is there any evidence from healthy people that climate and temperature significantly influences mood? And if one does influence the other, why?

The evidence

In a study published in *Psychological Science*, Keller *et al.* (2005) review a variety of studies investigating the relationship between climate and mood and cognition. Task performance in one study peaked at 22°C and dropped at cooler or warmer temperatures than 22°C (Allen and Fischer, 1998). More heuristic and less systematic processing has been found in people during sunny and warm days than on cloudy or cool days (Sinclair *et al.*, 1994). Studies such as this have led to the suggestion that low humidity and high levels of sunlight (and high barometric pressure and temperature) are associated with positive mood whereas high temperatures alone led to a negative mood or no change in mood. Evidence, however, is not entirely consistent.

For example, daily mood reports collected from almost five hundred undergraduates in Dallas during the autumn or spring found no relationship between season and mood (Watson, 2000). A study of shoppers recruited on sunny or cloudy, rainy days found that people recalled more of the ten unusual objects placed at a checkout when the weather was rainy (Forgas *et al.*, 2009). Others report that behaviour such as violence increases during high temperatures (Anderson, 2001) and that stock market returns are higher in the summer (Saunders, 1993), perhaps reflecting the possibility that the temperature inures traders to risk or makes them less risk-averse. Seasonal studies are also problematic in that sunny and warm days can be experienced in 'cooler' seasons (e.g. autumn). And there is a possibility that sunny days in spring and autumn can produce different effects (they are less novel

in the spring, for example?). Do people need to be directly exposed to this weather for mood to change, i.e. do they need to be outdoors? One study found that 93 per cent of the people in the individual countries studied spent their time indoors during good weather (Woodcock and Custovic, 1998).

To test these hypotheses, Keller *et al.* (2005) set up three experiments. In the first, they examined whether temperature or the length of time spent outdoors in warm weather affected mood. Data were collected from 97 people from April to June. They found no direct relationship between barometric pressure and temperature, and mood. But they did find a positive relationship between mood and time spent outside. A similar relationship was found for creativity, cognitive flexibility, openness to experience and digit span performance. People who spent more than 30 minutes outdoors on clear days had higher digit spans and showed a more flexible thinking style.

In a second experiment, the researchers manipulated the time spent outdoors. The first session took part indoors; participants then either danced or walked around a track or walked outdoors or on a treadmill. Again, temperature did not appear to affect mood but the outdoor condition did. When people were outdoors on days that were warm, clear and characterised by high pressure, their mood was significantly more positive than those indoors during the same meteorological conditions. (The mood of those indoors decreased.)

In both studies, participants were from a northern climate. In a third study, the researchers recruited 387 participants from the internet who indicated they were from either North America/Canada, southern US or Europe. They found that the more time that participants spent outdoors in the spring, the greater the association between temperature and mood. As temperatures increased in the summer, there was a negative relationship between time spent outdoors and mood: those who were outside in high temperatures showed reduced mood. The best temperature for mood improvement was 19.7°C. This mood declined after 45 minutes outdoors.

Conclusions

Keller *et al.* have shed some light on the relationship between mood and weather. It seems as if the important factor is the time people spend outdoors in warm weather on clear days. This improvement is not just seen in mood but also on some measures of cognitive ability. The length of time people spend outdoors appears to be important and the effects may be season-dependent. The positive effects found in spring may be because 'people have been deprived of such weather during the winter' (p. 724).

Emotion without cognition?

Related to research on mood and cognition is a broader issue in emotion research. This is whether emotion can occur without cognition. Some psychologists, such as Lazarus (1984), believe that emotions are produced only by cognitive processes – by anticipating, experiencing, or imagining the outcomes of important interactions with the environment. Others, such as Zajonc (1984), insist that cognitive appraisal is not necessary and that emotions are automatic, species-typical responses heavily influenced by classical conditioning.

Although the two sides of the debate appear to have been drawn sharply, it seems clear that both automatic processes and conscious deliberation play a role in the expression and feelings of emotion. Some examples of emotions clearly involve cognitive processes. For instance, a person can become angry after realising that someone's 'kind words' actually contained a subtle insult. This anger is a result of cognition. But sometimes, emotional reactions

and their associated feelings seem to occur automatically. As we saw, through the process of classical conditioning, stimuli can evoke emotional reactions before we have time to realise what is happening. In some cases, we may be acting in a hostile and angry manner without realising what we are doing. If cognitive processes are responsible for our anger, they are certainly not conscious, deliberate ones.

One of the problems with this debate (as with many other debates) is that the opponents sometimes define the same terms in different ways. For example, not everyone agrees which operations of the brain should be regarded as cognitive and which should not. According to Lazarus, (1984) many cognitive processes are unconscious and relatively automatic. But if cognitive processes need not be conscious, how can we tell whether a given process is cognitive? And if we cannot tell, how can we hope to decide whether cognition is necessary for all emotions? If our definition of cognition is too general, we would have to conclude that all responses require cognition.

Chapter review

Motivation

- Motivation is a general term for a group of phenomena that affects the nature, strength and persistence of an individual's behaviour. It includes a tendency to perform behaviours that bring an individual into contact with an appetitive stimulus or that move it away from an aversive one.
- Regulatory systems include four features: a system variable (the variable that is regulated), a set point (the optimum value of the system variable), a detector to measure the system variable and a correctional mechanism to change it.
- Psychologists believed that aversive drives were produced by deprivation and that reinforcement was a result of drive reduction. However, the fact that we cannot directly measure an individual's drive level makes it impossible to test this hypothesis. Many reinforcers increase drive rather than reduce it. Thus, most psychologists doubt the validity of the drive reduction hypothesis of reinforcement.
- The discovery that electrical stimulation of parts of the brain could reinforce behaviour led to the study of the role of brain mechanisms involved in reinforcement. Apparently, all reinforcing stimuli (including addictive drugs) cause the release of dopamine in the brain.
- Because high levels of drive or arousal can be aversive, several investigators proposed the optimum-level theory of motivation and reinforcement. This theory suggests that organisms strive to attain optimum levels of arousal; thus, reinforcement and punishment are seen as two sides of the same coin.

- Because drive cannot be directly measured, we cannot determine whether an individual's drive is above or below its optimum level.
- Perseverance is the tendency to continue performing a behaviour that is no longer being externally reinforced and is determined by the organism's previous history with intermittent reinforcement and its opportunity to develop behaviours that produce conditioned reinforcers.
- Learned helplessness involves learning that an aversive event cannot be avoided or escaped.

Eating and drinking

- The fluid in cells is called intracellular fluid and contains a little sodium but large amounts of potassium and other metabolites. The other source of fluid in the body is extracellular fluid and this is found in two places. Interstitial fluid surrounds the cell body and is salty; blood plasma is found in the capillaries, arteries and veins and allows living cells and blood to be suspended within it.
- The reduction in the concentration of sodium available across the membrane and the movement of water by osmosis dehydrating and shrinking the body's cells is called osmometric thirst.
- Another type of thirst (volumetric thirst) results from dehydration outside cells, i.e. a reduction in the level of blood plasma.
- Hunger is the feeling that precedes and accompanies an important regulatory behaviour: eating.

- Eating begins for both social and physiological reasons. Physiologically, the most important event appears to be the detection of a lowered supply of nutrients available in the blood.
- Detectors in the liver measure glucose level, and detectors elsewhere in the body measure the level of fatty acids. Both sets of detectors inform the brain of the need for food and arouse hunger.
- Detectors responsible for satiety, which appear to be located in the walls of the stomach, monitor both the quality and the quantity of the food that has just been eaten.
- Long-term control of eating appears to be regulated by the chemical leptin, which is released by overnourished fat tissue and detected by cells in the brain. It decreases meal size and increases metabolic rate, thus helping the body to burn up its supply of triglycerides.
- Genetic and environmental factors may interact to cause the person's weight to deviate from the norm.
- To be diagnosed as clinically obese a person must have a body mass index that is equal to or greater than 30 kg/m².
- Intervention programmes for obese people are successful if individuals self-monitor and continue to adopt the strategies they have been taught after the intervention period is over.
- In extreme cases, surgery of the intestine is an effective means of helping a person lose weight (bariatric surgery).
- People differ genetically in the efficiency of their metabolisms and this efficiency can easily lead to obesity. Particular eating habits, especially those learned during infancy, can override the physiological signals that would otherwise produce satiety.
- Experiences such as repeated fasting and refeeding (the yo-yo effect) are often accompanied by overeating.
- Sensory-specific satiety refers to a reduction in the pleasantness of a food eaten to satiety whereas the pleasantness of others is relatively unaffected.
- People eat more of a four-course than of a one-course meal and more of a meal containing a variety of pasta shapes and colours than one containing one shape and one colour.
- The hedonic response to food after satiety is thought to be mediated by the secondary taste cortex; the primary taste cortex helps to identify the food.
- Anorexia nervosa is an eating disorder in which the individual is obsessed with food and weight but deliberately reduces their intake of food and avoids it; the prevalence of the disorder is between 0.5 and 1 per cent worldwide, and most anorexics are young women.
- Studies have found metabolic differences in anorexic patients, but we cannot determine whether these differences are the causes or the effects of the disorder.
- Bulimia nervosa is an eating disorder which involves a loss of control of food intake; bulimic individuals will often binge and then use laxatives or vomiting to get rid of the consumed food.

Sexual behaviour

- Testosterone has two major effects on male sexual behaviour: organisational and activational.

- In the foetus, testosterone organises the development of male sex organs and of some neural circuits in the brain; in the adult, testosterone activates these structures and permits erection and ejaculation to occur.
- The sexual behaviour of female mammals with oestrus cycles depends on oestradiol and progesterone, but these hormones have only a minor effect on women's sexual behaviour.
- Women's sexual desire, like that of men, is much more dependent on androgens.
- The development of sexual orientation appears to have biological roots. A large-scale study of homosexuals failed to find evidence that child-rearing practices fostered homosexuality.
- Studies have identified three regions of the brain that are of different sizes as between in homosexual and heterosexual males. These results suggest that the brains of these two groups may have been exposed to different patterns of hormones early in life. In addition, twin studies indicate that homosexuality has a genetic component as well.

Aggressive behaviour

- Ethological studies of other species suggest that aggression is a means of averting violence: threat gestures warn of an impending attack, and appeasement gestures propitiate the potential aggressor.
- In males of most animal species, androgens have both organisational and activational effects on aggressive behaviour.
- Testosterone appears to increase in a variety of situations and contexts. Increases have been found before chess players play matches and in winners after matches; increased levels have been reported in prisoners convicted of violent crime and described by fellow inmates as being tough. These data are, however, correlational.
- Field studies on the effects of televised violence are not conclusive. Observational studies have revealed a modest relation between preference for violent television shows and boys' aggressiveness, but we cannot be sure that watching the violence causes the aggressiveness.
- An attempt to manipulate aggression by forcing children to watch violent or non-violent television programmes was inconclusive because many children resented their loss of choice.

Emotion

- Emotion refers to behaviours, physiological responses and feelings evoked by appetitive or aversive stimuli, although psychologists have defined emotion in various ways.
- Darwin believed that expression of emotion by facial gestures was innate and that muscular movements were inherited behavioural patterns.
- Ekman and his colleagues showed that members of the South Fore tribe recognised facial expressions of Westerners and made facial gestures that were clear to Westerners, suggesting that emotional expressions are innate behaviour patterns and universally found.

- There is controversy, however, over whether facial expressions reflect true emotions or whether they reflect the social communication of an emotion.
- A number of theorists have suggested that there is a group of basic emotions, although the exact number is controversial, as is the notion that there are basic emotions. The most widely accepted number of basic emotions is six or seven.
- Research has shown that those who are outwardly happy are most likely to have high self-esteem and are happy in other aspects of their lives.
- Expressions of emotion are not always frank and honest indications of a person's emotional state. They can be masked, modulated or simulated according to culturally determined display rules.
- When a person attempts to mask their expression of emotion, some leakage occurs, particularly in movements of the body. Presumably, we learn to control our facial expressions better because we are aware of the attention that other people pay to these expressions.
- Destruction to parts of the amygdala prevents the recognition of fear in facial expressions and activation in the amygdala is seen in healthy individuals exposed to facial expressions of fear. In healthy individuals, the left side of the amygdala is active during the experience of positive emotion.
- The orbitofrontal cortex is also important to emotion and may be involved in the regulation of socially appropriate behaviour that involves complex decision-making.
- People with damage to the orbitofrontal region are able to explain the implications of complex social situations but are unable to respond appropriately when put in these situations. Thus, this region appears to be necessary for translating judgements about the personal significance of events into appropriate actions and emotional responses.
- The affective asymmetry of emotion model suggests that EEG activation of the left frontal region may be involved in the experience of positive emotion whereas activation of the right frontal region is involved in the experience of negative emotion.
- James and Lange suggested that the physiological and behavioural reactions to emotion-producing situations were perceived by people as states of emotion and that emotional states were not the causes of these reactions.
- Although emotional states are sometimes produced by automatic, classically conditioned responses, some psychologists have suggested that the perception of our own emotional state is not determined solely by feedback from our behaviour and the organs controlled by the autonomic nervous system. It is also determined by cognitive assessment of the situation in which we find ourselves.
- Schachter and his colleagues found that information about the expected physiological effects of drugs (or placebos) influenced subjects' reports about their emotional state. In one study, subjects even tolerated more intense electrical shocks, apparently discounting their own fear.
- Appraisal theories suggest that emotion is experienced after the environment has been evaluated for threat, fear, joy or any other influential factor.
- Evolutionary theories argue that emotions are a means of adapting to change in the environment; these changes produce a restricted set of responses which are universal (hence, the emotions associated with them should also be universal).
- The debate over whether cognition is necessary for emotion continues. Ultimately, the argument rests on how cognition is defined.

Personality

Mapped out: Britain's personality clusters

Jonathan Leake and Helen Brooks

You are where you live. The growing mobility of modern Britain is creating, or reinforcing, particular personality types in different regions.

Londoners appear to be changing fastest, displaying sharply elevated levels of creativity, intellect, open-mindedness and extroversion when compared with people living in Wales, Scotland, Northern Ireland and the rest of Ireland.

People living in Wales, by contrast, emerge from the Cambridge University study as less extrovert, less conscientious and more anxious than the English, Scots or Northern Irish.

Similar differences appear in the English regions, with people from Devon, Cornwall, Northumberland and Tyneside being the least outgoing and the most neurotic.

Source: The Sunday Times, 14 April 2009.

WHAT YOU SHOULD BE ABLE TO DO AFTER READING CHAPTER 14

- Describe what psychologists mean by 'personality'.
- Describe and understand the methods used by psychologists to study personality.
- Describe and explain what is meant by trait theory and situationism.
- Describe and evaluate psychodynamic personality theory and humanistic approaches to personality.
- Describe and evaluate the trait theories of Cattell, Eysenck and Costa and McCrae.
- Evaluate the validity and reliability of personality tests.

QUESTIONS TO THINK ABOUT

- What is personality?
- Can we measure personality scientifically? If so, how?
- If individuals possess personality characteristics, how do we explain people's behaviour when they act out of character?
- Does personality mean the same thing in every culture? Is personality a linguistic rather than behavioural phenomenon?
- Does personality have a biological basis?
- Does personality change over time?
- Are there national differences in personality?

Explore the accompanying videos, simulations and animations on MyPsychLab. This chapter includes activities on: Locus of control • The psychodynamic approach • Maslow's hierarchy of needs • Self-actualisation • Check your understanding and prepare for your exams using the multiple choice, short answer and essay practice tests also available.

Towards a definition of personality

People have different styles of thinking, of relating to others, and of working, all of which reflect differences in personality – differences crucial to defining us as individuals. Common experience tells us that there is no one else just like us. There may even be significant differences in the personal characteristics of identical twins.

Such everyday observations provide a starting point for psychology's study of personality. But unlike such informal observations, psychology's approach to studying personality is considerably more calculated. For example, to many people, personality is nothing more than 'what makes people different from one another'. To psychologists, however, the concept is generally defined much more narrowly. **Personality** is a particular pattern of behaviour and thinking that prevails across time and situations and differentiates one person from another.

Psychologists do not draw inferences about personality from casual observations of people's behaviour. Rather, their assessment of personality is derived from results of special tests designed to identify particular personality characteristics. The goal of psychologists who study personality is to discover the causes of individual differences in behaviour.

This goal has led to two specific developments in the field of personality psychology: the development of theories that attempt to explain such individual differences and the development of methods by which individual patterns of behaviour can be studied and classified. Merely identifying and describing a personality characteristic is not the same as explaining it. However, identification is the first step on the way to explanation. What types of research effort are necessary to study personality? Some psychologists devote their efforts to the development of tests that can reliably measure differences in personality. Others try to determine the events – biological and environmental – that cause people to behave as they do. Thus, research on human personality requires two kinds of effort: identifying personality characteristics and determining the variables that produce and control them.

Trait theories of personality

As you will see in this chapter, the word 'personality' means different things to different people. The way in which personality is used by trait theorists is similar to the way in which we often think of personality in everyday life: a set of personal characteristics that determines the different ways we act and react in a variety of situations.

Personality types and traits

It has long been apparent that people differ in personality. The earliest known explanation for these individual differences is the humoral theory, proposed by the Greek physician Galen in the second century AD and based on then-common medical beliefs that had originated with the ancient Greeks. The body was thought to contain four humours, or fluids: yellow bile, black bile, phlegm and blood. People were classified according to the disposition supposedly produced by the predominance of one of these humours in their systems. Choleric people, who had an excess of yellow bile, were bad tempered and irritable. Melancholic people, who had an excess of black bile, had gloomy and pessimistic temperaments. Phlegmatic people, whose bodies contained an excessive amount of phlegm, were sluggish, calm and unexcitable. Sanguine people had a preponderance of blood (*sanguis*), which made them cheerful and passionate.

Although later biological investigations discredited the humoral theory, the notion that people could be divided into different **personality types** – different categories into which personality characteristics can be assigned – persisted long afterwards. For example,  Freud's theory, which maintains that people go through several stages of psychosexual development, predicts the existence of different types of people, each type having problems associated with one of these stages. We discuss some of these problems later in this chapter.

Personality types are useful in formulating hypotheses because, when a theorist is thinking about personality variables, extreme cases are easily brought to mind. But after identifying and defining personality types, one must determine whether these types actually exist and whether knowing a person's personality type can lead to valid predictions about their behaviour in different situations.

Most modern investigators view individual differences in personality as being in degree, not kind. Tooby and Cosmides (1990) have, for example, argued that the nature of human reproduction makes the evolution of specific personality types unlikely – fertilisation produces a reshuffling of the genes in each generation, making it highly unlikely that a single, unified set of genes related to personality type would be passed from one generation to the next.

Rather than classify people by categories, or types, many investigators prefer to measure the degree to which an individual expresses a particular personality trait. A **personality trait** is an enduring personal characteristic that reveals itself in a particular pattern of behaviour in different situations. A simple example illustrates the difference between types and traits. We could classify people into two different types: tall people and short people. Indeed, we use these terms in everyday language. But we all recognise

that height is best conceived of as a trait – a dimension on which people differ along a wide range of values. If we measure the height of a large sample of people, we will find instances all along the distribution, from very short to very tall, as Figure 14.1 illustrates. It is not that people are only either tall or short (analogous to a personality type) but that people vary in the extent to which they are one or the other (analogous to a personality trait).

We assume that people tend to behave in particular ways: some are friendly, some are aggressive, some are lazy, some are timid, some are reckless. Trait theories of personality fit this common-sense view. However, personality traits are not simply patterns of behaviour: they are factors that underlie these patterns and are responsible for them.

Identification of personality traits

Trait theories of personality do not pretend to be all-encompassing explanations of behaviour. Instead, they are still at the stage of discovering, describing and naming the regular patterns of behaviour that people exhibit (Goldberg, 1993). In all science, categorisation must come before explanation; we must know what we are dealing with before we can go about providing explanations. The ultimate goal of the personality psychologist is to explain what determines people's behaviour – which is the ultimate goal of all branches of psychology.

Allport's search for traits

Gordon Allport (1897–1967) was one of the first psychologists to search systematically for a basic core of personality traits. He began by identify-

ing all the words in an unabridged dictionary of the English language that described aspects of personality (Allport and Odbert, 1936). He found around 18,000 words, which he then further analysed for those that described only stable personality characteristics. He eliminated words that represented temporary states, such as 'flustered', or evaluations, such as 'admirable'. This still left him with over 4,000 words. Allport was interested in learning how many traits are needed to describe personality and exactly what these traits may be. For example, many of those 4,000 words, such as 'shy' and 'bashful', are synonyms. Although each synonym presumably makes some sort of distinction about a trait, a group of synonyms together might be used to describe the same underlying trait. Many trait theorists believe that the most basic set of personality traits ranges from 3 to 16 traits.

Allport's research stimulated other psychologists to think about personality in terms of traits or dispositions. In fact, most modern trait theories can be traced to Allport's earlier theoretical work. Like Allport, modern trait theorists maintain that only when we know how to describe an individual's personality will we be able to explain it.

Cattell: sixteen personality factors

In Chapter 11 you read about the importance of using factor analysis in defining intelligence. Factor analysis identifies variables that tend to be correlated. To use factor analysis to study personality, researchers must observe the behaviour of a large number of people. Usually, the observations are limited to responses to questions on paper-and-pencil tests, but occasionally, investigators observe people's behaviour in semi-natural situations. Statistical procedures then permit investigators to determine which items a given person tends to answer in the same way; they can then infer the existence of common factors. For example, a shy person would tend to say no to statements such as 'I attend parties as frequently as I can' or 'When I enter a room full of people, I like to be noticed.' In contrast, outgoing people would tend to say 'yes' to these statements.

To the degree that people possess orderly personality traits, they tend to answer certain clusters of questions in particular ways. Raymond Cattell (b. 1905) began his search for a relatively small number of basic personality traits with Allport and Odbert's (1936) list of adjectives. In addition, he collected data on people's personality characteristics from interviews, records describing their life histories, and from observing how people behave in particular situations. From this list, Cattell began to construct preliminary versions of a questionnaire called the 16PF. Then, using factor analysis, he analysed responses from thousands of people to whom the inventory had

Figure 14.1 The distribution of height. We can measure people's height, a trait, on a continuous scale. We can also look at the extremes and divide people into the categories 'short' and 'tall' types.

been administered. Eventually, he identified 16 personality factors.

Cattell referred to these 16 traits as source traits because, in his view, they are the cornerstones upon which personality is built: they are the primary factors underlying observable behaviour. He called groups of similar types of observable behaviour surface traits; he included such traits as kindness, honesty and friendliness because they are visible to others. They represent the surface of personality and spring forth from source traits, which lie deeper within the personality. Figure 14.2 illustrates a personality profile of a hypothetical individual rated on Cattell's 16 factors. The factors are listed in order of importance, from top to bottom. Look at the ratings to see whether you think they would help you to predict the person's behaviour.

Eysenck: three factors

Hans Eysenck (1916–1997) also used factor analysis to devise his theory of personality (Eysenck,

1970; Eysenck and Eysenck, 1985). His research identified three important factors: extraversion, neuroticism and psychoticism. These factors are bipolar dimensions. Extraversion is the opposite of introversion, neuroticism is the opposite of emotional stability, and psychoticism is the opposite of self-control. **Extraversion** refers to an outgoing nature and a high level of activity; **introversion** refers to a nature that shuns crowds and prefers solitary activities.

Neuroticism refers to a nature full of anxiety, worries and guilt; **emotional stability** refers to a nature that is relaxed and at peace with itself. **Psychoticism** refers to an aggressive, egocentric and antisocial nature; **self-control** refers to a kind and considerate nature, obedient of rules and laws. Eysenck's use of the term 'psychoticism' is different from its use by most clinical psychologists; his term refers to antisocial tendencies and not to a mental illness. A person at the extreme end of the distribution of psychoticism would receive the diagnosis of antisocial personality disorder.

Table 14.1 lists some questions that have high correlations or factor loadings on Eysenck's three factors. The

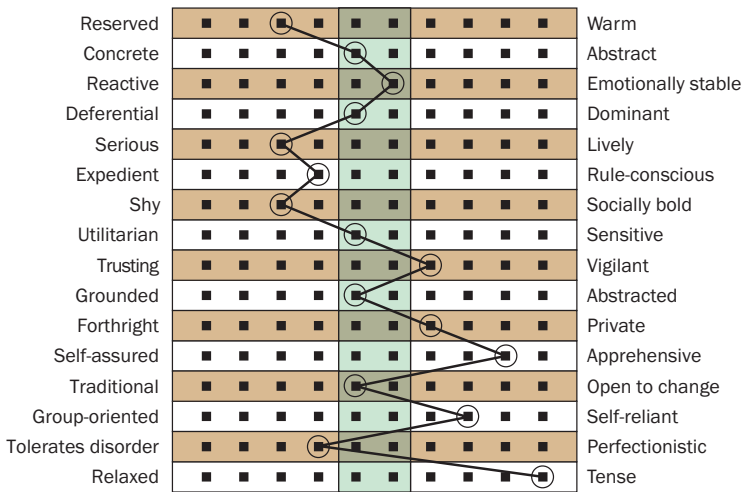

Figure 14.2 A hypothetical personality profile using Cattell's sixteen personality factors.

Cutting edge – Personality and music preferences

Can personality traits predict how you use the music you listen to? A study from the UK has found that British and American undergraduates who were open and intellectually engaged (enjoyed the arts, problem-solving, engaging in debate) and who had high IQ were more likely to use music in a cognitive or rational way (paying attention to it and appreciating the composition/musicianship) (Chamorro-Premuzic and Furnham, 2007). Neurotic, introverted and non-conscientious participants, on the other hand, were more likely to use music in an emotionally manipulative way – to cheer them up after a bad day, for example.

best way to understand the meaning of these traits is to read the questions and to imagine the kinds of people who would answer yes or no to each group. If a factor loading is preceded by a minus sign, it means that people who say 'no' receive high scores on the trait; otherwise, high scores are obtained by those who answer 'yes'.

According to Eysenck, the most important aspects of a person's temperament are determined by the combination of the three dimensions of extraversion, neuroticism and psychoticism – just as colours are produced by the combinations of the three dimensions of hue, saturation and brightness. Figure 14.3 illustrates the effects of various combinations of the first two of these dimensions – extraversion and neuroticism – and relates them to the four temperaments described by Galen.

More than most other trait theorists, Eysenck emphasises the biological nature of personality (Eysenck, 1991). For example, consider the introversion–extraversion dimension, which is biologically based, according to Eysenck, on an optimum arousal level of the brain.

Eysenck believes that the functioning of a neural system located in the brain stem produces different levels of arousal of the cerebral cortex. Introverts have relatively high levels of cortical excitation, whereas extraverts have relatively low levels. Thus, in order to maintain the optimum arousal level, the extravert requires more external stimulation than does the introvert. The extravert seeks stimulation from external sources by interacting with others or by pursuing novel and highly stimulating experiences. The introvert avoids external stimulation in order to maintain their lower arousal level at an optimum state. Different states of arousal are hypothesised to lead to different values of the extraversion trait for different people. This hypothesis is reviewed in the section on the biological basis of personality.

Most trait theorists accept the existence of Eysenck's three factors because they have emerged in factor analyses performed by many different researchers; these appear, in fact, to have the highest validity of all proposed personality factors (Kline, 1993).

Table 14.1 Some items from Eysenck's tests of extraversion, neuroticism and psychoticism

Factor	Loading
<i>Extraversion</i>	
Do you like mixing with people?	0.70
Do you like plenty of bustle and excitement around you?	0.65
Are you rather lively?	0.63
<i>Neuroticism</i>	
Do you often feel fed up?	0.67
Do you often feel lonely?	0.60
Does your mood often go up and down?	0.59
<i>Psychoticism</i>	
Do good manners and cleanliness matter much to you?	−0.55
Does it worry you if you know there are mistakes in your work?	−0.53
Do you like taking risks for fun?	0.51

Cutting edge – How extraverted is 'honey.bunny77@hotmail.de'?

Have you ever wondered if people's email addresses – the ones they themselves chose – reflect their personality or mask it? And is your impression of someone who emails you coloured by the email moniker they use? A group of German researchers examined 599 email addresses from young adults, measured the users' personality and then asked others to rate these emailers' personality based solely on the

email address (Back *et al.*, 2008). The researchers found a remarkable correspondence between the nature of the email address and personality type, with independent observers showing high levels of agreement with the users' own assessment of their personality. This was true for neuroticism, openness, agreeableness, conscientiousness and narcissism but not extraversion.

The five-factor model and the Big Five

Languages reflect the observations of a culture; that is, people invent words to describe distinctions they notice. An analysis of such distinctions by Tupes and Christal (1961), replicated by Norman (1963), led to the most widely accepted mode of personality traits: the **five-factor model** (FFM; McCrae and Costa, 1985, 1987, 1990). The FFM proposes that personality is composed of the following five primary dimensions:

- 1 Neuroticism
- 2 Extraversion
- 3 Openness
- 4 Agreeableness
- 5 Conscientiousness

These factors can be measured by the Neuroticism, Extraversion, and Openness Personality Inventory, or NEO-PI, which consists of 181 items that potentially describe the person being evaluated (McCrae and Costa, 1990). Studies have shown that people's assessment of their own personality agrees well with ratings by spouses and those who know them. The test items are brief sen-

tences, such as 'I really like most people I meet' or (for ratings by someone else) 'She has a very active imagination'. The person taking the test rates the accuracy of each item on a scale of 1 to 5, from strong disagreement to strong agreement. The scores on each of the five factors consist of the sums of the answers to different sets of items.

McCrae *et al.* (1986) validated the FFM through the factor analysis of a list of adjectives contained in a test called the California Q-Set. This test consists of 100 brief descriptions (such as 'irritable', 'cheerful', 'arouses liking' and 'productive'). The items were provided by many psychologists and psychiatrists who found the words useful in describing people's personality characteristics. Thus, the words are not restricted to a particular theoretical orientation. McCrae and his colleagues found that factor analysis yielded the same five factors as the analysis based on everyday language: neuroticism, extraversion, openness, agreeableness and conscientiousness.

The FFM is regarded by most personality psychologists as a fairly robust model of personality (Magai and McFadden, 1995). A study of the personalities of 163 men over 45 years found that neuroticism, extraversion and openness were positively correlated throughout the 45 years and that the traits remained relatively stable (Soldz and

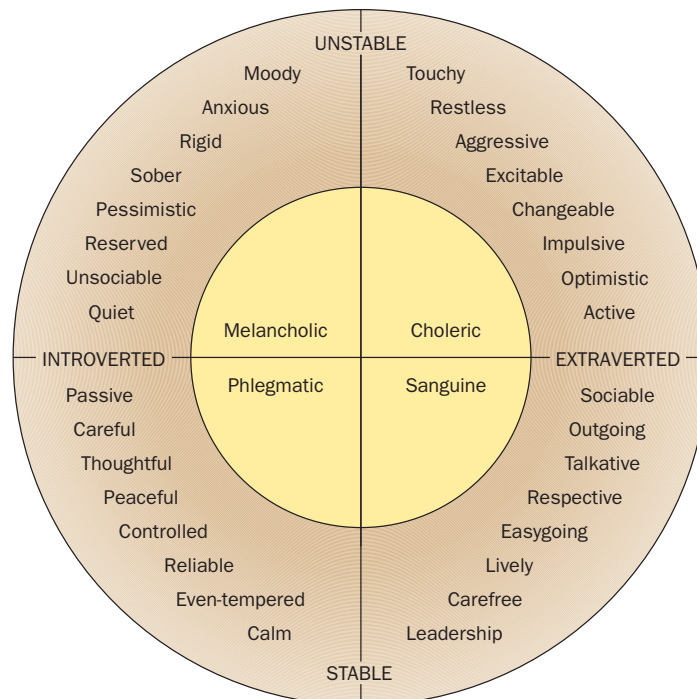

Figure 14.3 Eysenck's original theory illustrated for two factors. According to Eysenck, the two dimensions of neuroticism (stable versus unstable) and introversion–extraversion combine to form a variety of personality characteristics. The four personality types based on the Greek theory of humours are shown in the centre. Eysenck later added 'psychoticism' as the third trait.

Source: Eysenck, H.J., *The Inequality of Man*. London: Temple Smith, 1973. Reprinted with permission.

Vaillant, 1999). The Big Five Personality Inventory has been used to investigate various relationships between personality and other psychological variables, as you will see in this chapter and throughout the book – when a study has investigated conscientiousness or openness to experience, it is using the FFM model. For example, Zhao and Seibert (2006) investigated the differences between the personalities of managers and entrepreneurs. In a meta-analysis, they found that entrepreneurs scored more highly on the dimension of conscientiousness and openness to experience but scored lower on neuroticism and agreeableness. There was no difference between the two groups for extraversion.

Another group explored whether those who are always late for appointments differed in personality traits from those who turned up on time or early. Participants com-

pleted a personality questionnaire (the Big Five) and were invited to participate in an experiment a few days later (Back *et al.*, 2006). The researchers then examined whether any of the personality variables were related to the degree of punctuality. They examined three dependent measures – time of arrival, earliness and lateness. As you might predict, conscientiousness was significantly associated with punctuality – the more conscientious the participant, the less likely he or she was to turn up late and the more likely he or she was to turn up early. Agreeableness was associated with turning up on time and neuroticism was associated with turning up early. The researchers speculate that more specific components of these general traits – such as dependability – might better predict punctuality.

Personality – An international perspective

Any truly grand theory of personality must be able to encompass all cultures, countries and languages. If personality comprises three or five factors, which we all exhibit to a lesser or greater extent, then these factors should be exhibited or reported cross-culturally. If not, then the theory is culture-specific and describes only personality within a limited number of cultures.

One immediate problem in testing the universality of trait theories is that the way in which they are measured depends on language, and different cultures have slightly different words that they use to describe things. They also have words to represent events and objects that other cultures do not. Inuit, for example, have tens of words to describe the quality of snow. Individuals in less Arctic climates would obviously have no need for such a large vocabulary because snow appears only irregularly and does not impinge on their life in such a regular and intrusive way.

In personality, problems in demonstrating universality lie in taxonomy. Do the same words mean the same thing across cultures? For example, various cultures have attributed different meanings to the conscientiousness factor of the Big Five model (Caprara and Perugini, 1994). This factor means something different to the Dutch, Hungarians and Italians, and to the Americans, Germans, Czechs and Poles. Some reviewers have suggested that the best one can do is to find acceptable counterparts of the Big Five in all cultures; the first three factors of the model can be found in most cultures but the cross-cultural validity of others may be questionable (De Raad, 1998). However, there are more consistencies than inconsistencies across cultures.

McCrae *et al.* (2005) asked college students from 50 cultures, including Arabic and Black African cultures, to identify a

man or woman they knew well and rate them using the third person version of the Revised NEO Personality Inventory. The Big Five structure was replicated in almost all cultures (Morocco and Nigeria were two of the half dozen or so not to show this pattern). Women were more positive than men in rating others, especially when rating other women.

In a separate study of the geography of personality traits, Allik and McCrae (2004) examined whether respondents from 36 cultures differed according to the Big Five personality dimension. Cultures that were geographically close shared similar personality traits: the greatest geographical distinction was between European and American cultures, and Asian and African cultures. Americans and Europeans were significantly more extravert and open to experience but less agreeable than peoples from other cultures. Why?

The authors suggest that the results may be due to shared gene pools (China and Korea, for example, share genetic ancestry) or to features of those cultures. Studying the process of acculturation – the assimilation of a person's behaviour with that person's culture – might help identify which is correct. For example, a study of Chinese peoples who emigrated to Canada found that differences between these people and European Canadians attenuated the longer the Chinese lived in Canada (McCrae *et al.*, 1998). Openness and agreeableness, in particular, increased in the immigrant group but introversion remained stable and did not match levels seen in European Canadians. These data suggest that some personality traits might be adopted or enhanced by acculturation, but others may not.

Can cultures also differ according to the implicit or lay trait or context theories they hold? Implicit theories describe what people think about the stability (trait) or variability (context) of

Personality – Continued

personality traits, how consistent they believe such traits are across situations, how they predict behaviour from a person's personality traits, how they form an idea of a person's traits from little behavioural information and so on. Church *et al.* (2005) investigated cross-cultural implicit beliefs about personality in what they called two individualistic cultures – America and Australia – and two collectivistic cultures – Mexico and the Philippines. They hypothesised that the more individualistic the culture, the greater or stronger the culture's beliefs in traits, rather than situations, as determinants of behaviour. Implicit trait beliefs were stronger in Americans than in Mexicans or Filipinos, but implicit contextual beliefs were weaker.

We often hold stereotypes of our own and other nations that may not necessarily be true. The Brits have stiff-upper lips, Americans let it all hang out, Australians don't stand on ceremony and the French are supercilious. None might be accurate; some might.

To investigate whether our perceptions of our own and the culture of others are supported by empirical data, a team of international researchers asked respondents from 49 cultures across six continents to complete a National Character Survey which asked them to describe a typical member from a culture. These responses were compared with personality data collected via the NEO-PI-R (Terracciano *et al.*, 2005).

There was a significant relationship between cultural traits described by others and objectively assessed personality for only four cultures – New Zealand, Australia, Poland and Lebanon. The only significant relationships between self-reported cultural characteristics and personality scores were found in Poland and Japan. Poland, therefore, was the only culture where the people's views of the nation's characteristics were supported by objective data.

The study highlights the power of national stereotypes in our views of others and members of our own culture: such stereotypes are contradicted by empirical data.

Stability of personality traits across the lifespan

Longitudinal studies of personality show remarkable stability in personality factors (especially, extraversion). Cross-sectional studies, however, show less stability – not surprisingly, perhaps, because cross-sectional studies include people who differ in age (and, therefore, share different cultural influences).

A meta-analysis of American studies of undergraduates' personalities in the years between 1966 and 1993 (Twenge, 2001) found that correlations between year of study and extraversion were positive and strong: extraversion seemed to increase as the years went by. The increase in extraversion was large and explained between 14 and 19 per cent of the variance in personality over this time. Does this mean that extraversion increased across the years? The author cautions that this may not necessarily be true. It is possible, for example, that people had become more willing to describe themselves as extravert.

A review of the stability of personality in 152 longitudinal studies (allowing for 3,217 examples of test–retest reliability) found that the consistency of personality increased from childhood to young adulthood, increased still further from adulthood to 30 years, and stabilised between the ages of 50 and 70 years (Roberts and DelVecchio, 2000). These data suggest that personality traits are fairly stable across the lifespan, certainly until the age of 50. Even then, stabilisation is not so great as to indicate a marked change in personality.

The results were confirmed by Caspi *et al.* (2000) who monitored the personalities of children born between April 1972 and March 1973 in Dunedin, New Zealand, the country's fourth largest city. The children were studied from 3 years of age to 21. At the age of 3, children were classified by temperament and, in adulthood, they were asked to rate their own temperament. They also had their temperament rated by others (official records were also used to form an assessment of their temperament).

Children regarded as uncontrollable at the age of 3 grew up to be impulsive, unreliable and antisocial. Children who were regarded as inhibited were more likely to grow up to be more depressed, unassertive and have fewer sources of social support. The authors suggest that behaviour early in life may be strong predictors of behaviour later in life and argue that the earliest that one could use such measures to predict personality would be 2 years because this is when the child begins to develop adequate memory and strategies for remembering. At this point, children also become aware of being embarrassed and of being ashamed.

A Dutch study of 2,494 adults ranging in age from 16 to 91 years of age has found age differences in personality type (Allemand *et al.*, 2008). Although personality was fairly stable across all age groups, there were some differences. Specifically, older adults were more agreeable and more conscientious than were middle-aged or younger adults. The researchers suggest that this reflects 'an increase in personality maturity, in the sense of becoming emotionally more predictable and more attuned to social demands' (p. 767).

Cutting edge – Sex and profession differences in personality

A study of Israeli professionals has found significant personality differences between men and women and between members of different professions (Rubinstein and Strul, 2007). Women were found to be significantly more neurotic and extravert than were men, and artists were found to be more neurotic than were doctors, lawyers and clinical psychologists; artists were also more open to experience than were doctors.

More general sex differences were reported in a 55-culture study by Schmitt *et al.* (2008). In a sample of just over 17,500 participants, they found that women reported higher levels of neuroticism, extraversion, agreeableness and conscientiousness than did men and that these differences were much more pronounced in cultures that are healthy, prosperous and more egalitarian.

One study has suggested that some personality traits are more fluid than others. McCrae and Costa and their international team of researchers looked at changes in the Big Five personality traits from the age of 14 years to 30 years in a sample of Germans, British, Spaniards, Czechs and Turks ($N=5085$) (McCrae *et al.*, 2000). They found that neuroticism, extraversion and openness to experience decreased from 14 to 30 years but that agreeableness and conscientiousness increased. Similar trends were found after 30 years, but the changes were not as pronounced.

A similar pattern – some decline, some stability, but largely some change – has also been noted in a meta-analysis of longitudinal studies. Roberts *et al.* (2006) found that social dominance (a feature of extraversion), conscientiousness and emotional stability increase between the ages of 20 and 40, whereas social vitality and openness increase during adolescence, then decline to old age. Results from meta-analyses such as these suggest that personality traits are not fixed and immutable but are subject to change and evolution (although, generally, this change is not pronounced – a 35-year-old introvert is unlikely to become an uncontrollable 55-year-old extravert).

How we view ourselves in the past and the present

Anecdotal evidence suggests that we view our present selves more positively than we do our younger selves: we feel happier, more successful, able to get on better with others and so on. You saw in Chapter 12 that middle age is associated with general contentment (depression is less common in this period of life). Research, however, can be patchy. Some studies show that young and middle-aged people rate their present selves more positively than their younger selves, whereas older individuals (mean age, 73 years) feel more positively about the present for some attributes, more negatively about others and neutral about still others (Ryff, 1991). Other studies show that people rate themselves to be happier in the present than the past.

In a systematic study of people's appraisals of their past and present selves, Wilson and Ross (2001) asked university undergraduates to provide descriptions of their present selves and how they remember themselves at 16 years of age. People were more positive about their present than past selves. In a second study, participants

Cutting edge – Do you get better looking each day?

The country and western singer, Mac Davis, probably tongue-in-cheek, once sang 'Oh Lord, it's hard to be humble/When I'm perfect in every way/And I can't wait to look in the mirror/Because I get better looking each day.' A study from the University of Cardiff, however, lends support to Davis's cod-vanity.

Geoffrey Haddock (2006) asked women students to rate their present (now) and past selves (beginning of the academic year) for physical attractiveness. They were also asked how important physical attractiveness was to their sense of self. Participants rated their present selves as physically more attractive, but only if physical attraction was a feature they thought was important to their sense of self. In a second experiment, participants judged their current physical attrac-

tiveness and estimated how physically attractive they would be in five years' time. Participants rated their future selves to be more attractive than their current selves. However, this result was found only in participants who tended to make social comparisons with others.

While the results may reflect the fact that students actually do believe that they get more attractive with time, they could also suggest that our appraisals of ourselves are affected by time and that these are relative: we are more positive about the present than the past and are more positive about the future than the present. Whether Mac was right or not, Haddock's participants could have been singing the same tune.

evaluated themselves using a list of desirable attributes (broad-minded, common sense, self-confident, good coping skills, good social skills) and undesirable attributes (dishonest, rude, dull/boring). The same pattern emerged: past selves were viewed less favourably. Even a period of two months was sufficient to produce a less favourable view of the past self compared with the present self. In two more studies, the researchers found that people judged themselves to have improved more significantly than acquaintances. When people compared their past self to a peer at that age, they regarded themselves more favourably than they did their peer.

There are various explanations for why people regard their current self more positively than they do their past self. Perhaps people revise the past because they wish to see their present selves in a favourable light. Revising the past downward may be easier than inflating the past upward. By criticising their past selves, they can feel better about themselves without inflating their current view of themselves. The authors suggest that one way in which this research can be developed is by asking those who have views about the variability of attributes to rate themselves. For example, people who hold that attributes are fixed and relatively stable may regard their past and present selves differently from those who believe that attributes can change over time.

Heritability of personality traits

Several trait theorists, including Cattell and Eysenck, have asserted that a person's genetic history has a strong influence on their personality. Many studies have shown that some personality traits are strongly heritable (Emde *et al.*, 1992; McGue *et al.*, 1993; Jang *et al.*, 1998). As you saw in Chapter 3, the heritability of a trait can be assessed by comparing identical (monozygotic, MZ) with fraternal (dizygotic, DZ) twins, comparing twins raised together with twins raised apart, and comparing biological with adoptive relatives. Many studies have found that identical twins are more similar to each other than are fraternal twins on a variety of personality measures, which indicates that these characteristics are heritable (Loehlin, 1992).

Using various tests of Eysenck's factors of extraversion, neuroticism and psychoticism, Zuckerman (1991) found that identical twins were more similar than fraternal twins on every measure. Similar data have been reported for the Big Five (e.g., Loehlin *et al.*, 1998; Yamagata *et al.*, 2006) with correlations between MZ twins being consistently higher than those for the DZ twins.

The results of Big Five and ENP studies suggest that heredity accounts for between 40 and 70 per cent of the

variability in these three personality traits. Concordance rates for extraversion in MZ twins range between 0.45 and 0.60, and for DZ twins, between 0.15 and 0.3 (Zuckerman, 2005). When people rate the personalities of MZ and DZ twins they see on video, the CR rating for the MZ twins is 0.59 and for the DZ twins 0.23 (so viewers think the MZ twins behave more similarly than the DZ twins, even though they are not aware of their twin status). A similar pattern is seen for peer ratings. The concordance rates for MZ twins reared apart is between 0.3 and 0.6; for DZ twins, it is 0.

Slightly lower correlations are found for neuroticism, but the direction is the same; the CRs are higher for the MZ than DZ twins (Zuckerman, 2005). Thus, it would appear that the remaining 30–60 per cent of the variability is caused by differences in environment. In other words, some family environments should tend to produce extraverts, others should tend to produce introverts, and so on. But research indicates that the matter is not so simple.

Zuckerman (1995) reviewed several studies that measured the correlation in personality traits of pairs of identical twins raised together and raised apart. If family environment has a significant effect on personality characteristics, then the twins raised together should be more similar than those raised apart. But they were not. Taken as a group, these studies found no differences, indicating that differences in family environment account for none of the variability of personality traits in the twins who were tested. Another approach, comparing the personality traits of parents with those of their adopted children, suggests that family environment may account for approximately 7 per cent of the variability (Scarr *et al.*, 1981). If approximately 40–70 per cent of the variability in personality traits is caused by heredity and 0–7 per cent is caused by family environment, what is responsible for the remaining 23–50 per cent of the variability? The answer is that heredity and environment interact.

The major source of the interaction seems to be the effect that people's heredity has on their family environment (Plomin and Bergeman, 1991). That is, people's genetic endowment plays an important role in determining how family members interact with them. Identical twins agreed on their ratings of cohesion, expressiveness, conflict, achievement, culture, activity, organisation and control much more than the fraternal twins did; that is, identical twins were much more likely to have experienced similar family environments.

There are two possible explanations for these results: the family environments could have been more similar for identical twins than for fraternal twins, or the family environments could really have been the same in all cases but were simply perceived as different by the fraternal twins. Evidence suggests that the first possibility is correct, that is, the family environments really were more similar for iden-

tical twins (Loehlin, 1992). How can this be? One might think that each family has a certain environment and that everyone in the household comes under its influence.

Although there are aspects of a family that are shared by the entire household, the factors that play the largest role in shaping personality development appear to come from social interactions between an individual and other family members. These social interactions are different for different people. Because of hereditary differences, one child may be more sociable; this child will be the recipient of more social interaction. Another child may be abrasive and disagreeable; this child will be treated more coldly. In the case of identical twins, who have no hereditary differences, the amount of social interaction with each twin is likely to be similar.

Even physical attributes (which are largely hereditary) will affect a child's environment. A physically attractive child will receive more favourable attention than will an unattractive child. In fact, studies that examined videotaped interactions between mothers and their children confirm that heredity does have an important influence on the nature of these interactions (Plomin and Bergeman, 1991). Thus, although a child's environment plays an important part in their personality development, hereditary factors play a large role in determining the nature of this environment.

One caution about this interpretation is in order. Although the studies cited have been replicated in several cultures, none has investigated the effects of the full range of cultural differences in family lives. That is, when comparisons have been made between twins raised together and those raised apart, almost all have involved family environments within the same culture. It is possible that cultural differences in family environments could be even more important than the differences produced by a person's heredity; only cross-cultural studies will be able to test this possibility.

Are all personality traits a product, direct or indirect, of a person's heredity? The answer is no. Some personality

characteristics show a strong effect of shared environment but almost no effect of genetics. For example, twin studies have found a strong influence of family environment, but not of heredity, on belief in God, involvement in religion, masculinity/femininity, attitudes towards racial integration, and intellectual interests (Loehlin and Nichols, 1976; Rose, 1988). Thus, people tend to learn some important social attitudes from their family environments.

Neurobiological basis of personality

Patients with damage to the front of the brain, the orbitofrontal cortex, as you saw in the last chapter and Chapter 4, behave differently from those with damage to other areas of brain; they are more impulsive, engage in more inappropriate behaviour and report more anger and less happiness (Berlin *et al.*, 2004). Traumatic brain injury to the frontal lobe in children as young as 5 or as old as 14 is associated with personality changes 6 and 12 months following injury (Max *et al.*, 2006). Curiously, given the marked changes in 'personality' normally observed in frontal lobe patients, Berlin *et al.* (2004) found no significant differences between the groups on a standard measure of personality (the Big Five). Where, therefore, if anywhere, do the neural correlates of personality reside?

Several psychologists have attempted to relate extraversion, neuroticism and psychoticism to underlying physiological mechanisms (Eysenck and Eysenck, 1985; Gray, 1987; Zuckerman, 1995; Canli, 2006). Zuckerman (1995), for example, suggested that the personality dimensions of extraversion, neuroticism and psychoticism are determined by the neural systems responsible for reinforcement, punishment and arousal. People who score high on extraversion are particularly sensitive to reinforcement – perhaps their neural reinforcement systems are especially active. Table 14.2 summarises Zuckerman's hypothetical explanations for the three major personality dimensions.

Cutting edge – Personality and birth order

Do you have a brother or sister? Do you think that he or she is similar to or different from you? If you have many siblings, and you are the youngest or the oldest, have you noticed that you might behave slightly differently from brother or sister?

A study from the US of families with large numbers of siblings (equal to or greater than six) has found differences in personality between brothers/sisters which is dependent on birth order (Dixon *et al.*, 2008). The youngest sibling, as well

as the three youngest siblings, was significantly more extravert than the oldest, and oldest three siblings, when compared with their own family members and those from the other families. A review published in the 1980s concluded that younger siblings were more sociable.

One explanation for the finding may be that the younger sibling has to try harder for parental attention because of competition from other siblings: increased extraversion is reflected in increased assertiveness.

Table 14.2 Zuckerman’s hypothetical biological characteristics that correspond to personality dimensions

Personality trait	Biological characteristics
Extraversion	High sensitivity to reinforcement
Neuroticism	High sensitivity to punishment
Psychoticism	Low sensitivity to punishment; high optimal level of arousal

Infants who later become extraverts show higher activity levels, whereas adult extraverts show more reinforcement-seeking behaviour. Adult extraverts participate in more social activities, tend to shift from one type of activity to another, are optimistic and expect that their pursuits will result in reinforcing outcomes. However, unlike people who score high on psychoticism, they are sensitive to the effects of punishment and can learn to act prudently. People who score high on neuroticism are anxious and fearful. If they also score high on psychoticism, they are hostile as well. These people are particularly sensitive to the punishing effects of aversive stimuli. Zuckerman therefore suggests that the personality dimension of neuroticism is controlled by the sensitivity of the neural system responsible for punishment, which appears to involve the amygdala.

People who score high on psychoticism have difficulty learning when not to do something. Zuckerman suggests they have a low sensitivity to punishment and also have a high tolerance for arousal and excitation; in other words, we could say that their optimum level of arousal is abnormally high. As you saw in Chapter 13, some theorists hypothesise that people seek situations that provide an optimum level of arousal: too much or too little arousal is aversive. Therefore, a person with a high optimum level of arousal (a high tolerance for excitement) seeks out exciting situations and performs well in them. A neurotic would find these situations aversive, and their behaviour would become disorganised and inefficient. A person with a high tolerance for excitement makes a good warrior but does not fit in well in civilised society. This is a reformulation of Eysenck’s original theory. He argued that extraverts were less reactive to cortical excitation and, therefore, sought out stimulation. Extraverts do need more stimulation to feel good. Introverts, conversely, are cortically over-aroused which leads to them seeking out or avoiding situations that are stimulating. Eysenck’s theory was constructed at a time when EEG and ERP were the only useful methods of measuring excitation. Neuroimaging data show a complicated pattern. Introverts show more activation in some brain regions than do extraverts; conversely, extraverts show more activation in some brain regions than do introverts (Haier *et al.*, 1987).

Canli *et al.* (2001) predicted that extraversion would be correlated with greater brain activation when people watch pleasant images whereas neuroticism would be correlated with greater brain activation when participants watch unpleasant images. Their hypothesis was based on the assumption that extraverts would be more positively disposed and would respond enthusiastically to pleasant stimuli whereas neurotic participants would react intensely to negative stimuli. This is the pattern they found in an fMRI study of 14 women.

Canli *et al.* (2002) also found, however, that extraversion was associated with amygdala activation when participants watched happy faces. The more extravert the individual, the greater the activation in this structure. No other interaction between emotion and personality was found. Canli *et al.*’s findings are illustrated in Figure 14.4.

In a more explicit examination of personality and brain activation, Sigura *et al.* (2000) used Cloninger’s (1986) idea that we have three heritable personality types and correlated these types with regional blood flow using a form of PET. According to Cloninger, the three types are ‘novelty-seeking’ – a tendency towards seeking out novel stimuli and events; ‘harm avoidance’ – a tendency to avoid punishment and harm because individuals respond intensely to such stimuli; and ‘reward dependence’ – a tendency to seek reward and respond intensely to reward. Significant associations between novelty-seeking and brain activation were found in the left insula and the anterior cingulate cortex; a negative correlation was found between harm avoidance and activation in the left parahippocampal gyrus and regions of the frontal, temporal and parietal lobes.

The picture, therefore, is complex – perhaps not surprisingly given the febrile nature of personality and debate over whether it is a genuinely fixed series of traits. Perhaps the biological basis of personality may be found at a more genetic level. There have been associations reported, for example, between the presence of a serotonin gene (5HTT or SERT) and neuroticism scores (Lesch *et al.*, 1996). There are two variants of this gene – a long one and a short one. The short-allele version has been associated with high harm avoidance and neuroticism scores, and lower agreeableness scores (Lesch *et al.*, 1996; Hamer *et al.*, 1999; Greenberg *et al.*, 2000), and with depression and hostility (Mossner *et al.*, 2001; Sen *et al.*, 2004). Novelty-seeking and sensation-seeking have been associated with the presence of a specific dopamine receptor (D4DR) (Ebstein *et al.*, 1996). Its allele has two forms and the longer one has been linked to high-novelty seeking (Baijan *et al.*, 1996), although in reviews of all relevant studies, around half show this pattern (Prolo and Lincino, 2002). In one study of 4-year-old children, mothers of those children with the long form of the D4DR allele described them as having more problems with aggression (Schmidt *et al.*, 2004).

Of course, if this allele is important to more ‘negative’ personality types, perhaps those with the allele might respond in a specific way when they view negative images, such as fearful faces. Predicting that viewing such faces would lead to greater amygdala activation in these allele carriers, Hairi *et al.* (2002) found this activation in an fMRI study of 28 individuals.

Perhaps, in terms of understanding the possible genetic causes of personality expression, Wilson (1998, p. 247) best sums up our current status:

Reductionism across all levels is not a realistic goal for science. . . One could conceivably find all the particular genes that contribute to the genetic variance in a personality trait but not be able to account for the complex interactive influences with environment that shaped the trait. Genes and environment interact throughout development and although environment cannot change genes, it can affect this expression through releaser genes. Genes do not make personality traits or behavioural traits, they simply make proteins that in turn make nerves, biochemicals, and these affect physiology and ultimately, behaviour.

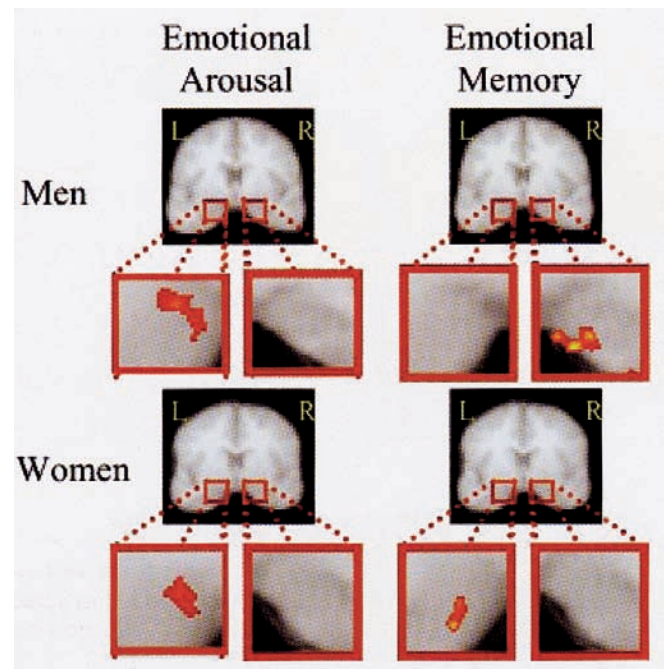

Figure 14.4 Areas of activation in the amygdalae of men and women as they recalled arousing, emotional pictures.

Controversies in Psychological Science – The state you’re in: a psycho-geography of personality

The issue

Can country or a state be said to have a ‘personality’? In what was perhaps the earliest study to explore this in a systematic way, the Catell 16PF was administered to six regions of the US (Krug and Kulhavy, 1973). It found that people from north-eastern, mid-west and west coast states had higher ‘creative productivity’ scores than those in south-eastern, south-western and mountain regions. Another report from the 1970s found that subscriptions to cultured and sophisticated magazines were more common in the north-east and west central parts of the US than the South (Zelinsky, 1974). A more recent study of self-perception in nine US regions found that respondents in the mid and south Atlantic regions rated themselves as ‘nervous’ or ‘worrying’ whereas those in New England, the mid Atlantic and Pacific regions scored more highly on broad-mindedness, curiosity and sophistication (Plaut *et al.*, 2002). The development of well-validated personality measures, such as the Five Factor Model which is biologically rooted and predicts stability in traits across time, has sparked a plethora of cross-cultural and transnational studies.

The evidence

Why should these different states show these different patterns of personality? In a recent review, Rentfrow *et al.* (2008) suggest at least three reasons: (1) people migrated to places that met their psychological and physical needs; (2) a social founder effect, where the intellectual history, customs and culture of a place established social norms for that environment which influenced behaviour and personality, and (3) socialisation, where personality traits are acquired that are consistent with the behaviour seen in the environment people were in, i.e. people behaved in a way that was consistent with the behavioural norm for that region.

In terms of social migration, Rentfrow *et al.* argue that a person high in extraversion, for example, might escape a suffocating small town to one where there is greater stimulation and creativity, and there is evidence from social psychology demonstrating that people seek out social situations that are consistent with their own beliefs and attitudes (Buss, 1987). Extraverts seek out stimulating environments; neurotic people do not (Furnham, 1981). The social influence of the social

Controversies in Psychological Science – Continued

founder effect might work in the same way as emotional contagion – if a personality trait is common in a region, it affects others and is imbibed by them. Environmental factors may also be important – as you saw in Chapter 11, people living in areas with little natural light are more inclined to be unhappy and those living in hot climates tend to experience more violence than those in cold ones (Magnusson, 2000; Anderson and Anderson, 1996).

In their ambitious study, Rentfrow *et al.* investigated whether US regions differed in terms of their extraversion, openness to experience, agreeableness, conscientiousness and neuroticism. They predicted that extraversion would be related to community involvement, preference for enterprising or social professions and interest in physical health (as others had suggested before: Ozer and Benet-Martinez, 2006); agreeableness would be related to religiosity, longevity and low levels of criminality (Ozer and Benet-Martinez, 2006; Roberts *et al.*, 2007); conscientiousness with health-protecting behaviour, longevity and low levels of crime; neuroticism with criminal behaviour and poor coping; and openness to experience with unconventional belief and preference for creative professions.

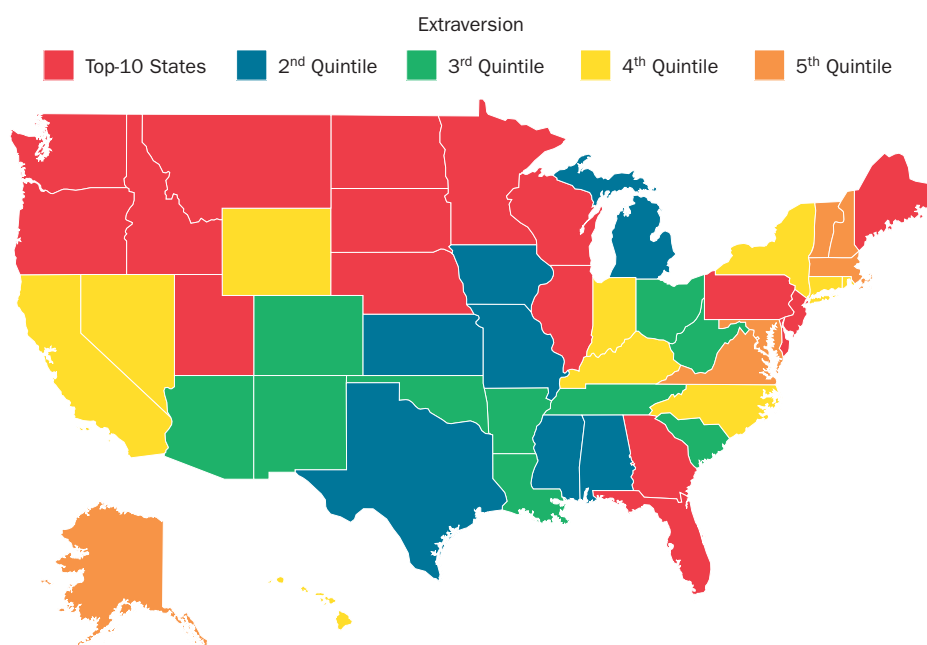

Rentfrow *et al.* used the internet to recruit 619,397 participants from 50 US states and Washington DC. Information about ethnicity, socio-economic status, education, etc. was requested, as was information about personality. Fifty-five per cent were women.

Conclusion

Rentfrow *et al.*'s findings were as follows (see also Figure 14.5 (a) – (e)):

- Levels of *extraversion* were associated with social involvement (such as club meetings, time spent in bars), involvement in business in healthcare professions (e.g. sales/nursing), high rates of robbery and murder, high religiosity and a higher proportion of people in artistic/investigative professions; but lower levels of jogging/exercising.
- Levels of *agreeableness* were associated with low crime and activities that were social (but not bar/club-related), religiosity and involvement in artistic/entertainment professions.
- Levels of *conscientiousness* were positively associated with murder and robbery (strangely – although when demographic variables were taken into account, this effect disappeared), religiosity and less time spent in bars.
- Levels of *neuroticism* were associated with incidents of robbery and murder and in less exercise taken at home.
- Levels of *openness to experience* were associated with liberal values, preference for artistic/investigative professions, and more tolerant views on marijuana, abortion and gay marriage.

The social learning approach

Some psychologists, such as Cattell and Eysenck, are interested in the ways in which people differ with respect to their personality traits. Other psychologists are more interested in the ways in which a person's personality is affected by environmental and cognitive variables. These psychologists view personality and its development as a process in which behavioural, cognitive and environmental variables interact to produce a person's personality. **Social learning theory** embodies the idea that both the consequences of behaviour and an individual's beliefs about those consequences determine personality.

Social learning theory stems partially from Skinner's experimental analysis of behaviour. Although Skinner's work has influenced contemporary personality theory, he should not be mistaken for a personality theorist. He was definitely not one. For Skinner, behaviour is explained entirely in terms of its consequences. Behaviour is consistent from one situation to the next because it is maintained by similar kinds of consequences across those situations. Behaviour changes only when the consequences for behaving change. Skinner's ideas have attracted the attention of some personality researchers because they are experimentally based and provide testable hypotheses for predicting an individual's behaviour within and across situations. Social learning theorists have modified and applied Skinner's ideas to their own work. One such researcher is Albert Bandura (b. 1925), who blended Skinner's ideas with his own ideas about how cognitive factors may influence behaviour.

Expectancies and observational learning

Cognitive processing, including the individual's interpretation of the situation, is central to social learning theory (Bandura, 1973, 1986). An important aspect of cognition for Bandura and other social learning theorists is **expectancy**, the individual's belief that a specific consequence will follow a specific action. Expectancy refers to how someone perceives the contingencies of reinforcement for their own behaviour. If a person does something, it may be because they expect to be rewarded or punished. In different situations, expectancies may vary. For example, a child may learn that he can get what he wants from his younger sister by hitting her. However, on one occasion, his parents may catch him hitting his sister and punish him. His expectancy may now change: he may still get what he wants by behaving aggressively, but if he is caught, he'll be punished. This new expectancy may influence how he

behaves towards his sister in the future (especially around his parents).

Expectancies also permit people to learn actions vicariously, that is, without those actions being directly reinforced. The vicarious nature of some learning experiences is obvious in children as they imitate the actions of others. A 3-year-old who applies deodorant to herself does so not because this behaviour has been reinforced in the past, but rather because after watching her mother do it, she expects it would be 'fun' for her to do so too.

Vicarious learning is better known as observational learning, which is learning through observing the kinds of consequence that others (called models) experience as a result of their behaviour. **Observational learning** is a form of learning in which an expectancy about reinforcement is formed merely by observing another's behaviour and the consequences it produces. Your own experience is no doubt filled with examples of observational learning – learning to dance, to make a paper aeroplane, to write italic, and to engage in many other activities. The more complex the behaviour, the more times we must observe it being executed and practise what we have observed before we can learn it well. Learning to tie a shoelace requires more attention to detail than learning to roll a ball across the floor.

Reciprocal determinism and self-efficacy

Unlike many personality researchers, Bandura does not believe that either personal characteristics (traits) or the environment alone determine personality (Bandura, 1978). Rather, he argues for **reciprocal determinism**, the idea that behaviour, environmental variables and person variables, such as perception, interact to determine personality, as illustrated in Figure 14.6. We know that our actions can affect the environment. We also know that the environment can affect our behaviour. Likewise, our thoughts may affect the ways in which we behave to

Figure 14.6 Patterns of interaction in reciprocal determinism. According to Bandura, behaviour, environment and personal variables, such as cognitions and expectations, interact to determine personality.

change the environment and, in turn, those changes can influence our thoughts. When our acts of kindness are met with kindness in return, we perceive the environment as friendly and are apt to show kindness under other, similar circumstances. Likewise, when we are treated rudely, we perceive the environment as unfriendly (perhaps hostile) and will be likely to attempt to avoid or change similar environments in the future.

According to Bandura (1982), **self-efficacy**, or one's expectations of success in a given situation, is an important determinant of whether one will attempt to make changes in one's environment. Each day, we make many decisions based on our perceptions of the extent to which our actions will produce reinforcement. Our actions are based on our evaluation of our competency. Moreover, self-efficacy not only determines whether we will engage in a particular behaviour, it also determines the extent to which we will maintain that behaviour in the face of adversity. For example, if you believe that you are unqualified for a job even though you really desire it, you are apt not to apply for an interview for that job. However, if you are confident of your qualifications for the job, you will surely attempt the interview. Even if you are turned down for that job, you may interview for a similar position because you are sure of your abilities. Low self-efficacy can hamper both the frequency and the quality of behaviour–environment interactions, and high self-efficacy can facilitate both.

Related to self-efficacy is the extent to which an individual feels optimistic or pessimistic about their life's circumstances. Seligman and Schulman (1986) have found that people (in the case of their study, life insurance agents) who can find something positive in less than desirable circumstances are generally more successful than are people who view those circumstances negatively. It seems that otherwise cheerless circumstances stimulate optimists to seek creative means of 'putting the circumstances right'. Pessimists are more likely to throw up their arms in despair and to give up. Thus, if there is a solution to be found for a problem, the optimist has the better chance of finding it.

Person variables

Like Bandura, Walter Mischel (b. 1930) believes that much of one's personality is learned through interaction with the environment. Also like Bandura, Mischel emphasises the role of cognition in determining how one learns the relationship between one's behaviour and its consequences. In addition, though, Mischel argues that individual differences in cognition, or **person variables** as he calls them, account for differences

in personality. Mischel (1984) proposed five person variables that figure significantly in social learning:

- 1 *Competences.* We each have different skills, abilities and capacities. What we know and the kinds of behaviour that have been reinforced in the past influence the kinds of action in which we will probably engage in the future.
- 2 *Encoding strategies and personal constructs.* We also differ in our ability to process information. The way we process information determines how we perceive different situations. One person may perceive going on a date as fun, and so look forward to it; another person may perceive going on a date as potentially boring, and so dread it.
- 3 *Expectancies.* On the basis of our past behaviour and our knowledge of current situations, we form expectancies about the effects of our behaviour on the environment. Expecting our behaviour to affect the environment positively leads to one course of action; expecting our behaviour to affect it negatively leads to another.
- 4 *Subjective values.* The degree to which we value certain reinforcers over others influences our behaviour. We seek those outcomes that we value most.
- 5 *Self-regulatory systems and plans.* We monitor our progress towards achieving goals and subject ourselves to either self-punishment or self-reinforcement, depending on our progress. We also modify and formulate plans regarding how we feel a goal can best be achieved.

Mischel's view is a dynamic one – people's thoughts and behaviours are undergoing constant change as they interact with the environment. New plans are made and old ones reformulated; people adjust their actions in accordance with their competences, subjective values and expectancies of behaviour–environment interactions. This is taken up in the Controversies in Psychological Science section.

Locus of control

Other social learning theorists, such as Julian Rotter (b. 1916), have argued that the extent to which one perceives oneself to be in control of particular situations is also an important element of personality. **Locus of control** refers to whether one believes that the consequences of one's actions are controlled by internal, person variables or by external, environmental variables (Rotter, 1954, 1966). A person who expects to control their own fate – or, more technically, who perceives that rewards are dependent upon their own behaviour – has an internal locus of control. A person who sees their life as

Controversies in Psychological Science – Do traits or situations best predict behaviour?

The evidence

Social learning theorists stress the importance of the environment to behaviour and place less emphasis on the role of personality traits. They argue that the situation often plays a strong role in determining behaviour. In contrast, trait theorists argue that personality traits are stable characteristics of individuals and that knowing something about these traits permits us to predict an individual's behaviour. Which of these views is correct? Is there a correct view?

The issue

Mischel (1968, 1976) has suggested that stable personality traits do not exist – or if they do, they are of little importance. Situations, not traits, best predict behaviour. He asks us to consider two situations: a party to celebrate someone's winning a large sum of money and a funeral. People will be much more talkative, cheerful and outgoing at the party than at the funeral. How much will knowing a person's score on a test of introversion–extraversion enable you to predict whether he or she will be talkative and outgoing? In this case, knowing the situation has much more predictive value than knowing the test score.

Mischel cites several studies in support of his position. One of the first of these studies was performed over 70 years ago. Hartshorne and May (1928) designed a set of behavioural tests to measure the traits of honesty and self-control and administered them to over 10,000 students in elementary school and high school. The tests gave the children the opportunity to be dishonest – for example, to cheat on a test, lie about the amount of homework they had done, or keep money with which they had been entrusted. In all cases, the experimenters had access to what the children actually did, so they could determine whether the child acted honestly or dishonestly. They found that a child who acted honestly (or dishonestly) in one situation did not necessarily act the same way in a different situation. The average correlation of a child's honesty from situation to situation – the cross-situational consistency – was below 0.3. The authors concluded that 'honesty or dishonesty is not a unified character trait in children of the ages studied, but a series of specific responses to specific situations' (p. 243).

Mischel (1968) reviewed evidence from research performed after the Hartshorne and May study and found that most personal characteristics showed the same low cross-situational consistency of 0.3 or lower. He concluded that the concept of personality trait was not useful. People's behaviour was determined by the situations in which they found themselves, not by any intrinsic personality traits. In a study of personality change following 11 September 2001 (Petersen and

Seligman, 2003), researchers made use of the internet to run an online experiment on positive emotion. Visitors to the website were asked to rate themselves on various positive psychological traits, such as bravery, gratitude, kindness, spirituality, hope, industry and so on. There were 24 traits in all. The questionnaire was uploaded in the spring of 2001 and the researchers were able to compare the responses of those who responded before 11 September with those who completed the survey after that date. Over 900 people had completed the survey before 11 September, while over 3,000 responded after that date. The majority of respondents were American.

When responses immediately before and after the event were compared, seven of the traits showed evidence of a significant increase. People responding after 11 September regarded themselves as more grateful, hopeful, kind, loving and spiritual than did pre-11 September respondents. They also declared a greater sense of leadership and emphasised the importance of teamwork more.

Other psychologists disagree with Mischel. For example, Epstein (1979) noted that personality traits are more stable than some of these measures had suggested. He noted that assessments of cross-situational consistency usually test a group of people on two occasions and correlate their behaviour in one situation with their behaviour in the other. He showed that repeated measurements across several days yielded much higher correlations. In a study of his own, a group of 28 undergraduates kept daily records of their most pleasant and most unpleasant experiences for a month. For each experience, they recorded the emotions they felt, their impulses to action and their actual behaviour. The correlation between a person's emotions, impulses, or behaviour on any two days was rather low – of the order of 0.3. However, when he grouped measurements (that is, correlated the ratings obtained on odd-numbered days with those obtained on even-numbered days), the correlation rose dramatically – up to around 0.8.

Although Mischel is sceptical about the value of the concept of personality trait, he has acknowledged that particular personality traits may be important as predictors of behaviour (Mischel, 1977, 1979). He also points out that some situations by their very nature severely constrain a person's behaviour, whereas others permit a wide variety of responses. For example, red lights cause almost all motorists to stop their cars. In this case, knowing the particular situation (the colour of the traffic light) predicts behaviour better than knowing something about the personality characteristics of the drivers. Conversely, some situations are weak and have little control over people's behaviour. As Zuckerman (1991) points out, an

Controversies in Psychological Science – *Continued*

amber light is such a situation; when drivers see an amber traffic light, some will stop if they possibly can and others will accelerate and rush through the junction. The difference between the two behaviours is likely determined by individual personality traits.

Personality and situations are usually conceived of as independent variables, but they are not always independent. In laboratory settings, experimenters assign people to various situations. Here, situation and personality are truly independent. However, as Bem and Allen (1974) pointed out, people in life outside the laboratory are able to exert some choice over the situations they enter. For instance, a party is a moderately powerful situation and tends to produce extraverted behaviours. Introverted people may stay away from parties to avoid situations that encourage behaviours with which they are not comfortable. Similarly, extraverts may avoid situations in which they are alone. The fact that people choose their own situations means that personality traits interact with situations. Emmons *et al.* (1986) found that people do, indeed, show consistent patterns in the types of situations they

choose; and when circumstances force them to be in situations they do not normally choose, they feel uncomfortable.

Conclusion

Acknowledging the stability of personality over many situations and the interaction between personality and situations, most psychologists agree that the original question, ‘Which is more important in determining a person’s behaviour, the situation or personality traits?’ has proved too simplistic. Some types of personality trait will prevail in most situations; some situations will dictate the behaviour of most people. But some interactions between situation and personality require the analysis of both variables. Figure 14.7 illustrates some of the important variables that control an individual’s personality development.

Fred enjoys most sports and he enjoys most social activities such as drinking and partying. Sometimes, however, he prefers to spend some time by himself. Are we justified in arguing that Fred has a ‘sociability’ trait? Or does the situation determine his behaviour?

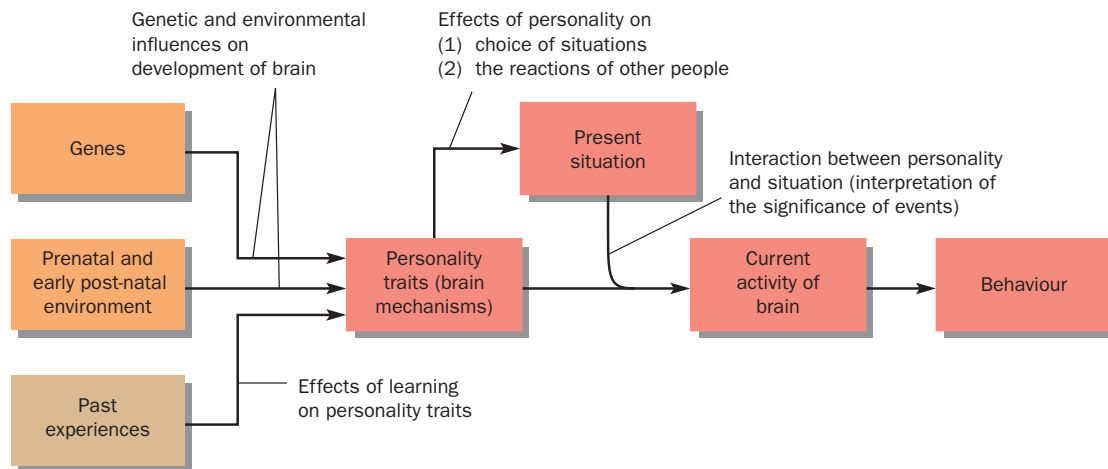

Figure 14.7 Personality traits and the interactions between traits and situations that determine behaviour.

being controlled by external forces unaffected by their own behaviour has an external locus of control, as you can see from Figure 14.8.

Rotter developed the I–E Scale, which assesses the degree to which people perceive the consequences of their behaviour to be under the control of internal or external variables. The I–E Scale contains 29 pairs of statements to which a person indicates their degree of agreement. A typical item would be:

The grades that I achieve depend on my abilities and how hard I work to get them.

The grades that I achieve depend mostly on my teacher and his or her tests.

The scale is scored by counting the number of choices consistent with either the internal or the external locus of

Figure 14.8 Internal and external loci of control. People having internal loci of control perceive themselves as being able to determine the outcomes of the events in their lives. People having external loci of control perceive the events in their lives to be determined by environmental variables.

control orientation. Scores may range from 0 to 23, with lower scores indicative of greater internal locus of control. Of all the populations Rotter has assessed with the I–E Scale, the highest level of internal locus of control was obtained from a group of Peace Corps volunteers (Rotter, 1966).

Rotter's scale has been used in hundreds of studies of social behaviour in a wide variety of situations. Consider some of the findings obtained from research using the I–E Scale:

- People having internal locus of control orientations will work harder to obtain a goal if they believe that

they can control the outcome in a specific situation. Even when told that a goal could be obtained with their own skill and effort, those having external orientations tended not to try as hard as those having internal orientations (Davis and Phares, 1967).

- People having internal orientations are also more likely to be aware of and to use good health practices. They are more apt to take preventive medicines, to exercise regularly and to stop smoking than are people having external orientations (Strickland, 1979). They are, however, more likely to blame themselves when they fail, even when failure is not their fault (Phares, 1984).

Psychology in action – Personality and romance

Since the pioneering study of Terman (1938) psychologists have sought to determine which factors contribute to a successful romantic relationship. One view suggests that the more similar two people are, the more successful their relationship. An alternative view, however, suggests that a successful relationship arises from the compatibility of a partner with a person's idea of an ideal mate.

To test this hypothesis, Zentner (2005) studied non-married students for nine months and examined the relationship between their satisfaction with their partner and the partner's qualities (whether similarities or proximities to the ideal partner). The study found that the closeness between a partner and a person's ideal of a romantic partner were better predictors of a satisfied relationship than was the similarity between partners. This gives rise to all manner of questions. For exam-

ple, if we say that we are attracted to people who share our personality characteristics, why does the similarity between the personality of ourselves and a partner play little role in successful romantic attraction?

Another factor that might predict romantic success (its longevity) is family history. The quality of parenting, for example, might influence the ways in which offspring form and develop their own relationships because of the ways in which children are brought up. Recent research examining the effect of parenting style and individual differences on competence in romantic relationships in young mid-western Americans has found that parenting styles that are nurturing are associated with more successful romantic relationships in offspring, even when the offspring's personality characteristics were taken into account (Donnellan *et al.*, 2005).

The psychodynamic approach

The work of Sigmund Freud had a profound and lasting effect on twentieth-century society but little long-term effect on modern psychology.

Terms such as ego, libido, repression, rationalisation and fixation are as familiar to many Western laypeople as to clinicians. Before Freud formulated his theory, people believed that most behaviour was determined by rational, conscious processes. Freud was the first to claim that what we do is often irrational and that the reasons for our behaviour are seldom conscious. The mind, to Freud, was a battleground for the warring factions of instinct, reason and conscience; the term **psychodynamic** refers to this struggle.

The development of Freud's theory

Sigmund Freud (1856–1939) was a Viennese physician who acquired his early training in neurology in the laboratory of Ernst Wilhelm von Brücke, an eminent physiologist and neuro-anatomist. Freud's work in the laboratory consisted mostly of careful anatomical observation rather than experimentation. Careful observation also characterised his later work with human behaviour; he made detailed observations of individual patients and attempted to draw inferences about the structure of the human psyche from these cases.

Freud left Vienna briefly and studied in Paris with Jean Martin Charcot, who was investigating the usefulness of hypnosis as a treatment for hysteria. Patients with hysteria often experience paralysis of some part of the body or loss of one of the senses, and no physiological cause can be detected. The fact that hypnosis could be used either to produce or to alleviate these symptoms suggested that they were of psychological origin. Charcot proposed that hysterical symptoms were caused by some kind of psychological trauma. Freud was greatly impressed by Charcot's work and became even more interested in problems of the mind.

Freud returned home to Vienna, opened his medical practice and began an association with Josef Breuer, a prominent physician. Freud and Breuer together published a book called *Studies on Hysteria*, and one of the cases cited in it, that of Anna O., provided the evidence that led to some of the most important tenets of Freud's theory. Breuer had treated Anna O. 12 years before he and Freud published their book. She suffered from a great number of hysterical symptoms, including loss of speech, disturbances in vision, headaches, and paralysis and loss of feeling in her right arm. Under hypnosis, Anna was asked to think about the time when her symptoms had started.

Each of her symptoms appeared to have begun just when she was unable to express a strongly felt emotion. While under hypnosis, she experienced these emotions again, and the experience gave her relief from her hysterical symptoms. It was as if the emotions had been bottled up, and reliving the original experiences uncorked them. This release of energy (which Breuer and Freud called catharsis) presumably eliminated the hysterical symptoms.

The case of Anna O. is one of the most frequently reported cases in the annals of psychotherapy. However, Breuer's original description appears to be inaccurate in some of its most important respects (Ellenberger, 1972). Apparently, the woman was not cured at all by Breuer's hypnosis and psychotherapy. Ellenberger discovered hospital records indicating that Anna O. continued to take morphine for the distress caused by the disorders Breuer had allegedly cured. Freud appears to have learned later that the cure was a fabrication, but this fact did not become generally known until recently. However, Breuer's failure to help Anna O. with her problems does not mean that we must reject psychoanalysis. Although Breuer's apparent success inspired Freud to examine the unconscious, Freud's theory of personality must stand or fall on its own merits when evaluated by modern evidence.

The case of Anna O., along with evidence obtained from his own clinical practice, led Freud to reason that human behaviour is motivated by instinctual drives, which, when activated, supply 'psychic energy'. This energy is aversive, because the nervous system seeks a state of quiet equilibrium. According to Freud, if something prevents the psychic energy caused by activation of a drive from being discharged, psychological disturbances will result.

Freud believed that instinctual drives were triggered by traumatic events in a person's life. During such an event, the individual is forced to hide strong emotion. Because it cannot be expressed normally, the emotion is expressed neurotically, that is, with excessive anxiety. The individual cannot recall the emotions or the events that produced them because they are embedded in the **unconscious**, the inaccessible part of the mind. Unconscious memories and emotions exert control over conscious thoughts and actions, causing the neurotic symptoms to linger and the emotions of the original traumatic event to stay secret.

Freud also believed that the mind actively prevents unconscious traumatic events from reaching conscious awareness. That is, the mind represses the memories of traumatic events, most of which are potentially anxiety-provoking, preventing their being consciously discovered. He used the idea of an iceberg as a metaphor to describe the mind. Only the tip is visible above water; the much larger and more important part of it is submerged. Likewise, the conscious mind hides a larger and more important part of

the mind – the unconscious. To understand a person's personality, we must tap his or her unconscious.

Freud, then, argued that our personalities are determined by both conscious and unconscious powers, with the unconscious exerting considerable influence on the conscious. To understand how the unconscious exerts its control over conscious thought and action, we need to explore Freud's view of the structure of personality.

Structures of the mind: id, ego and superego

Freud was struck by the fact that psychological disturbances could stem from events that a person apparently could no longer consciously recall, although they could be revealed during hypnosis. This phenomenon led him to conclude that the mind consists of unconscious, preconscious and conscious elements. The unconscious includes mental events of which we are not aware, the conscious entails mental events of which we are aware, and the preconscious involves mental events that may become conscious through effort.

Freud divided the mind into three structures: the id, the ego and the superego. The operations of the **id** are completely unconscious. The id contains the **libido**, which is the primary source of instinctual motivation for all psychic forces; this force is insistent and is unresponsive to the demands of reality. The id obeys only one rule: to obtain immediate gratification in whatever form it may take – this is called the **pleasure principle**. If you are hungry, the id compels you to eat; if you are angry, the id prompts you to strike out or to seek revenge or to destroy something. Freud (1933, p. 65) conceived of the id as

the dark, inaccessible part of our personality . . . We approach the id with analogies: we call it a chaos, a cauldron full of seething excitations . . . It is filled with energy reaching it from the instincts, but it has no organisation, produces no collective will, but only a striving to bring about the satisfaction of the instinctual needs subject to the observance of the pleasure principle.

The **ego** is the self; it controls and integrates behaviour. It acts as a mediator, negotiating a compromise among the pressures of the id, the counterpressures of the superego and the demands of reality. The ego's functions of perception, cognition and memory perform this mediation. The ego is driven by the **reality principle**, the tendency to satisfy the id's demands realistically, which almost always involves compromising the demands of the id and superego. It involves the ability to delay gratification of a drive until an appropriate goal is located. To ward off the demands of the id when these demands cannot be gratified, the ego

uses defence mechanisms (described later). Some of the functions of the ego are unconscious.

The **superego** is subdivided into the conscience and the ego-ideal. The **conscience** is the internalisation of the rules and restrictions of society. It determines which behaviours are permissible and punishes wrongdoing with feelings of guilt. The **ego-ideal** is the internalisation of what a person would like to be – their goals.

Freud believed the mind to be full of conflicts. A conflict might begin when one of the two primary drives, the sexual instinctual drive or the aggressive instinctual drive, is aroused. The id demands gratification of these drives but is often held in check by the superego's internalised prohibitions against the behaviours the drives tend to produce. Internalised prohibitions are rules of behaviour learned in childhood that protect the person from the guilt that they would feel if the instinctual drives were allowed to express themselves.

The result of the conflict is compromise formation, in which a compromise is reached between the demands of the id and the suppressive effects of the superego. According to Freud, phenomena such as dreams, artistic creations and slips of the tongue (we now call them Freudian slips) are examples of compromise formation.

In what many consider to be his greatest work, *The Interpretation of Dreams*, Freud wrote, 'The interpretation of dreams is the royal road to a knowledge of the unconscious activities of the mind' (1900, p. 647). To Freud, dreams were motivated by repressed wishes and urges. By analysing dreams, Freud thought repressed wishes and memories could be rediscovered. For example, Freud believed that the **manifest content** of a dream – its actual storyline – is only a disguised version of its **latent content** – its hidden message, which is produced by the unconscious. The latent content might be an unexpressed wish related to the aggressive instinctual drive.

For example, a person may desire to hurt or injure another person, perhaps a co-worker with whom they are competing for a promotion. However, if the person acted out this scenario in a dream, they would experience guilt and anxiety. Therefore, the aggressive wishes of the unconscious are transformed into a more palatable form – the manifest content of the dream might be that the co-worker accepts a job offer from a different company, removing any competition for the promotion. The manifest content of this dream manages to express, at least partly, the latent content supplied by the unconscious.

In addition to analysing his patient's dreams, Freud also developed the technique of free association to probe the unconscious mind for clues of intrapsychic conflict. **Free association** is a method of analysis in which an individual is asked to relax, clear his or her mind of current thoughts and then report all thoughts, images, perceptions and feelings that come to mind. During free

association, Freud looked for particular patterns in his patient’s report that might reveal wishes, fears and worries that the patient’s mind might be keeping hidden. For example, free association might reveal, among other things, the thought of beating someone up, an image of a knife, and perhaps a feeling of relief. Recognising a pattern in his patient’s report, he may draw conclusions about the client’s hidden desire to harm someone and about the reasons motivating both that desire and the relief experienced once the aggressive urge is satisfied.

Defence mechanisms

According to Freud, the ego contains **defence mechanisms** – mental systems that become active whenever unconscious instinctual drives of the id come into conflict with internalised prohibitions of the superego. The signal for the ego to utilise one of its defences is the state of anxiety produced by an intrapsychic conflict. This unpleasant condition motivates the ego to apply a defence mechanism and thus reduce the anxiety. The six important defence mechanisms are summarised in Table 14.3.

Repression

Repression is responsible for actively keeping threatening or anxiety-provoking memories from our conscious

awareness. For example, a person may have witnessed a brutal murder but cannot recall it later because of the uncomfortable emotions it would arouse. Freud believed that repression was perhaps the most powerful of the defence mechanisms.

Reaction formation

Reaction formation involves replacing an anxiety-provoking idea with its opposite. An often-cited example of a reaction formation is that of a person who is aroused and fascinated by pornographic material but whose superego will not permit this enjoyment. They become a militant crusader against pornography. Reaction formation can be a very useful defence mechanism in this situation, permitting acceptable interaction with the forbidden sexual object. The crusader against pornography often studies the salacious material to see just how vile it is so that they can better educate others about its harmful nature. Thus, enjoyment becomes possible without feelings of guilt.

Projection

Projection involves denial of one’s own unacceptable desires and the discovery of evidence of these desires in the behaviour of other people. For example, a man who is experiencing a great deal of repressed hostility may per-

Table 14.3 Freudian defence mechanisms

Defence mechanism	Description	Example
Repression	The mind’s active attempt to prevent memories of traumatic experiences from reaching conscious awareness	Failure to remember the death of a loved one or other highly upsetting events that occurred earlier in your life
Reaction formation	Replacing an anxiety-provoking idea with its opposite	Having intense feelings of dislike for a person but acting in a friendly manner towards them
Projection	Denial of one’s unacceptable feelings and desire and finding them in others	Denying that you have negative feelings towards someone, but asserting that person to have negative feelings towards you
Sublimation	Channelling psychic energy from an unacceptable drive into a more acceptable one	Diverting energy from the sex drive to produce a work of art
Rationalisation	Creating an acceptable reason for a behaviour that is actually performed for a less acceptable reason	Asserting that you donate money to charities because you truly are a generous person when really you want the tax relief for the donation
Conversion	The manifestation of a psychic conflict in terms of physical symptoms	A psychic conflict, perhaps aroused by a particular person, causes you to develop symptoms of deafness or blindness to avoid contact with them

ceive the world as being full of people who are hostile to him. In this way, he can blame someone else for any conflicts in which he engages.

Sublimation

Sublimation is the diversion of psychic energy from an unacceptable drive to an acceptable one. For example, a person may feel strong sexual desire but find its outlet unacceptable because of internalised prohibitions. Despite repression of the drive, its energy remains and finds another outlet, such as artistic or other creative activities. Freud considered sublimation to be an important factor in artistic and intellectual creativity. He believed that people have a fixed amount of drive available for motivating all activities, therefore surplus sexual instinctual drive that is not expended in its normal way can be used to increase a person's potential for creative achievement.

Rationalisation

Rationalisation is the process of inventing an acceptable reason for a behaviour that is really being performed for another, less acceptable reason. For example, a man who feels guilty about his real reasons for purchasing a pornographic magazine may say, 'I don't buy the magazine for the pictures. I buy it to read the interesting and enlightening articles it contains.'

Conversion

Conversion is the provision of an outlet for intrapsychic conflict in the form of a physical symptom. The conflict is transformed into blindness, deafness, paralysis or numbness. (This phenomenon has also been called hysteria, which should not be confused with the common use of the term to mean 'running around and shouting and generally acting out of control'.) For example, a person might develop blindness so that they will no longer be able to see a situation that arouses a strong, painful intrapsychic conflict. Anna O.'s problem would be described as a conversion reaction.

Freud's psychosexual theory of personality development

Freud believed that personality development involves passing through several psychosexual stages of development – stages that involve seeking pleasure from specific parts of the body called erogenous zones. As we will see, each stage of personality development involves deriving physical pleasure from a different erogenous zone. Freud used the term 'sexual' to

refer to physical pleasures and the many ways an individual might seek to gratify an urge for such pleasure. He did not generally use the term to refer to orgasmic pleasure.

Freud's theory of personality development has been extremely influential because of its ability to explain personality disorders in terms of whole or partial fixation – arrested development owing to failure to pass through an earlier stage of development. Freud believed that a person becomes fixated at a particular stage of development when they become strongly attached to the erogenous zone involved in that stage. Although normal personality development involves passing successfully through all the psychosexual stages, Freud maintained that most people become more or less fixated at some point in their development.

Because newborn babies can do little more than suck and swallow, their sexual instinctual drive finds an outlet in these activities. Even as babies become able to engage in more complex behaviours, they continue to receive most of their sexual gratification orally. The early period of the **oral stage** of personality development is characterised by sucking and is passive. Later, as babies become more aggressive, they derive their pleasure from biting and chewing.

Fixation at the oral stage may result from early (or delayed) weaning from breast to bottle to cup. Someone whose personality is fixated at the early oral stage might be excessively passive. 'Biting' sarcasm or compulsive talking can represent fixation at the later, more aggressive phase of the oral stage. Other oral stage fixation activities include habits such as smoking and excessive eating.

The **anal stage** of personality development begins during the second year of life; now babies begin to enjoy emptying their bowels. During the early part of this stage, called the expressive period, babies enjoy expelling their faeces. Later, in the retentive period, they derive pleasure from retaining them. Improper toilet training can result in fixation at the anal stage. People fixated at the anal expressive period are characterised as destructive and cruel; anal retentives are seen as stingy and miserly.

At around age 3, a child discovers that it is pleasurable to play with his penis or her clitoris, and enters the **phallic stage** (phallus means 'penis', but Freud used the term bisexually in this context). Children also begin to discover the sex roles of their parents, and they unconsciously attach themselves to the parent of the opposite sex. A boy's attachment to his mother is called the **Oedipus complex**, after the mythical Greek king who unknowingly married his mother after killing his father. For a time, Freud believed that a girl formed a similar attachment with her father, called the **Electra complex**, but he later rejected this concept. In Greek mythology, Electra, aided by her brother, killed her mother and her mother's lover to avenge her father's death.

In boys, the Oedipus complex normally becomes repressed by age 5, although the conflicts that occur

during the phallic stage continue to affect their personalities throughout life. A boy's unconscious wish to take his father's place is suppressed by his fear that his father will castrate him as punishment. In fact, Freud believed that young boys regarded females as castrated males. The conflict is finally resolved when the boy begins to model his behaviour on that of his father so that he achieves identification with the father. Failure to resolve this conflict causes the boy to become fixated at this stage. The boy then becomes preoccupied with demonstrations of his manhood, continually acting 'macho'.

Girls supposedly experience fewer conflicts than boys do during the phallic stage. According to Freud, the chief reason for their transfer of love from their mothers (who provided primary gratification during early life) to their fathers is penis envy. A girl discovers that she and her mother lack this organ, so she becomes attached to her father, who has one. This attachment persists longer than the Oedipus complex, because the girl does not have to fear castration as revenge for usurping her mother's role. Freud believed that penis envy eventually becomes transformed into a need to bear children. The missing penis is replaced by a baby. A girl who becomes fixated during the phallic stage develops strong feelings of being inferior to men, which are expressed in seductive or otherwise flirtatious behaviour. For example, she may become attracted to older men ('father figures') and attempt to seduce them to demonstrate her power over them and thereby relieve her feelings of inferiority.

After the phallic stage comes a **latency period** of several years, during which the child's sexual instinctual drive is mostly submerged. Following this period, the onset of puberty, the child, now an adolescent, begins to form adult sexual attachments to age-mates of the other sex. Because the sexual instinctual drive now finds its outlet in heterosexual genital contact, this stage is known as the **genital stage**.

Further development of Freud's theory: the neo-Freudians

Freud's theory created controversy in the Victorian era in which it was unveiled. Its emphasis on childhood sexuality and seething internal conflicts seemed preposterous and offensive. Yet the theory's proposal that our thoughts and behaviour as adults stem from unconscious forces as well as from our early childhood experiences was revolutionary and these were recognised by many scholars as genuinely original ideas. Freud attracted a number of followers who studied his work closely but who did not accept it completely. Each of these people agreed with Freud's view on the dynamic forces operating within the psyche. Each of them disagreed with Freud, though, on how much importance to place on the role of unconscious sexual and

aggressive instincts in shaping personality. Four psychodynamic theorists, Carl Jung, Alfred Adler, Karen Horney and Erik Erikson, have been particularly influential in elaborating psychodynamic theory.

Carl Jung: analytical psychology

Early in the twentieth century, several students of psychoanalysis met with Freud to further the development of psychoanalysis. One of these people was Carl Jung (1875–1961). Freud called Jung 'his adopted eldest son, his crown prince and successor' (Hall and Nordby, 1973, p. 23). However, Jung developed his own version of psychodynamic theory that de-emphasised the importance of sexuality. He also disagreed with his mentor on the structure of the unconscious. Unfortunately, Freud had little tolerance of others' opinions. After 1913, he and Jung never saw each other again. Jung continued to develop his theory after the split by drawing ideas from mythology, anthropology, history and religion, as well as from an active clinical practice in which he saw people with psychological disorders.

To Jung, libido was a positive creative force that propels people towards personal growth. He also believed that forces other than the id, ego and superego, such as the collective unconscious, form the core of personality. To Jung, the ego was totally conscious and contained the ideas, perceptions, emotions, thoughts and memories of which we are aware. One of Jung's more important contributions to psychodynamic theory was his idea of the **collective unconscious**, which contains memories and ideas inherited from our ancestors. Stored in the collective unconscious are **archetypes**, inherited and universal thought forms and patterns that allow us to notice particular aspects of our world (Carver and Scheier, 1992). From the dawn of our species, all humans have had roughly similar experiences with things such as mothers, evil, masculinity and femininity. Each one of these is represented by an archetype. For example, the shadow is the archetype containing basic instincts that allow us to recognise aspects of the world such as evil, sin and carnality. Archetypes are not stored images or ideas – we are not born with a picture of evil stored somewhere in our brain – but we are born with an inherited disposition to behave, perceive and think in certain ways.

Alfred Adler: striving for superiority

Like Jung, Alfred Adler (1870–1937) studied with Freud. Also like Jung, Adler felt that Freud overemphasised the role of sexuality in personality development. Adler argued that feelings of inferiority play the key role. Upon birth, we are dependent on others for survival. As we mature, we encounter people who are more gifted than

we are in almost every aspect of life. The inferiority we feel may be social, intellectual, physical or athletic. These feelings create tension that motivates us to compensate for the deficiency. Emerging from this need to compensate is a striving for superiority, which Adler believed to be the major motivational force in life.

According to Adler (1939), **striving for superiority** is affected by another force, social interest, which is an innate desire to contribute to society. Social interest is not wholly instinctual though, because it can be influenced by experience. Although individuals have a need to seek personal superiority, they have a greater desire to sacrifice for causes that benefit society as a whole. Thus, while Freud believed that people act in their own self-interest, motivated by the id, Adler believed that people desire to help others, directed by social interest.

Karen Horney: The Flight of the Vagina

Karen Horney (pronounced ‘horn-eye’; 1885–1952), like other Freudian dissenters, did not believe that sex and aggression are the primary themes of personality. She did agree with Freud, though, that anxiety is a basic problem that people must address and overcome.

According to Horney, individuals suffer from basic anxiety caused by insecurities in relationships. People often feel alone, helpless or uncomfortable in their interactions with others. For example, a person who begins a new job is often unsure of how to perform their duties, whom to ask for help, and how to approach their new colleagues. Horney theorised that to deal with basic anxiety, the individual has three options (Horney, 1950):

- 1 *Moving towards others.* Accept the situation and become dependent on others. This strategy may entail an exaggerated desire for approval or affection.
- 2 *Moving against others.* Resist the situation and become aggressive. This strategy may involve an exaggerated need for power, exploitation of others, recognition or achievement.
- 3 *Moving away from others.* Withdraw from others and become isolated. This strategy may involve an exaggerated need for self-sufficiency, privacy or independence.

Horney believed that these three strategies corresponded to three basic orientations with which people approach their life. These **basic orientations** reflect different personality characteristics. The self-effacing solution corresponds to the moving towards others strategy and involves the desire to be loved. The self-expansive solution corresponds to the moving against others strategy and involves the desire to master oneself. The resignation solution corresponds to the moving away strategy and involves striving to be independent of others.

Horney maintained that personality is a mixture of the three strategies and basic orientations. As the source of anxiety varies from one situation to the next, so may the strategy and basic orientation that is used to cope with it. Like Adler, Horney thought environmental variables influenced personality development. In her view, outlined in her book, *The Flight of the Vagina*, in order to understand personality one must consider not only psychodynamic forces within the mind, but also the environmental conditions to which those forces are reacting.

Erik Erikson: identity crisis

Erik Erikson (1902–94) studied with Anna Freud, Sigmund Freud’s daughter. He emphasised social aspects of personality development rather than biological factors. He also differed from Freud about the timing of personality development. For Freud, the most important development occurs during early childhood. Erikson emphasised the ongoing process of development throughout the lifespan. Erikson proposed that people’s personality traits develop as a result of a series of crises they encounter in their social relations with other people. Because these crises continue throughout life, psychosocial development does not end when people become adults.

Erikson’s theory of lifelong development has been very influential, and his term ‘identity crisis’ has become a familiar one. However, because his theory does not make many empirically testable predictions, it has received little empirical support.

Evaluation of psychodynamic theory and research

Freud’s psychodynamic theory has had a profound effect on psychological theory, psychotherapy and literature. His writing, although nowadays regarded as sexist, is lively and stimulating, and his ideas have provided many people with food for thought. However, his theory has received little empirical support, mainly because he used concepts that are poorly defined and that cannot be observed directly. How is one to study the ego, the superego or the id? How can one prove (or disprove) that an artist’s creativity is the result of a displaced aggressive or sexual instinctual drive? The writings of the neo-Freudians have had even less influence on modern research. Although the theories of Jung, Adler, Horney and Erikson have their followers, scientific research on personality has largely ignored them.

The emphasis by Freud and his followers on the potentially harmful effects of particular types of childhood environment has led some psychotherapists to conclude that their patients’ maladjustments and mental disorders are, by and large, caused by their parents. Many parents

have blamed themselves for their children's disorders and have suffered feelings of severe guilt. But many forms of mental disorders – particularly the most serious ones – are largely a result of heredity and are not affected much by family environment. Hence, the teachings of Freud and his followers have compounded the tragedy of mental illness by causing parents to be accused unjustly of poor parenting practices.

The one Freudian phenomenon that has undergone experimental testing is repression. This phenomenon is very important to Freud's theory because it is one of the primary ego defences and because it operates by pushing memories (or newly perceived stimuli) into the unconscious. Thus, experimental verification of repression would lend some support to Freud's notions of intrapsychic conflict and the existence of the unconscious.

The results of research on repression have not been conclusive. Typically, the researchers in repression experiments ask participants to learn some material associated with an unpleasant, ego-threatening situation, and they then compare their memory for the information with that of participants who learned the material under non-threatening conditions. If repression occurs, the threatened participants should remember less of the material than the non-threatened participants will. Some studies have reported positive results, but later experiments have shown that other, non-Freudian phenomena could explain them more easily (D'Zurilla, 1965). Perhaps the most important point here is that none of the experiments can really be said to have threatened the participants' egos, producing the level of anxiety that would lead to the activation of a defence mechanism. Any experimental procedure that did so would probably be unethical. Thus, it is difficult to test even the most specific prediction of Freud's theory. It is very hard, perhaps impossible, to prove that a person's behaviour and personality are products of unconscious conflicts. If a person admits to their sexual urges, psychoanalytic thinking would accept this as fitting the theory; if they deny them, they are repressing these urges and denying their existence. Can you see a problem here in scientifically accepting psychoanalytic explanations of personality?

The humanistic approach

The **humanistic approach** to the study of personality seeks to emphasise the positive, fulfilling elements of life. Humanistic psychologists are interested in nurturing personal growth, life satisfaction and positive human values. They believe that people are innately good and have an internal drive for **self-actualisation** – the realisation of one's true intellectual and

emotional potential. The two most influential humanistic theorists have been Abraham Maslow and Carl Rogers.

Maslow and self-actualisation

For both Freud and Abraham Maslow (1908–70), motivation is one of the central aspects of personality. However, where Freud saw strong instinctual urges generating tensions that could not be completely resolved, Maslow saw positive impulses that could be easily overwhelmed by the negative forces within one's culture. According to Maslow (1970), human motivation is based on a hierarchy of needs. Our motivation for different activities passes through several levels, with entrance to subsequent levels dependent on first satisfying needs in previous levels, as illustrated by Figure 14.9. If an individual's needs are not met, they cannot scale the hierarchy and so will fail to attain their true potential.

In Maslow's view, understanding personality requires understanding this hierarchy. Our most basic needs are physiological needs, including the need for food, water, oxygen, rest and so on. Until these needs are met, we cannot be motivated by needs found in the next level (or any other level). If our physiological needs are met, we find ourselves motivated by safety needs, including the need for security and comfort, as well as for peace and freedom from fear. Once the basic survival and safety needs are met, we can become motivated by attachment needs, the need to love and to be loved, to have friends and to be a friend. Next, we seek to satisfy esteem needs – to be competent and recognised as such. You are probably beginning to get the picture: we are motivated to achieve needs higher in the hierarchy only after first satisfying lower needs. If we are able to lead a life in which we have been able to provide ourselves with food and shelter and to surround ourselves with love, we are free to pursue self-actualisation.

Maslow based his theory partially on his own assumptions about human potential and partially on his case studies of historical figures whom he believed to be self-actualised, including Albert Einstein, Eleanor Roosevelt, Henry David Thoreau and Abraham Lincoln. Maslow examined the lives of each of these people in order to assess the common qualities that led each to become self-actualised. In general, he found that these individuals were very self-accepting of themselves and of their lives' circumstances, were focused on finding solutions to pressing cultural problems rather than to personal problems, were open to others' opinions and ideas, were spontaneous in their emotional reactions to events in their lives, had strong senses of privacy, autonomy, human values and appreciation of life, and had a few intimate friendships rather than many superficial ones.

Maslow (1964) believed that the innate drive for self-actualisation is not specific to any particular culture. He

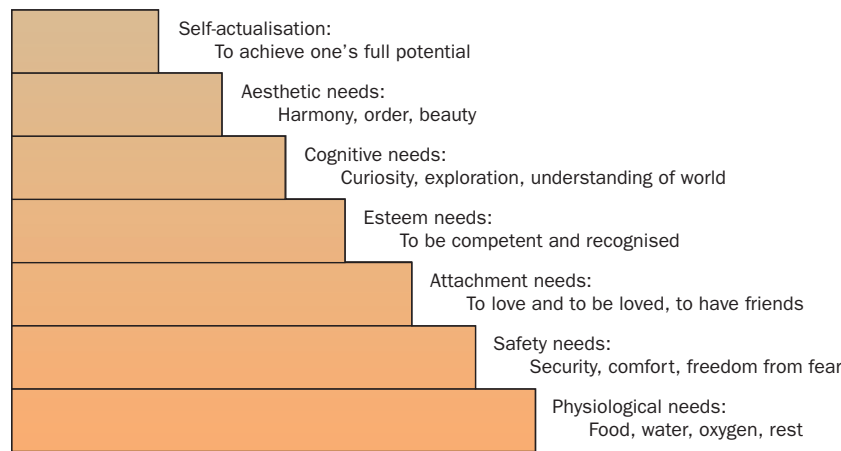

Figure 14.9 Maslow's hierarchy of needs. According to Maslow, every person's goal is to become self-actualised. In order to achieve this goal, individuals must first satisfy several basic needs.

viewed it as being a fundamental part of human nature. In his words, 'Man has a higher and transcendent nature, and this is part of his essence . . . his biological nature of a species which has evolved' (p. xvi).

Rogers and conditions of worth

Carl Rogers (1902–87) also believed that people are motivated to grow psychologically, aspiring to higher levels of fulfilment as they progress towards self-actualisation (Rogers, 1961). Like Maslow, Rogers believed that people are inherently good and have an innate desire for becoming better. Rogers, though, did not view personality development in terms of satisfying a hierarchy of needs. Instead, he believed that personality development centres on one's self-concept, or one's opinion of oneself, and on the way one is treated by others.

Rogers argued that all people have a need for positive regard, or approval, warmth, love, respect and affection flowing from others. Young children, in particular, show this need when they seek approval for their actions from parents and siblings. In Rogers's view, children often want others to like them to the extent that gaining positive regard is a major focus of their lives. The key to developing a psychologically healthy personality, though, is to develop a positive self-concept or image of oneself. How does one do this? Rogers's answer is that we are happy if we feel that others are happy with us. Likewise, we are also unhappy with ourselves when others are disappointed in or unsatisfied with us.

Thus, our feelings towards ourselves depend to a large extent on what others think of us. As children, we learn that there exist certain conditions or criteria that must be met before others give us positive regard. Rogers called these criteria **conditions of worth**.

Positive regard is often conditional. For example, parents may act approvingly towards their young child when he helps in the kitchen or in the garden but not when he pinches his younger sister or tells a lie. The boy learns that what others think of him depends on his actions. Soon, too, he may come to view himself as others view him and his behaviour: 'People like me when I do something good and they don't like me when I do something bad.'

Although conditions of worth are a necessary part of the socialisation process, they can have negative effects on personality development if satisfying them becomes the individual's major ambition. As long as the individual focuses chiefly on seeking positive regard from others, they may ignore other aspects of life, especially those that lead to positive personality growth. In Rogers's view, then, conditions of worth may stand in the way of self-actualisation. An individual may devote her life to satisfying the expectations and demands of others in lieu of working towards realising her potential. In this sense, the need for positive regard may smother an individual's progress towards self-actualisation.

According to Rogers, the solution to this problem is **unconditional positive regard**, or love and acceptance that has no strings attached. In a family setting, this means that parents may establish rules and expect their children to obey them, unless doing so would compromise the children's feelings of worth and self-respect. For example, if a child misbehaves, the parents should focus on the child's behaviour and not the child. In this way, the child learns that her behaviour is wrong but that her parents still love her. Unconditional positive regard allows people to work towards realising their potential unfettered by what others think of them.

In developing his theory, Rogers used unstructured interviews in which the client, not the therapist, directed the course of the conversation. He believed that if the therapist

provided an atmosphere of unconditional positive regard, a client would eventually reveal their true self, the kind of person they now are, as well as their ideal self, the kind of person that they would like to become. Rogers also gave the Q sort test to many of his clients. This test consists of a variety of cards, each of which contains a statement such as ‘I am generally an optimistic person’ or ‘I am generally an intolerant person’. The client’s task is to sort the cards into several piles that vary in degree from ‘least like me’ to ‘most like me’. The client sorts the cards twice, first on the basis of their real self and next in terms of their ideal self. The difference between the arrangement of the cards in the piles is taken as an index of how close the client is to reaching their ideal self. Rogers’s goal as a therapist was to facilitate the client’s becoming their ideal self. Rogers’s approach to therapy is discussed in more detail in Chapter 18.

Evaluation of the humanistic approach

The humanistic approach is impressive because of its emphasis on people seeking a healthy well-being. Indeed, the approach has wide appeal to those who seek an alternative to the more mechanistic and strictly biologically or environmentally determined views of human nature. However, critics point up two closely related problems with this approach.

First, many of the concepts used by humanistic psychologists are defined subjectively and so are difficult to test empirically. For example, how might we empirically examine the nature of self-actualisation? Few published studies have even attempted to answer this question. By now, you know the hallmark of a good theory – the amount of research it generates. On this count, the humanistic approach comes up short.

A second criticism of the humanistic approach is that it cannot account for the origins of personality. It is subject to the **nominal fallacy**; it describes personality, but it does not explain it. Humanistic psychologists believe that self-actualisation is an innate tendency, but there is no research that shows it to be so. Conditions of worth are said to hamper a child’s quest for self-actualisation and thus to alter the course of personality development away from positive psychological growth. However, the humanistic approach provides no objective explanation of this process. Although the humanistic approach may offer a positive view of human nature and give apparent purpose to life, this view is largely unsubstantiated. Before moving on to the next section, take time to look at Table 14.4 which summarises the major theories of personality we have discussed so far.

Table 14.4 A summary of the major personality theories				
Theory	Primary figures	Primary emphases	Primary strengths	Primary limitations
Trait	Allport, Cattell, Eysenck	An individual’s traits determine personality	Focuses on stability of behaviour over long periods; attempts to measure traits objectively	Largely descriptive; ignores situational variables that may affect behaviour
Psychobiological	Eysenck, Zuckerman	The role of genetics and the brain and nervous system in personality development	Emphasis on the interaction of biology and environment in determining personality; rigorous empirical approach	Reliance on correlation methods in determining the role of genetics in personality
Social learning	Bandura, Mischel, Rotter	Personality is determined by both the consequences of behaviour and our perception of them	Focuses on direct study of behaviour and stresses rigorous experimentation	Ignores biological influences on personality development; often more descriptive than explanatory
Psychodynamic	Freud, Jung, Adler, Horney, Erikson	Unconscious psychic conflicts; repression of anxiety-provoking ideas and desires	The idea that behaviour may be influenced by forces outside conscious awareness	Basic concepts are not empirically testable
Humanistic	Maslow, Rogers	Stresses the positive aspects of human nature and how to become a better person	Useful in therapeutic settings	Contains vague and untestable concepts; primarily descriptive

Assessment of personality

Think for a moment of your best friend. What is he or she like? Outgoing? Impulsive? Thoughtful? Moody? You can easily respond yes or no to these alternatives because you have spent enough time with your friend to know him or her quite well. After all, one of the best ways to get to know people – what they are like and how they react in certain situations – is to spend time with them. Obviously, psychologists do not have the luxury of spending large amounts of time with people in order to learn about their personalities. Generally, they have only a short period to accomplish this goal. From this necessity, personality tests were first developed. The underlying assumption of any personality test is that personality characteristics can be measured. This final section of the chapter describes the two main types of personality test: objective tests and projective tests.

Objective tests of personality

Objective personality tests are similar in structure to classroom tests. Most contain multiple-choice and true/false items, although some allow the person taking the test to indicate the extent to which they agree or disagree with an item. The responses that subjects can make on objective tests are constrained by the test design. The questions asked are unambiguous, and explicit rules for scoring the subjects' responses can be specified in advance. Examples include the Eysenck Personality Inventory and the NEO-PI, described earlier.

One of the oldest and most widely used objective tests of personality is the **Minnesota Multiphasic Personality Inventory (MMPI)**, devised by Hathaway and McKinley in 1939. The original purpose for developing the test was to produce an objective, reliable method for identifying various personality traits that were related to a person's mental health. Improvement in people's scores over the course of treatment would indicate that the treatment was successful.

In devising this test, Hathaway and McKinley wrote 504 true/false items and administered the test to several groups of people in mental institutions in Minnesota who had been diagnosed as having certain psychological disorders. These diagnoses had been arrived at through psychiatric interviews with the patients. Such interviews are expensive, so a simple paper-and-pencil test that accomplished the same result would be valuable. The control group consisted of relatives and friends of the patients, who were tested when they came to visit them. (Whether these people constituted the best possible group

of normal participants is questionable.) The responses were analysed empirically, and the questions that correlated with various diagnostic labels were included in various scales. For example, if people who had been diagnosed as paranoid tended to say true to 'I believe I am being plotted against', this statement would become part of the paranoia scale.

The current revised version of the MMPI, the MMPI-2, has norms based on a sample of people that is much more representative ethnically and geographically than the original sample (Graham, 1990). It includes 550 questions, grouped into ten clinical scales and four validity scales. A particular item can be used on more than one scale. For example, both people who are depressed and those who are hypochondriacal tend to agree that they have gastrointestinal problems. The clinical scales include a number of diagnostic terms traditionally used to label psychiatric patients, such as hypochondriasis, depression or paranoia.

The four validity scales were devised to provide the tester with some assurance that subjects are answering questions reliably and accurately and that they can read the questions and pay attention to them. The '?' scale ('cannot say') is simply the number of questions not answered. A high score on this scale indicates either that the person finds some questions irrelevant or that the person is evading issues that they find painful.

The L scale (lie) contains items such as 'I do not read every editorial in the newspaper every day' and 'My table manners are not quite as good at home as when I am out in company'. A person who disagrees with questions like these is almost certainly not telling the truth. A high score on the L scale suggests the need for caution in interpreting other scales and also reveals something about the participant's personality. In particular, people who score high on this scale tend to be rather naive; more sophisticated people realise that no one is perfect and do not try to make themselves appear to be so.

The F scale (frequency) consists of items that are answered one way by at least 90 per cent of the normal population. The usual responses are 'false' to items such as 'I can easily make other people afraid of me, and sometimes do it for the fun of it', and 'true' to items such as 'I am liked by most people who know me'. A high score on this scale indicates carelessness, poor reading ability or very unusual personality traits.

The K scale (defensiveness) was devised to identify people who are trying to hide their feelings to guard against internal conflicts that might cause them emotional distress. A person receives a high value on the K scale by answering 'false' to statements such as 'Criticism or scolding hurts me terribly' and 'At periods, my mind seems to work more slowly than usual'. People who score very low on this scale tend to be in need of help or to be unusually immune to criticism and social influences.

Some psychologists argue that validity scales are useless or even harmful in most testing situations. For example, consider the following item: ‘Before voting, I thoroughly investigate the qualifications of all candidates’. According to Crowne and Marlowe (1964), anyone who answers ‘yes’ to such a question has to be lying. But as McCrae and Costa (1990) note, people taking tests do not necessarily respond passively to each item, taking it at face value. Instead, their response is based on their interpretation of what they think the question means. They suggest (p. 40) that most people will say to themselves:

Surely these psychologists didn’t mean to ask if I actually study the voting records of every single political candidate, from President to dogcatcher. No one does, so that would be a stupid question to ask. What they must have meant to ask was whether I am a concerned citizen who takes voting seriously. Since I am and I do, I guess I should answer yes.

There is evidence to support McCrae and Costa’s suggestion. When psychologists calculate a person’s score on the MMPI, they usually apply a correction factor derived from the validity scales. Several studies have shown that the application of the correction factors to the scores of normal subjects actually reduces the validity of these scores. McCrae and Costa suggest that when the MMPI is administered to normal subjects for research purposes, such corrections should not be made. However, validity scales may be useful in situations in which subjects may be motivated to lie (for example, when a personality test is used to screen job applicants) or in cases in which the test is being used clinically to evaluate the possibility of mental illness or personality disorder.

As well as being used in clinical assessment, the MMPI has been employed extensively in personality research, and a number of other tests, including the California Psychological Inventory and the Taylor Manifest Anxiety Scale, are based on it. However, the MMPI has its critics. As we saw earlier, the five-factor model of personality has received considerable support. Some of its advocates have noted that the MMPI misses some of the dimensions measured by the NEO-PI, which includes tests of neuroticism, extraversion, openness, agreeableness and conscientiousness (Johnson *et al.*, 1984). Thus, these factors will be missed by a clinician or researcher who relies only on the MMPI. For this reason, many researchers, especially those interested in the psychobiology of personality, no longer use the MMPI.

Projective tests of personality

Projective tests of personality are different in form from objective ones and are derived from psychodynamic theories of personality. Psychoanalytically oriented psychologists believe that behaviour is determined by unconscious processes more than by conscious ones. Thus, they believe that a test that asks straightforward questions is unlikely to tap the real roots of an individual’s personality characteristics.

Projective tests are designed to be ambiguous so that the person’s answers will be more revealing than simple agreement or disagreement with statements provided by objective tests. The assumption of projective tests is that an individual will ‘project’ his or her personality into the ambiguous situation and thus make responses that give clues to this personality. In addition, the ambiguity of the test makes it unlikely that subjects will have preconceived notions about which answers are socially desirable. Thus, it will be difficult for a subject to give biased answers in an attempt to look better (or worse) than he or she actually is.

The Rorschach Inkblot Test

One of the oldest projective tests of personality is the **Rorschach Inkblot Test**, published in 1921 by Hermann Rorschach, a Swiss psychiatrist. The Rorschach Inkblot Test consists of ten pictures of inkblots, originally made by spilling ink on a piece of paper that was subsequently folded in half, producing an image that is symmetrical in relation to the line of the fold. Five of the inkblots are black and white, and five are colour. The participant is shown each card and asked to describe what it looks like. Then the cards are shown again, and the participant is asked to point out the features they used to determine what was seen. The

responses and the nature of the features the participant uses to make them are scored on several dimensions.

In the following example described by Pervin (1975), a person's response to a particular inkblot might be 'Two bears with their paws touching one another playing a game or could be they are fighting and the red is the blood from the fighting'. The classification of this response, also described by Pervin (p. 37), would be: large detail of the blot was used, good form was used, movement was noted, colour was used in the response about blood, an animal was seen, and a popular response (two bears) was made. A possible interpretation of the response might be:

Subject starts off with popular response and animals expressing playful, 'childish' behaviour. Response is then given in terms of hostile act with accompanying inquiry. Pure colour response and blood content suggest he may have difficulty controlling his response to the environment. Is a playful, childlike exterior used by him to disguise hostile, destructive feelings that threaten to break out in his dealings with the environment?

Although the interpretation of people's responses to the Rorschach Inkblot Test was originally based on psycho-analytical theory, many investigators have used it in an empirical fashion. That is, a variety of different scoring methods have been devised, and the scores obtained by these methods have been correlated with clinical diagnoses, as investigators have done with people's scores on the MMPI. However, the validity of these scoring techniques and the validity of the test in general is questionable (Groth-Marnat, 1997).

The Thematic Apperception Test

Another popular projective test, the **Thematic Apperception Test (TAT)**, was developed in 1938 by the American psychologists Henry Murray and C.D. Morgan to measure various psychological needs. People are shown a picture of a very ambiguous situation and are asked to tell a story about what is happening in the picture, explaining the situation, what led up to it, what the characters are thinking and saying, and what the final outcome will be. Presumably, the participants

will 'project' themselves into the scene, and their stories will reflect their own needs. As you might imagine, scoring is difficult and requires a great deal of practice and skill. The tester attempts to infer the psychological needs expressed in the stories. Consider the responses of one woman to several TAT cards, along with a clinician's interpretation of these responses (Phares, 1979, p. 273). The questions asked by the examiner are in parentheses.

Card 3BM. Looks like a little boy crying for something he can't have. (Why is he crying?) Probably because he can't go somewhere. (How will it turn out?) Probably sit there and sob himself to sleep. *Card 3GF.* Looks like her boyfriend might have let her down. She hurt his feelings. He's closed the door on her. (What did he say?) I don't know. *Card 10.* Looks like there's sorrow here. Grieving about something. (About what?) Looks like maybe one of the children's passed away.

Interpretation. The TAT produced responses that were uniformly indicative of unhappiness, threat, misfortune, a lack of control over environmental forces. None of the test responses were indicative of satisfaction, happy endings, etc. . . . In summary, the test results point to an individual who is anxious and, at the same time, depressed.

The pattern of responses in this case is quite consistent; few people would disagree with the conclusion that the woman is sad and depressed. However, not all people provide such clear-cut responses. As you might expect, interpreting differences in the stories of people who are relatively well adjusted is much more difficult. As a result, distinguishing among people with different but normal personality traits is hard.

One major problem with the TAT is in quantifying responses, such as the ones above. Often, responses are analysed qualitatively which makes assessing the reliability of the test difficult. Others have argued that subjecting the test to quantitative rigorous examination defeats the object of using the test which is to help guide a clinician's assessment of a patient's personality. However, even here, there are problems in that there is little agreement between clinicians regarding the assessment of the individual's responses on the TAT (Groth-Marnat, 1997).

Controversies in Psychological Science – Are projective tests reliable and valid?

The issue

Most empirical studies find that projective tests, such as the Rorschach Inkblot Test and the TAT, have poor reliability and little validity. For example, Eron (1950) found no differences between the scores of people admitted to mental hospitals and a group of college students. In a review of over 300 studies, Lundy (1985) found that the validity of the TAT appears to be lower when it is administered by an authority figure, in a classroom setting or when it is represented as a test. Lundy (1988) suggests that in such situations, the participants are likely to realise that they are talking about themselves when they tell a story about the cards and may be careful about what they say. Why are projective tests so unsuccessful?

The evidence

Projective tests have met with little success for a number of reasons: (1) there are few standardised procedures because different clinicians can present tests and present different parts of them in different ways; (2) norms are rarely available so that comparisons between how an individual performs and how he or she performs compared to the population cannot be reliably made; (3) the tests have low reliability – people can respond differently on a test depending on the examiner; and (4) the tests have low validity – they do not measure what they purport to measure.

Scott Lilienfeld and his colleagues at Texas, Emory and Pittsburgh Universities have conducted a comprehensive and critical review of the scientific status of projective tests. (Lilienfeld *et al.*, 2000). The review raises some important questions about the ways in which the tests are administered, used and interpreted. These concerns take on added significance when you consider that over 30 per cent of clinical psychologists who were members of the American Psychological Association reported using projective techniques either always or frequently, according to one survey (Watkins *et al.*, 1995), and over 80 per cent used the tests at least once or occasionally.

The most popular of the projective techniques used by respondents in the Watkins *et al.* (1995) study was the Rorschach Inkblot Test. The test was criticised in the 1950s and 1960s for poor standardisation. These criticisms were taken on board and when the test was corrected in the 1970s, detailed instructions for the administration and interpretation of the test, as well as the provision of some norms, were included (Exner, 1974). The correction became known as the Comprehensive System. Despite the improvement in standardisation, Lilienfeld *et al.* (2000) found that reliability continued to be low: clinicians agreed on only half of the characteristics

that the test purports to reveal about the individual (the test involves the clinician rating the individual's responses on over 100 characteristics).

The test also showed poor validity; although clinicians claimed that the test could identify mental disorder, researchers found that it was poor at detecting depression, anxiety and psychopathy. Some studies claimed to show that tests did reveal these disorders; others not: the picture was clearly inconsistent. This highlights the danger in using the test unthinkingly: it could identify people as mentally ill when they are not. Lilienfeld *et al.* (2001) cite a study of 123 volunteers at a blood donation centre who were asked to complete the test: one in six was identified as showing signs of schizophrenia.

The scores they receive on one day are often very different from those they receive on another day. But a test of personality is supposed to measure enduring traits that persist over time and in a variety of situations. The TAT has also been criticised for potential sex bias, mostly because of what are considered male-dominated themes, such as power, ambition and status, used to score the test (Worchel *et al.*, 1990).

According to Lilienfeld *et al.* (2000), the TAT suffers from the same early problems as the Rorschach: there are no standardised procedures (so clinicians can administer as many or as few of the scenes and in any order, as they wish) and no way of scoring the test in a standardised way (clinicians interpret the responses to the scenes intuitively). In fact, the number of psychologists using a standardised scoring system for TAT has been reported to be as low as 3 per cent. The TAT also suffers from the unavailability of population norms and from poor test–retest reliability. Attempts have been made to provide standardised scoring systems for the TAT (Westen *et al.*, 1990) which seem to show that it is good at describing people's perceptions of others, but these attempts may not be sufficiently rigorous to be clinically applicable.

Conclusion

Lilienfeld *et al.* (2000) suggest that we can draw six conclusions from a review of studies of the scientific status of projective tests:

- 1 the use of projective tests continues to be very controversial and psychiatrists need to be aware of this;
- 2 people can 'fake' responses on these tests;
- 3 the techniques are used for purposes for which they were not intended;
- 4 scoring can be unreliable and poor;

Controversies in Psychological Science – *Continued*

- 5 norms are either absent or poorly described;
- 6 the techniques may show a cultural bias favouring North Americans.

If projective tests such as the Rorschach and the TAT have been found to be of low reliability and validity, why do many clinical psychologists and psychiatrists continue to use them?

The primary reason seems to be tradition. The use of these tests has a long history and the rationale for the tests is consistent with psychodynamic explanations of personality. Many psychodynamic and clinical psychologists still argue that the tests are valuable for discovering and evaluating inner determinants of personality, whatever the evidence to the contrary.

Chapter review

Trait theories of personality

- We can conceive of personality characteristics as types or traits. The earliest theory of personality classified people into types according to their predominant humour, or body fluid. Today, most psychologists conceive of personality differences as being represented by degree, not kind.
- Personality traits are the factors that underlie patterns of behaviour. Presumably, these factors are biological in nature, although they may be the products of learning as well as heredity.
- The search for core personality traits began with Allport, who studied how everyday words are used to describe personality characteristics. Although he never isolated a core set of traits, his work inspired others to continue the search for such traits.
- Several researchers developed their theories of personality through factor analysis, a statistical method of reducing a large amount of data to two or three themes or ideas (called factors).
- Cattell's analyses indicated the existence of 16 personality factors; Eysenck's research suggested that personality is determined by three dimensions: extraversion (versus introversion), neuroticism (versus emotional stability) and psychoticism (versus self-control).
- McCrae and Costa's five-factor model, based on an analysis of words used to describe people's behavioural traits, includes extraversion, neuroticism, agreeableness, openness and conscientiousness. There is strong cross-cultural agreement on the first three factors but not on the fifth.

Psychobiological approaches

- Studies of twins and adopted children indicate that personality factors, especially extraversion, neuroticism and psychoticism, are affected strongly by genetic factors. However, there is little evidence for an effect of common family environment, largely because an individual's environment is strongly affected by heredity factors, such as personality and physical attributes.

- Zuckerman argues that extraversion is caused by a sensitive reinforcement system, neuroticism is caused by a sensitive punishment system (which includes the amygdala), and psychoticism is caused by the combination of a deficient punishment system and an abnormally high optimum level of arousal.
- Extraversion is associated with increased amygdala activation when viewing happy faces.

The social learning approach

- Social learning theory blends Skinner's notion of reinforcement with cognitive concepts such as expectancy to explain social interaction and personality.
- According to Bandura, people learn the relation between their behaviour and its consequences by observing how others' behaviour is rewarded and punished. In this way, people learn to expect that certain consequences will follow certain behaviours.
- Bandura has also argued that personality is the result of reciprocal determinism – the interaction of behaviour, environment and person variables such as perception.
- The extent to which a person is likely to attempt to change his or her environment is related to self-efficacy, the expectation that he or she will be successful in producing the change. People with low self-efficacy tend not to try to alter their environments; the opposite is true for people with high self-efficacy.
- Mischel has argued that personality differences are due largely to person variables – individual differences in cognition. These variables include competences, encoding strategies and personal constructs, expectancies, subjective values, and self-regulatory systems and plans.
- Rotter's research has shown that locus of control – the extent to which people believe that their behaviour is controlled by person variables or by environmental variables – is also an important determinant of personality.

- Traits and situations interact: some people are affected more than others by a particular situation, and people tend to choose the types of situation in which they find themselves. People's personality traits directly affect situational variables.

The psychodynamic approach

- Freud believed that the mind is full of conflicts between the primitive urges of the id and the internalised prohibitions of the superego.
- According to Freud, these conflicts tend to be resolved through compromise formation and through ego defences such as repression, sublimation and reaction formation. His theory of psychosexual development, a progression through the oral, anal, phallic and genital stages, provided the basis for a theory of personality and personality disorders.
- Freud's followers, most notably Jung, Adler, Horney and Erikson, embraced different aspects of Freud's theory, disagreed with other aspects, and embellished still other aspects.
- Jung disagreed with Freud about the structure of the unconscious and the role of sexuality in personality development, and saw libido as a positive life force.
- Adler also disagreed with Freud on the importance of sexuality. Instead, Adler emphasised the need to compensate for our inferiority and our innate desire to help others as the major forces in personality development.
- Horney argued that personality is the result of the strategies and behaviours people use to cope with anxiety, which she believed is the fundamental problem that all people must overcome in the course of normal personality development.
- Erikson maintained that personality development is more a matter of psychosocial processes than of psychosexual processes. He viewed personality development as involving eight stages, each of which involves coping with a major conflict or crises. Resolution of the conflict allows the person to pass to the next stage; failure to resolve it inhibits normal personality development.
- Although Freud was a brilliant and insightful thinker, his theory has not been experimentally verified, primarily because most of his concepts are unobservable and, therefore, untestable.
- Maslow argued that self-actualisation is achieved only after the satisfaction of several other important but lesser needs, for example, physiological, safety and attachment needs.
- Maslow's case study analysis of people whom he believed to be self-actualised revealed several common personality characteristics including self-acceptance, a focus on addressing cultural problems and not personal ones, spontaneity, preservation of privacy, an appreciation of life, and possession of a few very close friends.
- According to Rogers, the key to becoming self-actualised is developing a healthy self-concept. The primary roadblocks in this quest are conditions of worth – criteria that we must meet to win the positive regard of others. Rogers maintained that too often people value themselves only to the extent that they believe other people do. As a result, they spend their lives seeking the acceptance of others instead of striving to become self-actualised. Rogers proposed that only by treating others with unconditional positive regard could we help people to realise their true potential.
- Although the humanistic approach emphasises the positive dimensions of human experience and the potential that each of us has for personal growth, it has been criticised for being unscientific.
- Critics argue that its concepts are vague and untestable and that it is more descriptive than explanatory.

Assessment of personality

- Objective tests contain items that can be answered and scored objectively, such as true/false or multiple-choice questions.
- One of the most important objective personality tests is the Minnesota Multiphasic Personality Inventory (MMPI), which was empirically devised to discriminate among people who had been assigned various psychiatric diagnoses. It has since been used widely in research on personality.
- The MMPI's validity scales have been challenged by researchers who suggest that most people's responses can be taken at face value. More recently, researchers interested in personality have turned to tests not based on people with mental disorders, such as the NEO-PI.
- Projective tests, such as the Rorschach Inkblot Test and the Thematic Apperception Test, contain ambiguous items that elicit answers that presumably reveal aspects of participants' personalities; because answers can vary widely, test administrators must receive special training to interpret them. Unfortunately, evidence suggests that the reliability and validity of such tests is poor.

The humanistic approach

- The humanistic approach attempts to understand personality and its development by focusing on the positive side of human nature and people's attempts to reach their full potential: self-actualisation.

Social cognition and attitudes

Michael A. Hogg, Dominic Abrams and G. Neil Martin

Explore the accompanying videos, simulations and animations on MyPsychLab. This chapter includes activities on: Impression formation • The actor-observer effect • Unconscious stereotyping • Cognitive dissonance • Check your understanding and prepare for your exams using the multiple choice, short answer and essay practice test also available.

'MI5' fantasy conman faces life sentence for deception

Simon Freeman

A conman who wove an elaborate web of deceit – likened to the plot of a James Bond film – was facing a life sentence today after a decade preying sexually and financially on his credulous victims. In reality, Robert Hendy-Freegard, 34, was a barman at the Swan pub near the Harper Adams Agricultural College in Newport, Shropshire.

In the fabulous fantasy world that he constructed around him, he was an MI5 spy on an undercover investigation into an IRA cell.

Using sophisticated mental manipulation techniques and violence he convinced a number of students of his credentials and, under the guise of recruiting them to assist in his pretend missions, took over their lives.

Six were women, all were seduced – he was in sexual relationships with five at the same time – and most became engaged to him. Among the victims was a solicitor, who rated his bedroom techniques '11 out of 10', a psychologist and a pregnant company director.

WHAT YOU SHOULD BE ABLE TO DO AFTER READING CHAPTER 8

- Define social psychology and understand what social psychologists do.
- Understand how we process, store and use information about ourselves and other people.
- Understand the motives that influence how we form a conception of who we are.
- Understand how self-concept influences our perceptions and treatment of other people.
- Understand how we make inferences, especially causal inferences, about others' behaviour, and also about our own behaviour.
- Understand how attitudes are formed and changed

QUESTIONS TO THINK ABOUT

- Are the problems facing social psychology different from those in other branches of psychology?
- What makes social psychology similar to sociology, and what makes it similar to neuroscience?
- Does it matter where and when social psychology research is conducted?
- How quickly can you form a mental image of another person? What does the image contain? Is it purely visual, or does it capture something about their personality, group membership, or other 'social' information? How are such impressions formed?
- What determines whom you like and dislike? Why do you sometimes change your mind about a person?
- Why do you use stereotypes and is it possible to avoid them?
- Who are you? Would you answer this question differently if different people asked it? Why?
- Who would you trust to make an accurate judgement about your future prospects: a teacher, parent or yourself? What might influence the judgement made by each of these people?
- Try to persuade someone using a line of argument with which you personally disagree. Is persuasion simply a matter of using the right technique or are there other reasons why this is a difficult task? What tactics do you use, and why?

Social psychology

Most human activity is social. We spend most of our waking hours interacting with, thinking about, or being directly or indirectly influenced by other people. Our behaviour affects the way others think, feel and act and, in turn, their behaviour affects our thoughts, feelings and actions. Not for nothing is the great American social psychologist Elliot Aronson's best-selling book on social psychology called *The Social Animal* (latest edition published in 2007). Human interaction also structures the norms, conventions and institutions that make up the societies we live in.

The field of psychology that studies social behaviour is called **social psychology**. According to Gordon Allport (1968, p. 3), social psychology is study of 'how the thoughts, feelings, and behaviour of individuals are influenced by the actual, imagined, or implied presence of others'. In the next two chapters we explore the way in which people, as individuals or in groups, affect one another. We examine the complex interplay of basic cognitive processes and cognitive structures that we use to process and store information, and the nature of human relations and interactions that occur in everyday life. In this chapter we focus on social cognition and attitudes – how people process and store social information, and how social information affects social behaviour. In the following chapter we focus on social interaction between individuals, between groups, and among people within groups.

Doing social psychology

To a large extent we are all social psychologists but rather than being empirical scientists, we are more like intuitive social psychologists (Heider, 1958). To get by in life we need to have a well-developed understanding of why people behave as they do, what causes particular behaviours, and what effect our behaviour has on others. These common-sense understandings are often quite accurate, but sometimes they are not. For example, we 'know' that 'birds of a feather flock together' (similarity leads to attraction), but we also 'know' that 'opposites attract'. So, which is correct? Many of us may also think that friendship between people from different racial groups should reduce prejudice – but does it? How can we be sure? Under what circumstances is someone most likely to help someone in distress? To get someone to do you a favour, should you first make a modest request that they will agree to and then scale it up to the real request, or should you first make an outrageously large request that nobody in their right mind would agree to and then scale it down?

To answer these questions, social psychologists use a wide range of scientific methods including laboratory experiments, field experiments, surveys, observation of naturally occurring behaviour, and the analysis of what people say and write. Controlled laboratory experiments predominate because they are so well suited to establishing the causes of behaviour. However, some research questions are difficult to address in the laboratory. For example, it would be difficult to study a riot or an established street gang in the laboratory. Can you think of any other experiment which you would think would be impossible to set up (you'll be surprised at some of the experiments psychologists have conducted. . .)? Social psychologists can be quite tenacious and inventive. One early researcher tried to instigate a riot in the laboratory by wafting smoke under the locked door of the laboratory – some groups of participants kicked the door open and disengaged the smoke generator, and other groups calmly discussed the possibility that they were being observed (French, 1944).

Social psychologists develop formal theories about human behaviour that, unlike common-sense theories, are carefully grounded in data from systematic and well-controlled research. These theories sometimes confirm common-sense knowledge, but sometimes they do not, and many theories are concerned with how people develop and use this common-sense social psychological knowledge in the first place.

Social cognition and social knowledge

At the heart of social behaviour is our ability to make sense of a social situation in order to know what to expect and what to do. We often have ready-made explanations and interpretations of people and situations – explanations that are readily accessible in the society in which we live. In this way, people's social interpretations can vary from culture to culture, group to group, and across time. For example, Moscovici (1976) explored how Freudian concepts, such as unconscious motives, Oedipus complex, displacement and so forth, have become widely accepted and used in contemporary mass culture to account for people's behaviour. These **social representations** of the way people's minds work provide a framework for making sense of the world. This framework develops through many means, such as mass communication, informal conversation, and adherence to prescriptions of scientific and religious movements, and other group ideologies (Moscovici, 1983; also see Lorenzi-Cioldi and Clémence, 2001).

Social representations have far-reaching consequences for how we deal with one another. For example, whether insanity is considered to have a moral, biological, religious, physical or social cause will determine how it is responded to by policy-makers and the public (Jodelet, 1991). When Peter Sutcliffe, the British ‘Yorkshire Ripper’, was convicted in 1981 in the UK of over 20 rapes and murders he was deemed to be ‘criminal’ rather than ‘insane’, and was therefore imprisoned rather than hospitalised. Such distinctions are dependent more on society’s current social representations of good and evil, sanity and insanity than they are on objectively measurable criteria. However, as you will see in Chapter 18, criteria for diagnosing mental illness have progressed dramatically since then.

Against the background of particular social representations, values and norms, cognitive-inferential processes affect the way we understand, use and respond to our social environment (Augoustinos and Walker, 1995). For example, Echebarria-Echabe *et al.* (1994) examined how smokers and non-smokers account for the causes of smoking. Two representations appeared to be common: one which emphasised the psychological weakness of people who fall prey to the attractions of tobacco and another (defensive representation) which associated smoking with facilitative social factors and favourable stereotypes of smokers. When the potential conflict between non-smokers and smokers was made more salient, smokers became significantly more likely to adhere to the defensive representation.

Our ability to interpret social situations involves a range of basic cognitive-inferential processes, including memory for people, places, and events; concept formation skills; and sensory and perceptual abilities. Social cognition rests on an array of basic cognitive-inferential processes and on the way in which social information is stored, structured and retrieved from memory. Fiske and Taylor (1991, p. 13) have characterised the individual as a **motivated tactician**,

a fully engaged thinker who has multiple cognitive strategies available and chooses among them based on goals, motives, and needs. Sometimes the motivated tactician chooses wisely, in the interests of adaptability and accuracy, and sometimes. . . defensively, in the interests of speed or self-esteem.

A central and dominant theme in social psychology has been the development of our understanding of social cognition – how people attend to, perceive, interpret, store and respond to social information.

Forming impressions of people

All of us form impressions of others: friends, neighbours, lecturers, foreigners – virtually everyone we meet. We assign all sorts of characteristics to them. We may, for example, think of someone as friendly or hostile, helpful or selfish. Note that these are terms that not only describe the type of person someone is, but which also critically evaluates them. One of the major tasks of social psychology is to understand how we form these impressions.

In Solomon Asch’s words, ‘How do the perceptions, thoughts, and motives of one person become known to other persons?’ (Asch, 1952, p. 143). To answer questions like this, psychologists study **impression formation**, the way in which we form impressions, often first impressions, of others and attribute specific characteristics to them.

Cognitive algebra

One perspective on impression formation argues that our evaluation of other people is critically important as it underpins fundamental judgements of danger and safety and thus approach-avoidance decisions. Impressions of people are largely evaluative. This process has been referred to as **cognitive algebra** (Anderson, 1978). This perspective argues that people intuitively represent traits in terms of their desirability: they effectively assign values to traits, e.g. +1, 0, –1, –2), and they integrate the value of traits they assign to a person in order to arrive at an overall evaluation of that person. This information can be integrated in three different ways:

- *summation* – the larger the number of positive traits the more positive the overall impression;
- *averaging* – a limited number of highly positive traits yields a more positive impression than lots of positive traits with many of them only marginally positive (marginal traits bring down the average);
- *weighted averaging* – not only are traits averaged, but some traits are considered more important than others in a particular context and are thus weighted more heavily. Research suggests that the weighted averaging model best characterises impression formation.

Several factors influence weighting. For example, the same information may be weighted differently if you are forming an impression of a potential friend rather than a potential colleague. Weightings of particular attributes may also be influenced by what other person attributes are present. The meanings of specific attributes, and overall meaning of a combination of attributes, may influence the meaning and the valence of a particular attribute.

Generally, although attribute valence is important, so is the meaning of an attribute – when we evaluate someone as ‘cruel’ we not only evaluate that person negatively, but also know something about their behaviour. These and other considerations suggest people may not form impressions in such a piecemeal manner, but in a more holistic or gestalt manner that places a greater importance on the meaning of attributes. This idea underpins Asch’s **configural model** of impression formation.

Asch’s configural model

Over half a century ago, Asch (1946) noted that our impressions of others are formed by more complex rules than just a simple sum of the characteristics that we use to describe people. Asch was able to show that when we form impressions of other people, some perceptual features seem to have more influence than others in our final impression. For example, your impression of someone may be swayed by whether people are intelligent or not, and a friend’s may be swayed by whether people are approachable or not. Kelly (1955) refers to these idiosyncratic views of what is most important in characterising people as **personal constructs**. In one context, intelligence may be a more relevant dimension than approachability (e.g. evaluating someone as a member of a research team), whereas in another context the opposite may be true (e.g., evaluating someone as a charity fund-raiser). Asch called characteristics that are disproportionately influential in impression formation **central traits**. Central traits are very useful for organising and summarising large amounts of diverse information about a person you encounter.

To demonstrate this, Asch (1946) provided participants with a list of traits describing a hypothetical person. Some received a list that included the trait ‘warm’, whereas others received an identical list, except that the trait ‘warm’ was replaced by ‘cold’. Participants given the list including ‘warm’ were more likely to see the person as generous, happy and altruistic. But not all traits seemed to be so important. When the words ‘polite’ and ‘blunt’ were substituted for ‘warm’ and ‘cold’, no differences were observed in participants’ impressions. Kelley (1950) replicated Asch’s study in a more naturalistic setting where the target person was not hypothetical, but was a real person who really gave a guest lecture to a class. Kelley found the same results. Students who had had the lecturer described as ‘cold’ rated him to be more unsociable, self-centred, unpopular, formal, irritable, humourless and ruthless, than did those who had had him described as ‘warm’. Our perception of others seems to be based partially on central traits – which can vary from context to context, or from person to person.

Biases in impression formation

What determines whether a trait is central or not? One factor is the order in which information is available or is processed. Research suggests that the first information we process is the most important – there is a marked **primacy effect**. Getting to know someone takes time and usually requires many interactions. Perhaps the first time you saw someone was at a party when she was loud and boisterous, having a good time with her friends. But later, you learn that she is a mathematics student with excellent grades who is generally quite reserved. What is your overall impression of this person: loud and boisterous, or bright and shy? To determine whether first impressions might overpower later impressions, Asch (1946) presented one of the following lists of words to each of two groups of participants:

Intelligent, industrious, impulsive, critical, stubborn, envious

Envious, stubborn, critical, impulsive, industrious, intelligent

Notice that these lists contain the same words but in reverse order. After they saw the list, Asch asked the participants to describe the personality of the person having these characteristics. People who heard the first list evaluated the person much more favourably than people who heard the second list – a clear primacy effect.

Although sometimes more recent information can be influential (for example, when there is a lot of information and we are distracted), the general rule is that first impressions are most impactful and most enduring (Jones and Goethals, 1972).

The impressions we form of people are also disproportionately influenced by negative information. We tend to pay more attention to negative information, and although we like to think the best of people, bad impressions, once formed, are very difficult to change. By contrast, good impressions can easily change. One reason for this negativity bias is that people are probably especially sensitive to negative information because it can signify potential harm or danger (Skowronski and Carlston, 1989).

It will not surprise you to learn that sometimes there are social conventions and norms (sometimes legislation) that actually discourage us from forming impressions at all. For example, most of us would resist forming impressions based on race, gender or disability, particularly if we were serving on a selection panel for job applicants. People make an assessment of **social judgeability**, a perception of whether there is a legitimate and adequate

basis for judging a specific person before forming an impression. Sometimes, merely believing you are in a position to make a judgement (but in reality you lack good evidence) results in your making unwarranted evaluations of other people (Leyens *et al.*, 1992).

Impressions are also influenced by physical appearance. Immediate first impressions, which as we have just seen can be quite enduring, are often based on what we see, because other information about people's 'character' is not yet available. According to Zebrowitz and Collins (1997), appearance-based first impressions can actually be surprisingly accurate. However, there are obvious pitfalls. For example, the tendency to form more favourable first impressions of physically attractive people may cause one to hire people who are delightfully decorative but not much good at getting the job done (Heilman and Stopeck, 1985).

Schemas and categories

A central theme for social cognition is the concept of **schema** – although 'schemata' is the correct plural, social cognition theorists, perhaps embarrassingly, refer to 'schemas' (Fiske and Taylor, 1991). A schema is a mental framework or body of knowledge that organises and synthesises information about something. Schemas contain information about attributes and the relationship between attributes. We have schemas for specific people (for example, one's best friend), groups of people (for example, traffic wardens), ourselves, events (for example, how to order food at a restaurant), roles (for example, how the pilot of an aeroplane should behave in the cockpit), places and objects.

Schemas aid us in interpreting the world. The first time you visited your psychology professor in their office, for example, there were probably few surprises. Your 'professor' schema guided your expectations. However, you would probably be surprised if you saw that your professor's office was filled with skateboarding trophies, autographed photos of heavy metal bands, or dead animals mounted on the walls as hunting trophies. Such possessions are probably inconsistent with your impression of professors.

As an example of how schemas guide our interpretations, try to make sense of the following passage:

The procedure is actually quite simple. First you arrange things into different groups. Of course, one pile may be sufficient depending on how much there is to do . . . It is important not to overdo things. That is, it is better to do too few things at once than too many. In the short run this may not seem important, but complications can easily arise. A mistake can be expensive as well. At first

the whole procedure will seem complicated. Soon, however, it will become just another facet of life.

Source: Bransford and Johnson (1972), p. 722.

Does this passage make sense to you? What if I tell you that the title of the passage is 'Washing Clothes'? Now you can interpret the passage easily. The sentences make perfect sense within the context of your schema for washing clothes. Not surprisingly, research has demonstrated that understanding is improved when people know the title of the passage before it is read (Bransford and Johnson, 1972). Imagine a time when you turned on the radio and a discussion or phone-in left you clueless as to the topic being talked about because the exchanges were so vague and generic that you could only make sense of them when the interviewer gave a reminder of the topic that was under discussion.

Categories, prototypes and exemplars

Once you categorise a person (as an individual or as a member of a particular group), the schema of that person or group is activated. Research suggests that schemas can be organised as **prototypes** (Cantor and Mischel, 1979) or as **exemplars** (Smith and Zárate, 1992). A prototype is an abstract fuzzy set of attributes that define the category, where no instance may actually embody the attributes. An exemplar is a specific instance of the category. For example, if your schema of French people is the actor Gerard Depardieu then you have an exemplar representation, whereas if what comes to mind is a general notion of baguettes, cafés, berets, striped jumpers, and so forth then you have a prototype representation. Note that both types of schema are equally accurate or inaccurate as a 'true' description of the category as a whole.

Social categories simplify the social world by reducing an infinite diversity of people to a more limited number of categories of people, each described by a schema – men, women, Catholics, Danes, doctors, and so forth. Categories only form and persist to the extent that they make sense of the world and one's place within it. Of course, any specific person can fit into many categories (e.g. someone can be a female, an Italian, and an engineer), but the key point is that once a person is categorised the appropriate schema comes into play to influence perceptions, expectations and interaction.

Categories vary in inclusiveness. Highly inclusive categories have many members (for example, a nation) and thus tend to gloss over potentially important differences between people. More exclusive categories have fewer members (for example, a family). Although they capture differences more precisely, an exclusive category structure

would produce too many categories – it is a too fine-grained segmentation of the world. In general, the most cognitively accessible social categories are **basic level categories** which are neither too inclusive nor too exclusive. Basic level categories are default categories that we first use to generate context-specific schemas of people – these are often based on visible cues such as skin colour, physiognomy, sex and dress (Zebrowitz, 1996). However, many factors, including the social interactive context, our interaction goals, and our own personal history, can influence basic level categories and what categorisation and associated schema comes into play in a particular context.

Schema acquisition and development

We tend to acquire and develop our schemas through exposure to instances of the category – face-to-face encounters, media presentations, second-hand accounts, and so forth. As one encounters more instances of a category one's schema is likely to become less exemplar-based and more prototype-based. Research suggests that such prototype-based schemas can become tightly organised into a single mental construct that is very rapidly activated in an all-or-nothing fashion by category cues (Schul, 1983). Such schemas are highly resistant to change (Fiske and Neuberg, 1990), which can be particularly problematic in the case of schemas of groups.

Group schemas and stereotypes

Schemas of social groups are particularly significant since they characterise large numbers of people in terms of a small number of properties that submerges the variety of differences that exist between people. Schemas of social groups are almost always shared among people in one group. For example British people often believe that Americans are 'brash', the French think the British are 'cold', and so forth. Shared schemas of social groups are best described as **stereotypes**, and because they are closely associated with prejudice, discrimination and intergroup relations we will return to them in the next chapter (Leyens *et al.*, 1994).

According to Tajfel (1981), such stereotypes are learned early in childhood through normal socialisation rather than direct experience. Research suggests that children's use of stereotypes and expression of negative attitudes towards out-groups peak at around the age of 7 and then decline by 8 or 9 years of age. This may reflect cognitive developmental changes that affect the way children understand the meaning of categories and attributes, and changes in role-taking skills (Aboud, 1988; Durkin, 1995). Prejudice, a topic discussed in much greater depth in the next chapter, usually refers to a person's expression of negative views of and behaviours

Some of the best comedy comes from caricature – the exaggeration of stereotypes or stereotypical features. Two recent colourful examples are Sacha Baron-Cohen's creations, Borat and Bruno

towards members of an ethnic group that differs from their own (Brown, 1995). A key component of prejudice is the belief that the ethnic or 'out-group' is highly dissimilar to the 'in-group' (the person's own social or racial group).

Language is one important factor that can enhance or magnify perceived dissimilarities between groups and this is no more evident than when comparing different nationalities or cultures (Giles and Johnson, 1987; Giles and Coupland, 1991). Language is a communicative glue, bonding otherwise highly dissimilar individuals. Not only can it allow communication between the in-group members, it can also prevent or inhibit communication with out-group members.

Durkin and Judge (2001) explored whether people's speaking a language that was unfamiliar would affect children's view of them. They reviewed evidence showing that children as young as 4 can show prejudicial attitudes towards ethnic groups (Aboud and Skerry, 1984; Aboud, 1988). While the prejudice 'increases' up to age 6 or 7, there is evidence of a tailing off in the behaviour from middle childhood onwards (Doyle and Aboud, 1995). Children rate people who speak their own 'national' language and in their own accent more positively than they do ethnically different groups (Doyle *et al.*, 1988). Some have suggested that children hold these views about out-groups because they interpret different external signs as threatening and as alien to them. As children get older, they are able to realise – because their capacity for thinking is enhanced – that external attributes can be overlooked and that internal attributes can be appreciated.

Durkin and Judge (2001) found that when children viewed videotapes of foreign families or English-speaking families that behaved badly or not, 6-year-olds judged the foreign-language family least favourably. When the family behaved badly, this placed it at even greater social distance from the children. At age 8, social distance from the anti-social foreign-language family was still significantly great but liking and attributions did not differ between the different family types. These 8-year-olds also placed social distance between themselves and the prosocial foreign-language family, a greater distance than that between them and the prosocial English-speaking family. Language-based differences were all but eliminated in the 10-year-old group, a finding that is compatible with other studies showing that 'prejudice' is less evident in this group.

While the younger children's negative views of the foreign-language family may be due to distrust or to the perception of this family as the out-group, an alternative explanation could be that the foreign-language family was difficult to understand: it was perceived as less likeable and viewed less positively because they could not be understood, not because they were foreign. Alternatively, the children may be motivated to view their own in-group more positively than they did out-groups, because they had a more favourable view of that group, a notion proposed in social identity theory (Tajfel and Turner, 1986). A consequence of this view is that the positive gloss that people place on their own group extends to individuals within that group; the esteem in which the group is held enhances the esteem of the individual. The theory would

predict, for example, that identifying with your nation would be closely associated with an in-group preference for that nation. But research suggests that this relationship is not always evident (Rubin and Hewstone, 1998; Verkuyten, 2001).

Verkuyten (2001) hypothesised that children who have a strong sense of national identification would report greater feelings of self-esteem after positively evaluating their in-group; evaluating the out-group will not raise self-esteem significantly. For those children who do not have a great sense of national identity, it was hypothesised that positively evaluating the in-group and the out-group leads to a momentary feeling of self-esteem. These hypotheses were tested in 21 classrooms in 12 Dutch primary schools. There were 484 children, aged between 10 and 12, all of Dutch nationality and having parents who were born in the Netherlands.

The children were asked what they thought about having friends from different nationalities (Dutch, American, German and Turkish) and, immediately after assessing their feelings about each nation, were asked to indicate how they felt at that moment (on a seven-point scale from 'very good' to 'very bad'). National identification was also assessed (the children were asked how important it was for them to be Dutch, whether they considered themselves to be really Dutch, and so on). Finally, the children were asked how socially distant they felt from other nationalities. The story given was that a child in the class was being frequently excluded socially because they came from another country. The children were asked whether their teacher would do something about it, whether other children in the classroom would disapprove and whether children would report this to their teacher.

Those children who regarded themselves as having a strong sense of national identity reported less social distance between themselves and other Dutch children and greater distance between themselves and children from other countries than did children who showed a low sense of national identity. Changes in the level of esteem, however, seemed unrelated to national identity. Reporting less social distance between them and the in-group and out-group temporarily improved mood. National identity did affect the magnitude of these increases, however. For example, Dutch children with a great sense of national identity and who reported little social distance between themselves and their in-group, reported more positive feelings after rating the in-group. There was little increase after rating the out-group. The children who had a low sense of national identity and who showed little social distance between the in- and out-groups, reported similar positive feelings after rating each group.

The study indicates that the association between these children's views of other nationalities and their perception of their own nation depends on (1) how greatly they identify with their own nation and (2) the social distance they

perceive between themselves and children from the same or different countries.

Automaticity of stereotypes

Images of another group (the out-group) are generally less favourable than images of one's own group (the in-group) and provide a relatively positive evaluation of oneself. For example, a stereotype that characterises an out-group as lazy and unmotivated is an excellent justification for an intergroup relationship where your own group has control over that group.

Once someone is categorised as a member of a particular group, the schema of that group (stereotype) influences the impression of that person. For example, if students believe that professors are pompous, boring and opinionated, then once you, as a student, categorise someone as a professor you will automatically tend to assume that they are pompous, boring and opinionated, and that impression will influence the entire interaction. The expectation may even, over a period of time, change the professor's behaviour to conform to your schema (Snyder, 1984).

Like other schemas, stereotypes are relatively automatically and unconsciously activated in particular contexts (Bargh, 1989) – they have the property of **automaticity**. Particular cues (for example, a Welsh accent) can automatically activate a categorisation (Welsh), which in turn automatically engages the appropriate stereotype. For example, in a classic study, Devine (1989) presented people with (negative) African-American primes (words like 'lazy', 'slavery', 'Negroes') far too quickly for people to be aware of them. She found that participants interpreted a subsequent neutral act, by someone merely called Donald, in ways that were consistent with negative stereotypes of African-Americans. Whether someone scored high or low on a racial prejudice scale did not affect susceptibility to preconscious priming – an effect that was replicated by Fazio *et al.* (1995). Other research has, however, shown that the effect is more marked for people who score high on unobtrusive measures of possessing racist attitudes (Lepore and Brown, 1997).

The property of automaticity has been exploited by the **implicit association test (IAT)** (Greenwald *et al.*, 2002) which is able quite reliably to elicit our hidden prejudices. The test has been placed on the Web (see address at end of this chapter) – so you can discover if you are prejudiced, or rather, just how prejudiced you are.

Implicit biases or prejudice can be expressed towards various types of people, the obese for example (Teachman *et al.*, 2003). Beachgoers in Connecticut were given a newspaper article which stated that obesity was caused either by genetics, or by overeating and lack of exercise. The IAT was then administered in which participants

decided whether words paired with the adjective 'good' or 'bad' were appropriately paired. So, the pairing of 'thin people' with 'good' and 'fat people' with 'bad' would be expected to be responded to more quickly as an appropriate pairing than would 'fat people' and 'good'. Participants also completed a questionnaire measuring their attitudes towards obesity and obese people.

Although the participants claimed to hold no explicit biases towards fat people, their implicit responses suggested otherwise. People associated 'fat people' with more negative attributes (lazy, bad) than positive ones (motivated, smart). In line with Crandall's (1994) reasoning, this bias was greater when people had been previously primed to think that obesity was caused by controllable factors such as overeating and lack of exercise than by uncontrollable genetic factors.

In a follow-up study, the implicit test was prefaced by stories which evoked sympathy towards fat people, or evoked sympathy towards people who use wheelchairs (what the researchers called a comparable 'stigmatised' group) or were neutral. Ninety women participated at Yale University. Reading empathic stories about fat people did not reduce implicit fat bias, compared with reading neutral stories. When overweight participants were added to this sample, there was evidence of in-group bias. Fat people were more likely to show less implicit bias after reading the empathetic material.

The results suggest that while people may claim that they do not hold negative (stereotypical) views of fat people, their implicit cognitions and behaviour suggest otherwise.

If stereotyping is largely an automatic process over which we have only limited conscious control, what can be done to combat it? One solution might be to make the category–stereotype link more conscious by thinking hard about it and suppressing the stereotype immediately it comes to mind. Over time, stereotype suppression might inhibit stereotype activation. An alternative view, which makes equal sense, is that the more you try to suppress the stereotype the firmer the cognitive or associative link between the category and the stereotype, and thus the more entrenched the automatic activation effect. Macrae *et al.* (1994) call this effect 'stereotype rebound'.

When good intentions backfire: stereotypes, influence and behaviour

A female assistant is working alongside her male boss on a complex decision task. Will he treat her any differently from a male assistant? Research by Vescio *et al.* (2005) examined the idea that powerful men use stereotypes to judge women when the stereotype seems contextually relevant and when they are focusing on the weakness of

women in that context, that is, if the task is in an area in which women are stereotyped as weak.

Male and female students believed they were participating in an academic competition involving teams. Half the participants were led to believe that good leaders focused on eliminating weaknesses in their teams; the other half that good leaders focused on maximising strengths. Their task was to select from among four male and four female members those who should represent the team, and assign them roles of team captain, player and non-player. They were also asked to email an explanation for their decision to each member. The results showed that weakness-focused men, not women, used their stereotypes of subordinate women more strongly by assigning fewer valued positions in the group to those women. At the same time, these men praised the subordinate women more highly, as shown in Table 15.1. So these powerful men effectively acted in a patronising way towards subordinate women, denying them an opportunity for advancement but delivering positive messages to them.

Next Vescio and colleagues investigated how male leaders who patronised and focused on weakness might affect the behaviour of male and female subordinates. Being patronised makes people angry but because women tend to avoid overtly aggressive responses Vescio and colleagues predicted that low-power women may respond more passively to being patronised. In contrast, low-power men seemed likely to respond competitively, by endeavouring to perform better. A male leader assigned male or female participants a low-power role as a team member, and then either praised the member or did not, and assigned the member to a valued or devalued position in the group. Both male and female team members reported feeling angrier when they were patronised than when they were not but, as shown in Table 15.2, on a 23-item test males performed better after being patronised whereas females did not. As Vescio and colleagues conclude, leadership styles often focus on eliminating weaknesses, but people are likely to be more motivated and perform better, and

Table 15.2 Performance as a function of position assignment, praise, and participant's gender

	Valued position		Devalued position	
	Praised	Not praised	Praised	Not praised
Female participants	10.48	9.69	9.02	9.99
Male participants	10.00	10.19	11.86	10.5

less likely to be the unwitting victims of patronising stereotypes, when leaders focus on ways in which subordinate group members can promote the goals of the group.

Facing racial stereotypes

Physical appearance is a powerful cue to category membership. For example, we rely heavily on sex or skin colour to assign people to gender or racial/ethnic categories, and then generate stereotypical assumptions about their attributes and behaviours. We can even be quite discriminating in our perception of and reaction to physical appearance cues. For example, research in the United States has shown that African-American prisoners who have more Afro-centric facial features receive more severe sentences than African-American prisoners with less Afro-centric features.

Blair *et al.* (2004) analysed the facial features of a random sample of black and white prison inmates who had been given equivalent sentences. They hypothesised that strongly Afro-centric facial features might unwittingly (or wittingly) influence sentencing decisions. They defined Afro-centric features as being typical of those seen in African-Americans – e.g. ‘dark skin, wide nose, full lips’.

The sample comprised 216 black and white inmates at the Florida Department of Corrections and their facial photographs were presented to two groups of undergraduates who rated the degree to which facial features were typical of African-Americans. While there was little difference in the severity of the sentence given to the black and white prisoners, there were significant differences in the harshness of the sentence within the black sample. Those with stereotypically Afro-centric features were significantly more likely to have received harsher sentences than were those with less Afro-centric physical characteristics.

The results indicate that although bias and stereotyping were not evident in sentencing – black and white criminals with equivalent criminal histories were given comparable sentences – more subtle forms of stereotyping were significantly influencing sentencing decisions.

Table 15.1 Position assignment and praise of female subordinates as a function of leader's gender and social influence focus

	Male leaders		Female leaders	
	Weakness focused	Strength focused	Weakness focused	Strength focused
Position assignment	3.79	4.47	4.76	4.58
Praise	4.42	3.84	3.69	3.62

Cutting edge – Sexist humour: does it make you sexist?

People who express sexist attitudes – an antagonism towards women (perhaps, itself, a sexist definition) – tend to suppress them for external reasons rather than internal ones. That is, these views would violate some social norm and are, therefore, not expressed. Sexist jokes tend to re-enforce sexist beliefs. Highly sexist men are far more likely to accept a sexist norm after exposure to sexist jokes: when asked to pretend to be managers who had made sexist remarks to a woman employee, highly sexist men felt less guilty about it after reading sexist jokes than neutral ones (Ford *et al.*, 2001). But can exposure to sexist humour create sexist beliefs?

A group of US researchers asked participants to read a series of scenarios and pretend to empathise with people in them (Ford *et al.*, 2008). In the scenario, participants were told that a discus-

sion has taken place about workmates' favourite jokes. Some of these jokes were sexist (e.g. 'How can you tell if a blonde's been using the computer? There's Tippex on the screen'). The next scenario involved a discussion of views in which sexist beliefs were defended seriously. Finally, a vignette was presented in which the National Council of Women's aims were stated and its request for donations made clear. Participants were asked how much they would give to the organisation.

Highly sexist people exposed to sexist humour were less likely to give to the organisation. In a second experiment, the amount of money participants would cut from the organisation was measured. Sexist individuals exposed to sexist humour recommended greater budget cuts than those exposed to neutral comedy.

Conceptual and historical issues in social psychology

So far, you have seen how social psychologists have studied basic social behaviours such as impression formation and stereotypes. That social psychologists study these topics and in an experimental way owes a lot to the branch's history and development. The empirical study of social behaviour emerged in the second half of the nineteenth century (with a group in Germany calling themselves students of *Völkerpsychologie* – folk psychology – who focused on the collective mind, in contrast to Wundt).

In the early 1900s, America superseded Germany as the powerhouse of social psychology – a process which was accelerated in the 1930s by an enormous influx of leading German social psychologists fleeing Nazism. The ensuing global conflict, the Second World War, then posed urgent applied social psychological questions that created an explosion of research activity that focused on, for example, small group processes (Lewin, 1951), attitudes and attitude change (Hovland *et al.*, 1953), and prejudice (Adorno *et al.*, 1950).

From the late 1940s, social psychology grew prodigiously, in terms of programmes, publications, and profile within psychology. During the 1950s and early 1960s small group research flourished (for example, the study of group cohesion, leadership, communication networks, group influence – Shaw, 1976), as did the study of interpersonal relationships as social exchanges (Thibaut and Kelley, 1959), and the study of attitude change as the resolution of cognitive dissonance (Festinger, 1957). The mid-1960s through the 1970s was characterised by attri-

bution theories that focused on how people, as intuitive scientists, develop causal explanations of their social world as a basis for behaviour (Kelley, 1973).

Generally speaking, there are two camps in social psychology: those who believe that group behaviour is not qualitatively different from individual or interpersonal behaviour (we can call them 'individualists') and those who believe it is ('collectivists'). The debate mostly bubbles along in the background, but from time to time it seems to become a major preoccupation. The 1960s was one such occasion, when social psychology seemed to be deep in crisis (Elms, 1975). Critics felt that the discipline was asking the wrong questions, providing inadequate explanations of trivial behaviours and using primitive methodologies. The resolution of the crisis had two contrasting prongs. Social psychologists in the United States developed social cognition (discussed extensively in this chapter) in a drive for better methodology and better theory (Fiske and Taylor, 1991), and social psychologists in Europe developed what they called a more social social psychology (Tajfel, 1984) in a drive for socially relevant research (for example, the study of prejudice and intergroup conflict) and theories that linked cognitive and social processes.

The late 1960s and early 1970s, therefore, saw the emergence of a crisis of confidence in social psychology. Social psychologists were concerned that social psychology was theoretically immature, methodologically unsophisticated, inappropriately dependent on scientific method, and focused too much on individuals and interpersonal interaction and too little on language and collective phenomena. Out of this angst arose a diversity of 'resolutions'. The two most successful are social cognition with sophisticated methodologies and theories that continue to dominate social psychology (Nisbett and

Ross, 1980; Fiske and Taylor, 1991; Devine *et al.*, 1994; Moskowitz, 2005), and social perspectives that focus on culture (Smith *et al.*, 2006), collective representations (Moscovici, 1976), and intergroup relations and social identity (Tajfel, 1984; Hogg and Abrams, 1988).

There is another set of responses that rejects traditional social psychological methods, theories and research foci altogether, and instead focuses on subjectivity, language and qualitative methods (Potter and Wetherell, 1987; Edwards, 1997). Two recent trends in social psychology are evolutionary social psychology (Buss and Kenrick, 1998) and social neuroscience (Ochsner and Lieberman, 2001). The former focuses on the evolutionary and adaptive origins of social behaviours and social-cognitive processes. The latter maps social behaviours and social-cognitive processes onto functions, structures and processes within the brain.

Self and identity

Some of the most significant and influential schemas are those we have about ourselves. Not surprisingly, the self is an important focus for social psychological research – a review published in 1997 found that there had been 31,000 social psychological publications on the self over the preceding 20 years (Ashmore and Jussim, 1997), and journal exists dedicated to the topic (*Self and Identity*).

Self-knowledge

Knowledge about ourselves is very much like knowledge about other people. If you were asked who you were, how would you respond?

You might say your name, that you are a student and perhaps that you are also an athlete or have a part-time job. Alternatively, you could talk about your family, your nationality, ethnicity or religion. There are many ways you could potentially describe yourself, all of which would reflect your **self-concept** – your knowledge, feelings and ideas about yourself. In its totality, the self is a person's distinct individuality. At the core of the self-concept is the **self-schema** – a mental framework that represents and synthesises information about who you are. The self-schema is a cognitive structure that organises the knowledge, feelings and ideas that constitute the self-concept.

Social psychologists believe that we have many different selves that can be more or less discrete and come into play in different contexts – the subjective experience of self is highly context dependent. Selves not only describe how we are, but also how we would like to be, called possible selves (Markus and Nurius, 1986). Higgins (1987) takes

this idea further in his **self-discrepancy theory**. He distinguishes between the actual self (how one really is), the ideal self (how one would like to be), and the 'ought' self (how one thinks one ought to be). The latter two are 'self-guides' which mobilise different types of self-related behaviours. The ideal self engages 'promotional' goals – we strive towards achieving the ideal, whereas the 'ought' self engages 'prevention' goals – we strive to avoid doing what we ought not to do (Higgins, 1998).

How do we learn who we are – how do we form self-schemas? Introspection is one way, but the overwhelmingly social nature of human existence means that we learn much more about ourselves from how others treat us, and from how we think others view us. Research on **self-fulfilling prophecies** shows that others' expectation about us can change the way we behave. For example, Snyder (1984) reports a series of studies in which experimental participants behaved in a more extravert manner simply because others were primed with the false expectation that they, the participants, were extraverts. Expectations constrained participants to behave in a more extravert manner, and biased interpretations of neutral behaviour so it appeared more extravert. In this way participants gradually really did behave in a more extravert manner. Another example comes from research by Steele and Aronson (1995) into **stereotype threat**, which shows that because African-American students are aware of social expectations concerning academic underperformance, they can actually reduce effort and thus underperform.

Social impact on behaviour can affect self-conception because, according to self-perception theory (Bem, 1972), we often learn most about ourselves by simply observing how we behave. If there is no obvious coercion to behave as we do, then we assume that the behaviour reflects the type of person we are (see attribution theory, below). If you notice that you often drink coffee of your own free will you would be forgiven for deducing that you are the kind of person who likes coffee.

In addition to introspection and self-perception, another powerful source of self-knowledge is social comparison. According to **social comparison theory** (Festinger, 1954) people need to feel confident about the validity of their perceptions, attitudes, feelings and behaviours. This sense of validity often comes from the fact that other people who are similar to us agree with us. In this way, attitudes about ourselves may be grounded in belonging to groups of people who have similar views about who we are – views that reinforce and confirm our own self-attitudes.

Orientations of self-knowledge

We are all aware of two contrasting orientations to life – one in which we are adventurous, optimistic and

approach-oriented (the glass is half full), and one in which we are more cautious, avoidant and defensively-oriented (the glass is half empty). This general distinction has recently been reconceptualised by **regulatory focus theory** (Higgins, 1997, 1998). Regulatory focus theory proposes that people have two separate self-regulatory systems, termed promotion and prevention, which are concerned with the pursuit of different types of goals.

The *promotion system* is concerned with the attainment of one's hopes and aspirations, termed *ideals*. It generates sensitivity to the presence or absence of positive events. People in a promotion focus adopt *approach-strategic means* to attain their goals. For example, promotion-focused students are likely to seek ways to improve their grades, to find new challenges and to treat problems as interesting obstacles to overcome. Promotion-focused individuals are also especially likely to recall information relating to the pursuit of success by others (Higgins and Tykocinski, 1992) and are most inspired by positive role models, who emphasise strategies for achieving success (Lockwood *et al.*, 2002). In addition, they tend to show especially high motivation and persistence on tasks that are framed in terms of gains and non-gains (Shah *et al.*, 1998).

The *prevention system* is concerned with the fulfilment of one's duties and obligations, termed *oughts*. It generates sensitivity to the presence or absence of negative events. People in a prevention focus use *avoidance strategic means* to attain their goals. For example, prevention-focused students might be more concerned with avoiding new situations or new people, to concentrate more on avoiding failure rather than achieving the highest possible grade. Prevention-focused individuals are especially likely to recall information relating to the avoidance of failure by others (Higgins and Tykocinski, 1992) and are most inspired by negative role models, who highlight strategies for avoiding failure (Lockwood *et al.*, 2002). In addition, they tend to show high motivation and persistence on tasks that are framed in terms of losses and non-losses (Shah *et al.*, 1998).

The two self-regulatory systems can be activated either chronically or temporarily. Differences in chronic promotion and prevention focus can arise from differences in the quality of a child's relationship with a caregiver (Higgins and Silberman, 1998). Caregivers can initiate a chronic promotion focus by, for example, hugging and kissing a child for behaving in a desired manner (a positive event) and withdrawing love as discipline (absence of a positive event). Conversely, a chronic prevention focus will likely result if caregivers encourage a child to be especially alert to potential dangers (absence of a negative event) and punish and shout at a child when they behave undesirably (a negative event).

In addition to these chronic individual differences, regulatory focus can also change more quickly from situation to situation. Situational variability can be induced experimentally through, for example, task feedback or task instructions. In one study (Higgins *et al.*, 1994), students were asked to report on either how their hopes and aspirations had changed over time (activating a promotion focus) or how their sense of duty and obligation had changed over time (activating a prevention focus). The participants read about several episodes that occurred over the course of a few days in the life of another student. In each of these episodes the student was pursuing a desired goal by employing either approach strategic means ('Because I wanted to be at school for the beginning of my 8.30 psychology class which is usually excellent, I woke up early this morning'), or avoidance strategic means ('I wanted to take a class in photography at the community centre, so I didn't register for a class in Spanish that was scheduled at the same time'). Higgins *et al.* predicted that participants would recall better the episodes which described strategic means that were consistent with their induced self-regulatory focus. Consistent with this prediction, participants in a promotion focus recalled better the episodes in which the student used approach strategic means whereas participants in a prevention focus recalled better the episodes in which the student used avoidance strategic means.

One interesting line of research has applied the principles of regulatory focus theory to intergroup discrimination (Sassenberg *et al.*, 2003). Participants with either a chronic or temporarily induced promotion or prevention focus were asked to distribute positive resources (money) or negative resources (withdrawal of money) between anonymous members of their own laboratory group (in-group) and anonymous members of another laboratory group (out-group).

Given that promotion-focused individuals have been shown to be especially sensitive to the presence or absence of positive outcomes whereas prevention-focused individuals are especially sensitive to the presence or absence of negative outcomes, Sassenberg *et al.* predicted that intergroup discrimination would be shown only when the available means for favouring the in-group were consistent with participants' chronic (or temporary) regulatory focus. Consistent with this prediction, participants discriminated under a promotion focus when positive but not negative resources had to be distributed and under a prevention focus when negative but not positive resources had to be distributed. In other words, under a promotion focus, group members focused on approaching positive in-group events and under a prevention focus group members focused on avoiding negative events.

Self-awareness

The above may give the impression that people spend all their time thinking about themselves, but this is not the case. People are not consciously aware of themselves all the time – if people were, then probably very little would ever get done. **Self-awareness** comes and goes for different reasons and with different consequences. Often we just get on with life without being particularly aware of ourselves, whereas at other times we can be obsessively self-absorbed or absolutely mortified over how others view us.

Duval and Wicklund (1972) believe that self-awareness is a state in which one is aware of oneself as an object, much as one might be aware of a tree or another person. Not surprisingly, standing in front of a mirror is a very effective way to become self-aware. Carver and Scheier (1981) argue that self-awareness can have at least two foci: the private self (one's private thoughts, feelings and attitudes), and the public self (how others see one, one's public image). Hence, self-awareness can also be raised simply by being in the presence of other people – for example, giving a public talk or performance. Private self-awareness directs behaviour at matching one's internal standards, whereas public self-awareness directs behaviour at promoting a good impression in the eyes of others. In contrast to heightened self-awareness, reduced self-awareness can produce a sense of **de-individuation** (Zimbardo, 1970; Diener, 1980) that may be associated with disinhibited, impulsive and anti-normative behaviour.

Being self-aware causes one to exert effort to try to address any discrepancy between one's actual self and how one feels one would like to be or ought to be. According to self-discrepancy theory (Higgins, 1987), described above, failure to resolve a discrepancy between the actual and the ideal self produces dejection-related emotions (disappointment, dissatisfaction, sadness), whereas failure to resolve an actual, 'ought' discrepancy produces agitation-related emotions (anxiety, fear).

Types of self and identity

Actual and possible selves can take many different forms. The enormous variety of human existence offers us a dazzling kaleidoscope of different ways in which we can define and conceptualise our selves. However, since selves are largely grounded in human interaction, various forms of human interaction may produce a more limited number of types of self. In particular, researchers distinguish between selves and identities that are grounded in individuality, interpersonal relationships, and group and category memberships.

Social identity theorists such as Hogg and Abrams (1988) and Tajfel and Turner (1986) distinguish between

the personal self (personal identity: self defined in terms of idiosyncratic attributes or personal relationships) and the collective self (social identity: the self defined in terms of group attributes). Brewer and Gardner (1996) distinguish among individual self (defined by personal traits that differentiate one from all other people), relational self (defined by dyadic relationships), and collective self (defined by group memberships). From a more cultural perspective (see below), Markus and Kitayama (1991) distinguish between the independent self (self defined as autonomous and separate from other people) and the interdependent self (self defined in terms of specific relationships people have with others). These distinctions are certainly not the same as one another, but there is a general notion that people can define themselves perhaps as I, you and I, or we.

Social identity

Social identity theory distinguishes between personal self/personal identity, and collective self/social identity (Tajfel and Turner, 1986; Hogg and Abrams, 1988). Social identity theorists believe that one's self-concept comprises a large array of different identities that fall into two broad types: personal identities that derive from our close interpersonal relationships (for example, friendships and romantic relationships) and our idiosyncratic characteristics (for example, being humorous), and social identities that derive from the social groups to which we belong (ethnicity, gender, profession, age group). Features of the immediate social context – situation, people, goals, activities and so forth – influence what aspect of the self-concept we experience and use to process information and plan action in that particular context.

Social identities are uniquely associated with group behaviours – for example, the stereotypes we spoke of above, but also other group behaviours such as conformity and discrimination that we discuss in the next chapter. Social identities are attached to group memberships and derive their descriptive and evaluative properties from perceptions of the nature of the evaluative relations (for example, status) that exist between groups. In this way, intergroup relations influence self-conception. Social identity is associated with group and intergroup behaviours because the process of categorising ourselves and others as group members causes us to view ourselves and others only in terms of the defining attributes of membership of the relevant group, called the group prototype (Turner *et al.*, 1987). This causes us to perceive and treat others stereotypically, and causes us and fellow group members to enact the defining features (perceptions, attitudes, feelings, behaviours) of our group.

Self-motives

What motivates the different ways that we may want to conceptualise ourselves? Research suggests that there are three general classes of motivations. One motive is self-assessment – a desire to find out the truth about ourselves however disappointing or unfavourable the truth may be (Troe, 1986). Another motive is self-verification – a desire to confirm what we already know about ourselves, by looking for self-consistent information (Swann, 1987). The third motive is self-enhancement – a desire to find out favourable things about ourselves (Kunda, 1990). Sedikides (1993) conducted a series of six experiments to compare the relative strength of these three motives, and concluded that self-enhancement is by far the strongest, with self-verification a distant second, and self-assessment an even more distant third.

Because self-enhancement is so important, people have a formidable repertoire of strategies and techniques to construct or maintain a favourable self-concept (Baumeister, 1998). For example, they take credit for suc-

cess but deny blame for failure; they forget failure feedback more readily than success feedback; they accept praise uncritically but receive criticism sceptically and dismiss it as being based on prejudice; and they self-interestedly interpret ambiguous self-attributes and perform a biased search of self-knowledge.

Self-esteem

The reason why people pursue self-enhancement is because it elevates **self-esteem**. Research overwhelmingly shows that it is adaptive for people to have a relatively positive sense of themselves, there is a positivity bias, and that a negative self-image can be quite dysfunctional (Taylor and Brown, 1988). People vary in their general level of self-esteem. People with higher self-esteem tend to pursue self-enhancement, whereas people with lower self-esteem tend to avoid self-derogation. Using the language of Higgins's (1998) regulatory focus theory, the former have a promotion orientation and the latter a prevention orientation. Although low self-esteem can be dysfunctional, research tends to discredit the popular

Cultural differences in self and identity – An international perspective

The same person can experience self in an array of different personal or collective ways depending on context. There is, however, another tradition of research that focuses on enduring differences in self-conception that are grounded in cultural differences (Markus and Kitayama, 1991; Oyserman *et al.*, 2002; Triandis, 1989).

The key cultural difference is between individualistic and collectivist societies (Hofstede, 1980). Western societies such as Britain and the United States tend to be individualistic – they emphasise the unique individual and separateness from others, and encourage individual choice and loose ties among people. Eastern societies such as Japan and India tend to be collectivist – they emphasise group loyalty, relations among people, and the collective good. According to Triandis *et al.* (1985), collectivist societies are associated with allocentrism (people who value cooperation, social support, equality and honesty), and individualistic societies with idiocentrism (people who strive for achievement, pleasure, social recognition and a comfortable life, and who experience anomie and a degree of social alienation).

More recently, Markus and Kitayama (1991) have identified the key cultural difference in self-conception to be between independent and interdependent self-construal. The independent construal emphasises the uniqueness of the self, its autonomy from others, and self-reliance. Although other people have an influence on a person's behaviour, a person's self-concept is largely defined independently. The interde-

pendent construal emphasises the interconnectedness of people and the role that others play in developing an individual's self-concept. In the interdependent construal, what others think of the individual, or do to the individual, matter – the person is extremely sensitive to others and strives to form strong social bonds with them.

Students from India (a collectivist Eastern culture) judge the self to be more similar to others, whereas American students (members of an individualist culture) judge the self to be more dissimilar to others (Markus and Kitayama, 1991). Markus and Kitayama have also shown that Japanese students tend to associate positive feelings with interpersonal behaviours and tend not to associate such feelings with personal achievements. In contrast, American students tend to feel satisfaction in their accomplishments. In a similar vein, comparing workers' intentions to leave their organisations, Abrams *et al.* (1998) found that Japanese workers were influenced by the evaluations they expected from their friends, family and co-workers, whereas British workers were not.

Vignoles *et al.* (2000) note that despite cultural differences in self-conception, the need to have a distinctive and integrated sense of self is universal; however, self-distinctiveness means something different in individualist and in collectivist cultures. In the former it is the isolated and bounded self that gains meaning from separateness, whereas in the latter it is the relational self that gains meaning from its relations with others.

belief that low self-esteem is associated with social problems such as violence (Baumeister *et al.*, 1996). On the contrary, violence is more closely associated with narcissism – high self-esteem in conjunction with a feeling of being superior and special.

People may not pursue self-esteem for its own sake. Leary *et al.* (1995) suggest that self-esteem is an internal indicator of social acceptance and belonging – it is a ‘sociometer’. The idea here is that the most basic human motive is to belong and to be properly socially connected. Feeling good about one’s self – self-esteem – is an extremely powerful indicator that one has succeeded in this pursuit.

Social inference

Causal attribution

As mentioned right at the start of this chapter, we are all intuitive social psychologists (Jones, 1990), using naive or common-sense psychological theories (Heider, 1958) to make sense of our social world. In order to interact with people and get on in life we need to have a basic understanding of how people work – we need to know why people do what they do. This knowledge is essential if we are to be able to navigate our way through life in such a way that we can make good things happen for us and avoid bad things that might happen to us. The most powerful knowledge we can have about people is causal knowledge – if we know what causes people to behave in certain ways then we are able to predict and influence what people will do. For example, most of us know that if we are nice to people they are likely to agree to do small

favours for us, and that people who feel threatened or cornered can often lash out aggressively.

The explanation of how people develop a common-sense causal understanding of human behaviour is called **attribution theory** (Hewstone, 1989). Strictly speaking, there are a number of variants of attribution theory that emphasise different aspects. Kelley’s (1967) covariation model is probably the best established, and so we will focus on that.

Disposition versus situation

In deciding the causes of behaviour, the most important thing we need to know is whether the behaviour is a reflection of the person’s disposition to behave in that way or a reflection of situational constraints that made them behave in that way. We need to assess the relative importance of situational and dispositional factors (Heider, 1958). **Situational factors** are stimuli in the environment. **Dispositional factors** are individual personality character-

istics. One of the tasks of socialisation is to learn what behaviours are expected in various situations. Once we learn that in certain situations most people act in a specific way, we develop schemas for how we expect people to act in those situations. For example, when people are introduced, they are expected to look at each other, smile, say something like ‘How do you do?’ or ‘It’s nice to meet you’, and perhaps offer to shake the other person’s hand. If people act in conventional ways in given situations, we are not surprised. Their behaviour appears to be dictated by social custom – by the characteristics of the situation.

As we get to know other people, we also learn what to expect from them as individuals. We learn about their dispositions – the kinds of behaviours in which they tend to engage across all sorts of situations. We learn to characterise people as friendly, generous, suspicious, pessimistic or greedy by observing their behaviour in a variety of situations. Sometimes, we even make inferences from a single observation (Krull and Erickson, 1995). If someone’s behaviour is very different from the way most people would act in a particular situation, we attribute their behaviour to internal or dispositional causes. For example, if we see a person refuse to hold a door open for someone in a wheelchair, we assign that person some negative dispositional characteristics.

Kelley’s covariation theory of attribution

Kelley (1967) has suggested that we attribute the behaviour of other people to external (situational) or internal (dispositional) causes on the basis of consideration of three aspects of the behaviour: its consensus, its consistency and its distinctiveness (Kelley, 1967; Kelley and Michela, 1980).

Consensual behaviour – a behaviour shared by many people – is usually attributed to external causes. The behaviour is assumed to be constrained or demanded by the situation. For example, if someone asks an acquaintance for the loan of a coin to make a telephone call, we do not conclude that the person is especially generous if they comply. The request is reasonable and costs little; lending the money is a consensual behaviour – most people would do it. However, if a person has some change but refuses to lend it, we readily attribute the behaviour to dispositional factors such as being a stingy or mean person.

We also base our attributions on **consistency** – on whether a person’s behaviour occurs reliably in the same situation. For example, if you meet someone for the first time and notice that she speaks slowly and without much expression, stands in a slouching posture, and sighs occasionally, you will probably conclude that she has a sad disposition. Now, suppose that after she has left, you

mention to a friend that the young woman seems very passive. Your friend says, ‘No, I know her well, and she’s usually very cheerful.’ With this new evidence about her behaviour you may reassess and wonder what happened to make her act so sad – was it something in the situation? If a person’s pattern of behaviour is consistent, we attribute the behaviour to internal causes. Inconsistent behaviours lead us to seek external causes.

Finally, we base our attributions on **distinctiveness** – the extent to which a person performs a particular behaviour only in a particular situation. Behaviours that are distinctively associated with a particular situation are attributed to situational factors; those that occur in a variety of situations are attributed to dispositional factors. For example, suppose that your partner is always very attentive towards you and other people but seems very dismissive to you whenever a particular group of his friends are around. You are unlikely to conclude that he is a dismissive type of person; you are more likely to conclude that this particular group of friends has a bad influence on him. Because his dismissive behaviour occurs only under a distinctive circumstance (the presence of the group of friends), you attribute it to external causes. Table 15.3 summarises Kelley’s ideas about the factors that determine internal or external attributions.

Implications and extensions of attribution theory

Attribution theory has a number of interesting implications and extensions. Earlier in this chapter we described how people can learn about themselves by investigating the causes of their behaviour. According to **self-perception theory** (Bem, 1972), if people can internally attribute their behaviour then they have gained knowledge about themselves.

Another intriguing idea, suggested by Schachter (1964), is that the emotions we experience have two distinct components: an undifferentiated state of generalised

physiological arousal and a cognitive label attached on the basis of an attributional analysis of what caused the arousal. So, arousal in the presence of a snarling lion is experienced as fear whereas arousal in the presence of an attractive member of the opposite sex may be experienced as sexual desire or passion. If Schachter is right, then there are interesting therapeutic implications – for example, if someone who is anxious can be persuaded to reattribute their arousal to something amusing then anxiety could be transformed into happiness (Valins and Nisbett, 1972).

Schachter and Singer (1962) conducted an experiment that did indeed show that different emotions could be produced by different labels. Participants were injected with a drug that produces arousal and were told that the cause of the arousal was the drug, or they were not told anything. All participants then waited in a room with a euphoric or an angry confederate. Participants who had not been informed of the cause of the arousal attributed their arousal to the behaviour of the confederate and actually reported feeling euphoric or angry. This was a controlled laboratory experiment. Subsequent research has shown that the nature of physiological arousal associated with different emotions, particularly strong emotions, is often different and so the emotions are intrinsically different – emotions may be based less on cognitive labelling than Schachter first suggested (Reisenzein, 1983; Forsterling, 1988). However, anyone who has observed small children will know how easily tears can be changed to laughter by simply doing something funny to entertain the child.

Attributional biases

Although causal attribution is an important way in which people make sense of their world, it is quite clear that we do not rely on causal attributions all the time. If we did then we would be completely immobilised by cogitation. Attribution and other inferential processes help us to con-

Table 15.3 Kelley’s theory of attribution		
Principle	Attribution of external causality	Attribution of internal causality
Consensus	High. Person lends coin for telephone call, performing a socially acceptable behaviour	Low. Person refuses to lend coin and seems mean
Consistency	Low. Usually cheerful person acts sad and dejected; we wonder what event has caused the sadness	High. We meet a person who speaks slowly and slouches, and conclude that we have met a person who is sad by nature
Distinctiveness	High. A child is rude only when playing with a certain friend; we conclude that the friend is a bad influence	Low. A child acts impudently and says mean and nasty things to everyone they meet. We conclude that the child is rude

struct representations and theories of the world, and in many cases simple cues rapidly engage these fully-fledged interpretations. In other words, we often rely on fully-fledged schemas, such as stereotypes, as described in detail earlier in this chapter.

When we do perform causal attributions we are actually doing something quite complex. Formal science is all about understanding the causes of things, and we all know how difficult formal science is. Not surprisingly, lay attributions fall well short of the rigour of formal science. Although day-to-day attributions are adequate for our everyday social interactional needs, attributional accuracy is compromised by the nature of human information processing and social cognition – it is marked by an array of biases and errors (Nisbett and Ross, 1980).

Actor–observer effects and the fundamental attribution error

When attributing someone's behaviour to possible causes, an observer tends to overestimate the significance of dispositional factors and underestimate the significance of situational factors. This kind of bias is called the **fundamental attribution error** (Ross, 1977) or the correspondence bias (Gilbert and Malone, 1995). It also reflects essentialism (Haslam *et al.*, 1998) – a tendency to consider behaviour to reflect underlying and immutable, often innate, properties (essences) of people or the groups they belong to.

For example, if we see a driver make a mistake, we are more likely to conclude that the driver is careless than to consider that external factors (perhaps a crying baby in the back seat) may have temporarily distracted him.

The fundamental attribution error is remarkably potent (but see below). Even when evidence indicates otherwise, people seem to prefer dispositional explanations to situational ones. For example, consider a well-known study by Jones and Harris (1967). Students read essays that other students had either freely chosen or been instructed to write in support of or in opposition to Fidel Castro. The students had to infer the writers' true attitude towards Castro. Where the writers had been free to choose, the students reasoned that those who wrote a pro-Castro essay were in favour of him, and those who wrote an anti-Castro essay were against him. Surprisingly, even when it was made quite clear that the writers had been instructed what essay to write, the students still believed that those who wrote a pro-Castro essay were in favour of him, and those who wrote an anti-Castro essay were against him. The students disregarded situational factors and made a dispositional attribution, thus committing the fundamental attribution error.

In contrast, when trying to explain our own behaviour, we are much more likely to attribute it to characteristics

of the situation than to our own disposition. In other words, we tend to see our own behaviour as relatively variable and strongly influenced by the situation, whereas we see the behaviour of others as more stable and due to personal dispositions. When we try to explain our own behaviour, we are not likely to make the fundamental attribution error (Sande *et al.*, 1988). The fact that we tend to make different kinds of attributions for our own and others' behaviour is called the **actor–observer effect**.

A study of college-age male–female couples demonstrates the actor–observer effect (Orvis *et al.*, 1976). Each partner was asked separately to describe disagreements in the relationship, such as arguments and criticism. Each partner was also asked to explain his or her attribution of the underlying causes of the disagreements. When describing their own behaviour, each person tended to refer to environmental circumstances, such as financial problems or not getting enough sleep. However, when describing their partner's behaviour, participants often referred to specific negative personality characteristics, such as selfishness or low commitment to the relationship.

Why do we tend to commit the fundamental attribution error when we observe the behaviour of others but not when we explain the causes of our own behaviour? Jones and Nisbett (1971) suggested two possible reasons. First, we have a different focus of attention when we view ourselves. When we are doing something, we see the world around us more clearly than we see our own behaviour. However, when we observe someone else doing something, we focus our attention on what is most salient and relevant: that person's behaviour, not the situation in which they are placed.

A second possible reason for these differences in attribution is that different types of information are available to us about our own behaviour and that of other people. We have more information about our own behaviour and we are thus more likely to realise that our own behaviour is often inconsistent. We also have a better notion of which stimuli we are attending to in a given situation. This difference in information leads us to conclude that the behaviour of other people is consistent and thus is a product of their personalities, whereas ours is affected by the situation in which we find ourselves.

Even though we may be aware of the difference in attributions that we make as actors or observers, this does not seem to prevent the actor–observer effect. For example, Krueger *et al.* (1996) asked pairs of participants (one actor and one observer) to describe the actor on a series of trait adjectives and to rate the consistency of relevant behaviour. Participants then predicted one another's ratings. The actor–observer effect was obtained. Moreover, actors, but not observers, were aware that observers rated actors' behaviour as more consistent than actors themselves did.

The fundamental attribution error is also less ‘fundamental’ than was once thought – it is influenced by culture. As you might expect from our earlier comparison of individualist and collectivist cultures, it is more prevalent in the former than the latter types of society (Morris and Peng, 1994). People in individualist societies are more inclined to explain behaviour in terms of individual dispositions and free will, whereas people in collectivist societies are more inclined to explain behaviour in terms of social obligations and situational constraints.

The fundamental attribution error is also influenced by more immediate social contexts and individual goals. For example, Schmid and Fiedler (1998) examined closing speeches made by trainee lawyers and university students acting as prosecutors or defending lawyers. Prosecutors tended to attribute internal causality to the defendants, whereas defence lawyers tried to support negative intentional attributions to the victim. When an audience of laypeople was asked to judge the speeches, and recommend sentencing, its decisions reflected the attributions made in the speeches.

False consensus

Another attribution error is the tendency for people to believe that their own behaviour is widely shared and that their own views are consensual – an error called **false consensus**. For example, Sherman *et al.* (1984) found that male school students who smoked believed that a majority of their peers did so too, whereas non-smokers believed that a majority did not smoke. Obviously, both groups cannot be correct.

One explanation for false consensus is that people tend to surround themselves with similar others and thus actually encounter a disproportionate number of people who behave like they do (Ross, 1977). Thus, when people conclude that other people are more similar to themselves than they actually are, the error may be a result of a bias in selecting people to be with. Another possible explanation is that we dwell so much on our own behaviour that it effectively inhibits proper comparisons that might lead us to realise that others do not necessarily think or act as we do. A third possibility is that in order to have a stable perception of reality we need to believe that our perceptions, attitudes and behaviours are correct, and so we exaggerate the degree of consensual support we have. If you believe the world is flat, then it helps you believe this is true if you can believe that lots of other people agree with you (Marks and Miller, 1987). However, recent research suggests that this social projection of one’s own beliefs involves the inclusion of others in the same social category as oneself (Spears and Manstead, 1990; Krueger and Clément, 1997), and it is increased when we are more self-attentive or self-conscious (Fenigstein and Abrams, 1993).

Self-serving biases

Some biases seem to be designed to protect or enhance our self-esteem or self-image (Hoorens, 1993) – these are called **self-serving biases**. These may take a number of forms, and sometimes we may not even be aware of them. For example, people seem to feel more positive about letters of the alphabet that are contained within their own names as compared with letters that do not appear in their name (the ‘name letter effect’). Hoorens and Nuttin (1993) examined the name letter effect among children and university students. Participants tended to think these letters appeared more frequently in other words relative to non-name letters. Moreover, because of their association with oneself, ‘mere ownership’ of the name letters was sufficient to make them more attractive.

Self-serving biases of this type also find expression in the attributions we make. For example, when we attempt to attribute causes to our own behaviour – to explain the reasons for our actions – we tend to attribute our accomplishments and successes to internal causes and our failures and mistakes to external causes. Suppose that you receive an outstanding score on a test. If you are like most people, you will feel the high score is well deserved. After all, you are an intelligent individual who studied hard for the test. Your attributions reflect internal causes for the test score: you are bright and a hard worker. Now suppose that you fail the test – what sorts of attribution do you tend to make? Again, if you are like most people, you may blame your low score on the fact that it was a difficult, even unfair, test, or on the lecturer for being so picky about the answers they counted as wrong. Your attributions in this case blame external causes for the low score – the test’s difficulty and the pickiness of your lecturer in marking it. One possible explanation for the self-serving bias is that people are motivated to protect and enhance their self-esteem (Sedikides and Gregg, 2003). Simply put, we protect our self-esteem when we blame failure on the environment and we enhance it when we give ourselves credit for our successes.

However, people differ in their **attributional style** – the extent to which they attribute their outcomes to stable and global causes (Metalsky *et al.*, 1987). In general, people with a ‘depressogenic’ style are more likely to attribute their failures to these stable and global causes (for example, lack of ability that will affect performance in many ways), resulting in a sense of hopelessness and depression. On the other hand, there is some evidence that depressogenic attributional style is associated with very high levels of achievement among students, perhaps because such students actively test the limits of their capability, and set very high standards for themselves (Houston, 1994).

This sort of bias can also occur at the group level, where it is called the **ultimate attribution error**. People tend to attribute in-group failures and out-group successes to external factors such as luck, and in-group successes and out-group failures internally to properties of the groups and their members (Pettigrew, 1979). This clearly makes the group that you belong to, the in-group, appear much more positive than the group you do not belong to, the outgroup, and thus is a self-serving bias.

Another self-serving attributional phenomenon is the **belief in a just world** – the belief that people get what they deserve in life (Lerner, 1977; Furnham, 2003).

According to this idea, when misfortune or tragedy strikes, people tend to blame the victim instead of attributing the source of the problem to situational factors outside the victim's control. As a result, an innocent victim may be blamed for circumstances over which they had no control, and any suffering is seen as being deserved. Common examples of this include the tendency to blame unemployed people, destitute people, rape victims, and even victims of genocide for their plight. People may also be complacent about HIV infection because they overly attribute it to risky behaviour by

homosexuals (the belief that 'gays deserve AIDS') and thus not relevant to themselves (Ambrosio and Sheehan, 1991).

Although there is a sense in which the belief in a just world may reflect the fundamental attribution error, social psychologists believe it is also, and perhaps more importantly, a self-serving bias. By seeing people as bringing bad things on themselves by being bad people, we can reason that we are good, sensible people and thus these things will not happen to us. In this way the world appears more within our control and less fickle and unpredictable. An interesting twist, which is consistent with this idea, is self-blame. People may sometimes blame themselves for their plight in order to avoid the frightening conclusion that the world is a completely unpredictable place where anything may happen irrespective of what you do (Miller and Porter, 1983). Belief in a just world also varies across cultures. In a study of people from 12 countries, Furnham (1983) discovered that the susceptibility to the belief in a just world attribution error was positively correlated with wealth and social status. That is, across many countries (which included countries from both Eastern and Western cultures), a person was more likely to commit this kind of attributional error if they were wealthy and had high social status.

Psychology in action – Attributional processes in relationships

People do not always engage in attributions in order to understand their world. However, people do tend to spend a great deal of time communicating their attributions, or negotiating with one another over their attributions. This is particularly the case in close interpersonal relationships (friendship and marriage), where attributions are communicated to fulfil a variety of functions – to explain, justify or excuse behaviour, or to attribute blame and instil guilt (Hilton, 1990).

Interpersonal relationships seem to go through three basic phases: formation, maintenance and dissolution. At each stage attributional communications can take a different form and serve different functions. During the formation stage, attributions reduce ambiguity and facilitate communication and an understanding of the relationship – they bring people together by providing a shared attributional framework. In the maintenance phase, the need to make attributions decreases because stable personalities and relationships have been constructed. The dissolution phase is characterised by an increase in attributions in order to regain an understanding of the relationship, or to deal with divergent attributions.

A notable feature of many interpersonal relationships is precisely this attributional conflict, where partners proffer divergent causal interpretations of behaviours, and disagree over what attributions to adopt. Often partners cannot even

agree on a cause–effect sequence, one exclaiming, 'I withdraw because you nag', the other, 'I nag because you withdraw'.

Correlational studies show that happily married (or non-distressed) spouses tend to credit their partners for positive behaviours by citing internal, stable, global and controllable factors to explain them. Negative behaviours are explained away by ascribing them to causes viewed as external, unstable, specific and uncontrollable. Distressed couples behave in exactly the opposite way. In addition, it appears that while women engage in attributional thought about the relationship, men do so only when the relationship becomes dysfunctional. In this respect, and contrary to popular opinion, men may be the more diagnostic barometers of marital dysfunction.

Do attributional dynamics produce dysfunctional marital relationships, or do dysfunctional relationships distort the attributional dynamic? This important causal question has been looked at by Fincham and Bradbury (1987), who obtained responsibility attributions, causal attributions and marital satisfaction measures from 39 married couples on two occasions 10–12 months apart. Attributions made on the first occasion were found reliably to predict marital satisfaction 10–12 months later, but only for wives. Another longitudinal study (though only over a two-month period) confirmed that attributions do have a causal impact on subsequent relationship satisfaction. Subsequent, more extensive and

Psychology in action – Continued

better-controlled longitudinal studies have replicated these findings for both husbands and wives.

Srivastava *et al.* (2006) asked over 100 couples to indicate their satisfaction with their romantic relationship and investigated whether optimists were more satisfied (and whether partners of optimists were more satisfied). Both results were found: those who were most optimistic, and those partnered with very optimistic people, were significantly more likely to be satisfied with their relationship. A feature of this satisfaction that was important was perceived support – when they argued, partners who sought quick conflict resolution through conversation, for example, were more satisfied with the way in which the argument was resolved after a week had passed.

How long-term is this effect of optimism? When the researchers followed up couples after a year, it was men's overall optimism that predicted relationship success. Male optimists' relationships lasted longer than did non-optimists'.

Why is optimism so important? Srivastava *et al.* (2006) suggest that optimists may attribute a partner's negative outbursts or behaviour as temporary, reflecting a state-specific reaction rather than a global personality disposition. They may also focus more on a partner's positive characteristics, thus ignoring or playing down a partner's negative mood. They act as a more 'secure base' for their partners and thus provide much needed social support that is always there, unconditionally.

Heuristic judgements

Social cognition refers to ways in which we make inferences about people, social inferences, and the world we live in, and then store these inferences as schemas that guide our perception and judgement. An important basis for social inference is, as we have seen, to find causes for people's behaviour through attribution processes. However, as we have also seen, these processes are often not very accurate or reliable. Often we do not use attribution processes at all to make inferences about people, but instead use cognitive short-cuts or inferential rules called **heuristics**. Two of the most important heuristics that people use are representativeness and availability (Tversky and Kahneman, 1974).

The representativeness heuristic

When we meet someone for the first time, we notice their clothes, hairstyle, posture, manner of speaking, hand gestures and many other characteristics. Based on our previous experience, we use this information to make tentative conclusions about other characteristics that we cannot immediately discover. In doing so, we attempt to match the characteristics we can observe with schemas or stereotypes we have of different types or groups of people. If the person seems representative of one of these schemas, we conclude that they fit that particular category (Lupfer *et al.*, 1990). In making this conclusion, we use the **representativeness heuristic** – we classify an object into the category to which it appears to be the most similar.

The representativeness heuristic is based on our ability to categorise information. We observe that some charac-

teristics tend to go together (or we are taught that they do). When we observe some of these characteristics, we conclude that the others are also present. Most of the time this strategy works; we are able to predict people's behaviour fairly accurately. Tversky and Kahneman (1974) describe someone called Steve: he is 'very shy and withdrawn, invariably helpful, but with little interest in people or in the world of reality. A meek and tidy soul, he has a need for order and structure, and a passion for detail'. Chances are you will infer that Steve is a librarian rather than a farmer, surgeon or trapeze artist – and you are probably quite likely to be correct. What we know about Steve seems to be quite representative of what we 'know' about librarians.

In relying on the representativeness heuristic we often subscribe to the **base-rate fallacy** – we overlook statistical information about the relative size of categories and therefore the probability that the person will belong to the category. If you described a person as being athletic and interested in surfing you are probably better off simply inferring she is Chinese than Australian (for every Australian there are 60 Chinese).

Learning to play the odds, so to speak, and so to avoid being misled by distinctive characteristics, is particularly important in certain intellectual endeavours. For example, doctors who are experienced in making diagnoses of diseases teach their students to learn and make use of the probabilities of particular diseases and not to be fooled by especially distinctive symptoms. In fact, Zukier and Pepitone (1984) posed a problem to first-year medical students and to residents who had completed their clinical training. The inexperienced students were tricked by the base rate fallacy but the residents played the odds, as they had been taught to do.

The availability heuristic

When people attempt to assess the importance or the frequency of an event, they tend to be guided by the ease with which examples of that event come to mind – by how available these examples are to the imagination. This mental short-cut is called the **availability heuristic**. In general, the things we are able to think of most easily are more important and occur more frequently than things that are difficult to imagine. Thus, the availability heuristic works well – most of the time.

Some events are so vivid that we can easily picture them happening. We can easily picture getting mugged while walking through the heart of a large city at night or being involved in an aeroplane crash, probably because such events are often reported in the news and because they are so frightening. Thus, people tend to overestimate the likelihood of such misfortunes happening to them. Tversky and Kahneman (1982) demonstrated the effect of availability by asking people to estimate whether English words starting with ‘k’ were more or less common than words with ‘k’ in the third position (for example, ‘kiss’ versus ‘lake’). Most people said that there were more words starting with ‘k’. In fact, there are more than twice as many words having ‘k’ in the third position as those having ‘k’ in the first position. But because thinking of words that start with a particular letter is easier than thinking of words that contain the letter in another position, people are misled in their judgement.

Many variables can affect the availability of an event or a concept and thus increase its effect on our decision-making. For example, having recently seen a particular type of event makes it easier for us to think of other examples of that event. This phenomenon is called **priming**. Many first-year psychology students demonstrate this phenomenon when, after first learning the symptoms of various clinical disorders, they start ‘discovering’ these very symptoms in themselves.

Higgins *et al.* (1977) demonstrated the effects of priming on judging the personality characteristics of strangers. They had participants work on a task that introduced various descriptive adjectives. Next, the experimenters described an imaginary person, saying that he had performed such feats as climbing mountains and crossing the Atlantic in a yacht. Finally, they asked the participants to give their impressions of this person. Those participants who had previously been exposed to words such as ‘adventurous’ reported favourable impressions, whereas those who had been exposed to words such as ‘reckless’ reported unfavourable ones. The priming effect of the descriptive adjectives had biased their interpretation of the facts.

The availability heuristic also explains why personal encounters tend to have an especially strong effect on our

decision-making. For example, suppose that you have decided to buy a new car. You have narrowed your choice down to two makes, both available for about the same price. You read an article in a consumer magazine that summarises the experiences of thousands of people who have purchased these cars, and their testimony shows clearly that one of them has a much better repair record. You decide to purchase that make, and mention the fact to a friend later that day. She says, ‘Oh, no! Don’t buy one of those. I bought one last year, and it has been nothing but trouble. I’d had it for only two weeks when it first broke down. I got it towed to a garage, and they had to order a part from the manufacturer. Since then, I’ve had trouble with the air conditioner and the transmission.’ Would this experience affect your decision to buy that make of car?

Most people would take this personal encounter very seriously. Even though it consists of the experience of only one person, whereas the survey in the consumer magazine represents the experience of thousands of people, a vivid personal encounter is much more available and memorable than a set of statistics, and tends to have a disproportionate effect on our own behaviour (Borgida and Nisbett, 1977).

The cognitive accessibility of social information can also have dramatic effects on our behaviour and performance. Bargh *et al.* (1996) found that when participants had been primed with the stereotype of elderly people, they walked away from the experiment more slowly than unprimed participants. Dijksterhuis *et al.* (1998) extended this intriguing research to explore the effects of making specific individuals salient. Participants were first asked to unscramble some sentences that contained within them words that describe the traits associated with the elderly stereotype. This primed the elderly stereotype by making the attributes of elderly people more accessible in participants’ minds. Next, half the participants were asked to make judgements about a specific elderly person, Princess Julianna, the 89-year-old Dutch Queen Mother. This made a specific ‘exemplar’ accessible. Participants were then directed to the lifts at the end of the corridor where another experimenter was waiting. The time taken for them to reach this second experimenter was recorded. In contrast to Bargh *et al.*’s (1996) results, when Princess Julianna was primed, participants walked significantly faster than when the general stereotype of elderly people had been primed.

These two studies illustrate that when general stereotypes are activated we may automatically adopt some of the stereotypical characteristics ourselves, but when images of specific extreme individuals are activated we automatically make a contrast between ourselves and the exemplar, making us react in opposition to the characteristics of the individual. We assimilate ourselves to

stereotypes but contrast ourselves from individuals. For example, Dijksterhuis *et al.* (1998) also found that participants performed better on a test when the stereotype of professor had been primed than when the stereotype of a supermodel had been primed. However, they performed worse on the test when the specific example of Albert Einstein had been primed than when the specific example of Claudia Schiffer had been primed.

Attitudes and attitude change

The study of **attitudes** – relatively enduring sets of beliefs, feelings and intentions towards an object, person, event or symbol – is one of the most important fields of study in social psychology (Pratkanis *et al.*, 1989; Eagly and Chaiken, 1993). Some early definitions of social psychology actually defined social psychology as the study of attitudes.

The nature of attitudes

Many social psychologists believe that attitudes have three different components: affect, behavioural intention and cognition. The affective component consists of the kinds of feeling that an attitude object (person, activity, physical object) arouses. The behavioural intentional component consists of an intention to act in a particular way with respect to a particular object. The cognitive component consists of a set of beliefs about an object. Social psychologists have studied all three aspects of attitudes.

Affective components of attitudes

Affective components of attitudes can be very strong and pervasive. The bigot feels disgust in the presence of people from a certain religious, racial or ethnic group; the nature lover feels exhilaration from a pleasant walk through the woods. Like other emotional reactions, these feelings are strongly influenced by direct or vicarious classical conditioning (Rajecki, 1989).

Direct classical conditioning is straightforward. Suppose that you meet someone who seems to take delight in embarrassing you. She makes clever, sarcastic remarks that disparage your intelligence, looks and personality. Unfortunately, her remarks are so clever that your attempts to defend yourself make you appear even more foolish. After a few encounters with this person, the sight of her or the sound of her voice is likely to elicit feelings of dislike and fear. Your attitude towards her will be negative.

Vicarious classical conditioning undoubtedly plays a major role in transmitting parents' attitudes to their chil-

dren. People are skilled at detecting even subtle signs of fear, hatred and other negative emotional states in people, especially when they know them well. Thus, children often vicariously experience their parents' prejudices and fears even if these feelings are unspoken. Children who see their parents recoil in disgust at the sight of members of some ethnic group are likely to feel the same emotion and thus, over time, develop the same attitude.

Simply being exposed repeatedly to an otherwise neutral object or issue over time may influence our attitude towards it – generally in a favourable direction. This attraction for the familiar is called the **mere exposure effect**. One of the first studies to demonstrate this effect used several neutral stimuli – towards which there were no positive or negative feelings – such as nonsense words, photographs of the faces of unknown people, and Chinese characters (Zajonc, 1968). The more the participants saw the stimuli, the more they liked the stimuli later. Stimuli that were seen only once were liked more than ones never seen before. Even when the stimuli were flashed so briefly that they could not be recognised, participants usually preferred a stimulus that had been previously presented to a novel one that they could not recognise (Kunst-Wilson and Zajonc, 1980). The mere exposure effect probably reflects our tendency to feel positive about things that do not pose a threat to us. Our feelings towards a person, event or object will naturally improve if, on repeated exposure, we discover that no threat is posed.

Cognitive components of attitudes

We acquire most beliefs about a particular attitude object quite directly: we hear or read a fact or opinion, or other people validate our expressed beliefs. However, we can often develop fairly nebulous likes and dislikes (affect) and then develop our beliefs subsequently, to justify our feelings. For example, you may feel you dislike Honda cars, but really not have many beliefs about them. This affective orientation will guide the sorts of belief you subsequently hold about Hondas – you are more likely then to believe unfavourable than favourable things about Hondas. This illustrates an important point: although we can separate out different components of attitudes in order to describe them in a textbook, in reality they are inextricably linked.

We form and change our attitudes throughout our lives; however, children have an enormous task ahead of them: they come into the world with no attitudes, and so have very rapidly to learn attitudes in order to orient themselves to people, events and objects in their world. One way they do this is by simply imitating the behaviour of people who play an important role in their lives.

Children usually repeat opinions expressed by their parents. In Northern Ireland, many children label themselves as Catholics or Protestants long before they know the values for which these religious organisations stand. Often they ask their parents, ‘Are we Catholics or Protestants?’ without considering whether they might have any choice in the matter. The tendency to identify with the family unit (and, later with peer groups) provides a strong incentive to adopt the group’s attitudes.

Attitudes and behaviour

Attitudes have a behavioural intention component – a motivation or expressed intention to behave in some way or other that is consistent with the affective and cognitive components of an attitude. For example, many people have negative attitudes towards smoking and express the intention not to smoke. However, we all know that the expressed intention to behave according to an attitude certainly does not guarantee that we actually behave in that way – people who intend not to smoke often smoke. Intentions and behaviour are not the same thing.

People do not always behave as their expressed attitudes and beliefs would lead us to expect. In a classic example, LaPiere (1934) drove across the western United States with a Chinese couple. They stopped at over 250 restaurants and lodging places and were refused service only once. Several months after their trip, LaPiere wrote to the owners of the places they had visited and asked whether they would serve Chinese people. The response was overwhelmingly negative; 92 per cent of those who responded said that they would not. Clearly, their behaviour gave less evidence of racial bias than their expressed attitudes did. This study has been cited as evidence that attitudes do not always influence behaviour – indeed hundreds of studies of the relationship between attitudes and behaviour suggest, that on average, attitudes predict only 2–3 per cent of behaviour (Wicker, 1969). One way to think of this is that only 2 or 3 times out of 100 do people actually do what they say – perhaps we should not be quite so harsh on our politicians.

However, all is not lost. If it were, then commercial advertising would be a waste of time, as advertising largely tries to change behaviour by changing people’s attitudes towards products. There are ways in which we can be much more accurate at predicting behaviour from attitudes. Attitude specificity is one important influence on attitude–behaviour congruence. If you measure a person’s general attitude towards a topic, you will be unlikely to be able to predict their behaviour. Behaviours, unlike attitudes, are specific events. However, as the attitude being measured becomes more specific, the person’s behaviour becomes more predictable.

For example, Weigel *et al.* (1974) measured people’s attitudes towards a series of topics that increased in specificity from ‘a pure environment’ to ‘the Sierra Club’ (an American organisation that supports environmental causes). They used the participants’ attitudes to predict whether they would volunteer for various activities to benefit the Sierra Club. A person’s attitude towards environmentalism was a poor predictor of whether they would volunteer; their attitude towards the Sierra Club itself was a much better predictor (see Table 15.4). For example, a person might favour a pure environment but also dislike organised clubs or have little time to spare for meetings. This person would express a positive attitude towards a pure environment but would not join the club or volunteer for any activities to support it.

In another study, Davidson and Jacard (1979) monitored women’s attitudes towards birth control as a predictor of use of the contraceptive pill over the next two years. They found that pill use over the next two years was most strongly predicted by a very specific measure of ‘Attitude towards using birth control pills during the next two years’ (a correlation of 0.57), and least strongly in contrast to the most general measure of ‘Attitude towards birth control’ (correlation of 0.08).

Reasoned action and planned behaviour

Probably the most systematic account of how attitudes and behaviour are related has been developed by Fishbein and Ajzen (see Ajzen, 1989) in their **theories of reasoned action** and of **planned behaviour**. Someone’s intention to behave in a certain way is strengthened if (1) they have a positive attitude towards the behaviour, (2) they believe many people that matter also have a favourable attitude towards the behaviour, (3) they believe they have the resources and opportunity to engage in the behaviour, and (4) the intention is very specific to one particular behaviour. For example, consider someone who loves going to Wagnerian operas, all of whose friends also love

Table 15.4 Correlation between willingness to join or work for the Sierra Club and various measures of related attitudes

Attitude scale	Correlation
Importance of a pure environment	0.06
Pollution	0.32
Conservation	0.24
Attitude towards the Sierra Club	0.68

Source: Based on Weigel, R., Vernon, D.T.A. and Tognacci, L.N., Specificity of the attitude as a determinant of attitude–behavior congruence, *Journal of Personality and Social Psychology*, 1974, 30, 724–8.

going to Wagnerian operas, and who has a ticket to go to *The Ring*, which is on in his city tonight and who has nothing else to do tonight. If he expressed the strong intention of going to *The Ring* tonight which he is likely to do, then you can probably pretty accurately predict that this is what he will do. In contrast, consider someone who loves going to Wagnerian operas, but all of whose friends do not, and who has no ticket to the opera. He is unlikely to express a strong intention of going to *The Ring* tonight, and you are much less likely to know exactly what he will be doing.

D. Parker *et al.* (1995) surveyed almost 600 drivers in Britain, and found that they could quite accurately predict whether those drivers would engage in specific reckless driving behaviours, for example cutting in and reckless weaving, by measuring their attitudes towards the behaviour, the amount of support they perceived for this behaviour from their friends, and whether they had the resources and opportunity to behave in this way (for example, they had a car, they could get away with it, they had done it in the past and so knew what to do).

Attitude accessibility and attitude strength

Attitudes are cognitively represented in memory. Thus, like any other cognitive representations they are likely to have a greater influence on behaviour if they are readily accessible – easily and readily recalled. Indeed, research does show that attitudes affect behavioural intentions, and thus behaviour, more strongly if the attitudes are more accessible in memory (Doll and Ajzen, 1992). Our attitudes can also vary in strength. A strong attitude is one that has a strong associative link with the attitude object and thus, once activated, the attitude has a more automatic link with behavioural intentions and ultimately behaviour (Fazio *et al.*, 1986). So, for example, if you absolutely love chocolate and think about eating chocolate all the time then your attitude towards chocolate is strong and accessible and is probably a very good predictor of your intention to eat chocolate – an intention which probably maps tightly onto your behaviour. If, on the other hand, you quite like lobster and occasionally think about eating lobster then your attitude towards lobster is less strong and accessible, and is a poor predictor of your intentions and behaviour.

Social identity and norms

Another factor that influences the attitude–behaviour relationship is the extent to which an attitude is an important aspect of the kind of person we are. Self-defining attitudes, ones that define our identity, particularly our social identity as a group member, are more likely to be expressed as behaviour. More specifically, attitudes are more likely to

express themselves as behaviour if the attitudes (and associated behaviour) are normative properties of a social group with which people identify (Terry and Hogg, 1996). To test this idea, Terry and Hogg (1996) measured attitudes and intentions relating to taking regular exercise and adopting sun-protective behaviours. They found a much tighter attitude–intention link among student participants who identified strongly with a student peer group for whom they felt regular exercise and adopting sun-protective behaviour was a strong group-defining norm.

Attitude change and persuasion

People often attempt to persuade us to change our attitudes. Social psychological research on persuasion has taken its form from an early and highly influential programme of research by Hovland *et al.* (1953). Hovland and colleagues famously asked, ‘Who says what to whom and with what effect?’ – a question which identifies the three key aspects of persuasive communication: the source of the communication, the content of the message and the audience or target of the communication.

The source

Credibility and attractiveness are two aspects of the source of a message that have a major affect on persuasiveness. A message tends to be more persuasive if its source is credible. Source credibility is high when the source is perceived as knowledgeable and is trusted to communicate this knowledge accurately. For example, in one study, people developed a more favourable attitude towards different types of medicine when the information appeared in the prestigious medical journal *New England Journal of Medicine* than when it appeared in a mass-circulation tabloid (Hovland and Weiss, 1951). Research by Bochner and Insko (1966) showed that credible sources are not only more persuasive but they can also induce the greatest amount of attitude change. Bochner and Insko took advantage of the fact that their student participants believed that 8 hours of sleep a night was required to maintain good health. They then exposed them to one of two sources of opinion, a high credibility Nobel Prize-winning sleep physiologist or a less credible YMCA instructor, who said that less sleep was optimal. Both sources shifted the students’ attitudes when the sources advocated between 7 and 3 hours’ sleep, but when they advocated 1 or 2 hours the credible source was significantly more effective than the less credible source at changing attitudes.

Messages also have more impact when the source is physically attractive. For example, physically attractive people are more likely than physically unattractive people to persuade others to sign a petition (Chaiken, 1979).

Individuals who are asked to endorse products for advertisers are almost always physically attractive or appealing in other ways. Since people tend to like people who are similar to them more than people who are not, similarity should have the same effect. However, this does not seem to be the case. People are more persuaded by similar others when the issue is a matter of taste (for example, musical preference), but more persuaded by dissimilar others when the issue is a matter of fact (for example, who won the Tour de France in a particular year) (Petty and Cacioppo, 1981).

The message

As you would expect, aspects of the message itself are important in determining its persuasive appeal. For example, is an argument that provides only one side of an issue more effective than one that presents both sides? The answer depends on the audience. If the audience either knows very little about the issue or already holds a strong position with respect to it, one-sided arguments tend to be more effective. If the audience is well informed about the issue, however, a two-sided argument tends to be more persuasive (McAlister *et al.*, 1980).

How effective are scare tactics embedded in the message in changing someone's attitude? Some research suggests that frightening messages are very effective. Leventhal *et al.* (1967) found that people were more likely to stop smoking when the message was accompanied by a graphic video of surgery on a patient affected by lung cancer. Other research finds the opposite. Janis and Feshbach (1953) found much more improvement in dental hygiene practices among participants who had been exposed to a low-fear message (facts about tooth decay and gum disease) than those exposed to a high-fear message (graphic visual images of disease). Yet other research has shown that scare tactics may be effective in bringing about change, but only when combined with instructive information about how to change one's behaviour (Cialdini *et al.*, 1981). According to Janis (1967), a little bit of fear is good for motivation to attend to the message and to change one's attitudes and behaviours, but too much fear can distract us from the message so that we are unable to conceive of ways to put the message into action (Keller and Block, 1995).

The audience

Research on the audience or target of the communication identifies a number of factors that influence how easily persuaded people may be. One finding is that people who have very low or very high self-esteem are less easily persuaded than people with average self-esteem, because the former are either too anxious to pay attention or too self-

assured to be influenced (Rhodes and Wood, 1992). There are no straightforward sex differences in persuadability, but complex interactions (Carli, 1990). For example, Covell *et al.* (1994) studied the effect of tobacco and alcohol advertisements on Canadian adult and adolescent males and females and discovered a sex difference among the adolescents only – female adolescents were more influenced than male adolescents by advertisements that were strongly image-oriented. As with sex, there is no clear relationship between age and persuadability – some research finds no age effect whereas other studies find that younger and older people are more easily persuaded than people in their middle years (Visser and Krosnick, 1998).

The process of attitude change through persuasion

Petty and Cacioppo (1986) have proposed the **elaboration likelihood model** to account for attitude change through persuasion (Figure 15.1). According to this model, persuasion can take either a central or a peripheral route. The central route requires a person to think critically about the argument being presented, to weigh its strengths and weaknesses, and to elaborate on the relevant themes. At issue is the substance of the argument, not its emotional or superficial appeal. The peripheral route, on the other hand, refers to attempts at persuasion in which the change is associated with positive stimuli – a professional athlete, a millionaire, or an attractive model – which actually may have nothing to do with the sub-

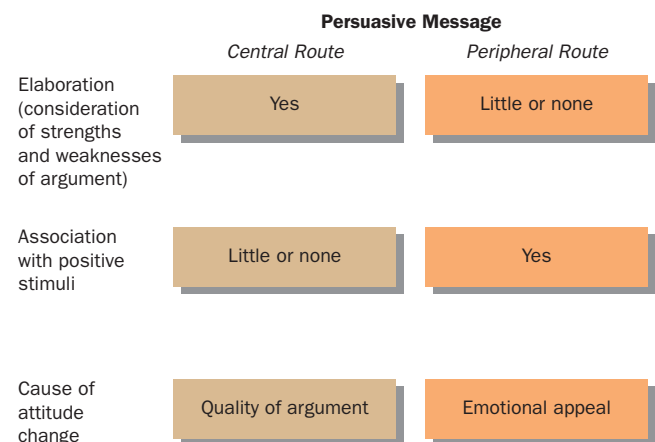

Figure 15.1 The elaboration likelihood model of attitude change. Persuasive messages may centre either on a substantive argument that requires an individual to think about the argument's strengths and weaknesses (the central route) or on a superficial argument that is associated with positive stimuli (the peripheral route).

stance of the argument. Selling products by associating them with attractive people or by implying that buying the product will result in emotional, social or financial benefits are examples of the use of peripheral attitude change techniques.

Very closely related to Petty and Cacioppo's distinction between central and peripheral route processing, is Chaiken's distinction between systematic and heuristic processing (Bhoner *et al.*, 1995). People can systematically consider all aspects of a message, or they can very superficially rely on simple heuristics such as thinking that longer arguments or arguments with more statistical facts and figures must be more true, or that all messages from politicians are lies. People are more likely to resort to heuristic processing if they have limited time to process the message or if they are in a good mood. So, to change attitudes towards consumer products it is quite effective to bombard hurried people with advertisements that put them in a good mood and present statistical/scientific information from people dressed as scientists. This encourages heuristic processing and encourages the heuristic that messages backed by science must be true. One difference between the elaboration likelihood model and the heuristic-systematic model is that whereas a message is processed either centrally or peripherally at any one time, it can be processed systematically and heuristically at the same time.

Resistance to persuasion

Far more attempts at persuasion fail than succeed. Researchers have identified three major factors: reactance, forewarning and inoculation. Reactance refers to a tendency to resist persuasion, or even move one's attitudes in an opposite direction, when a deliberate persuasion attempt is detected. People do not like to have their personal freedom limited by being pressured to change their attitudes. When people are forewarned of an influence attempt they are less easily influenced, particularly as regards attitudes that are considered important. Forewarning allows people to generate defensive counterarguments to protect their attitudes.

Related to forewarning, is inoculation. Inoculation is a process where people are exposed to a weak version of a persuasive argument – much like inoculation against an illness. This allows people to build up resistance, in this case specific counterarguments, against the full-blown persuasive attempt. Research on inoculation was prompted by the way that American prisoners of war in the Korean War of the 1950s were easily brainwashed to denounce the American way of life and endorse Communism. It was thought that this had happened because the soldiers had never heard any attacks on the

American way of life, and so were completely unprepared to protect their attitudes (McGuire, 1964). McGuire and Papageorgis (1961) conducted a study where student participants who strongly endorsed truisms such as 'It's a good idea to brush your teeth after every meal', were exposed to a strong attack on these truisms and then had their attitudes remeasured. Some participants were prepared for the attack by being provided with supporting arguments defending their position, some were inoculated by being exposed to a mild form of the attack, and some were not prepared at all. Supportive defence and inoculation reduced attitude change relative to no defence, but inoculation was significantly more effective.

What kinds of argument do you think would be effective in persuading you to change your attitude towards a prominent political figure? How would you describe these arguments in psychological terms? Based on social psychological knowledge about the relationship between attitudes and behaviour, what advice would you give an organisation that wanted to combat waste (for example, excessive paper use, excessive energy use)? Would you recommend changing employees' attitudes in order to change their behaviour?

Cognitive dissonance

Although we usually regard our attitudes as causes of our behaviour, our behaviour also affects our attitudes. Two major theories attempt to explain the effects of behaviour on attitude formation: cognitive dissonance and self-perception.

The oldest theory is cognitive dissonance theory, developed by Leon Festinger (1957). According to **cognitive dissonance theory**, when we perceive a discrepancy between our attitudes and behaviour, between our behaviour and self-image, or between one attitude and another, an unpleasant state of anxiety, or dissonance, results. For example, a person may successfully overcome a childhood racial prejudice but may experience unpleasant emotional arousal at the sight of a racially mixed couple. The person experiences a conflict between the belief in their own lack of prejudice and the evidence of prejudice from their behaviour. This conflict produces dissonance, which is an aversive state that people are motivated to reduce. A person can reduce dissonance by (1) reducing the importance of one of the dissonant elements, (2) adding consonant elements, or (3) changing one of the dissonant elements.

Suppose that a student believes that he is very intelligent but he invariably receives poor grades in his courses. Because the obvious prediction is that intelligent people get good grades, the discrepancy causes the student to experience dissonance. To reduce this dissonance, he may

decide that grades are not important and that intelligence is not very closely related to grades. He is using strategy 1, reducing the importance of one of the dissonant elements – the fact that he received poor grades in his courses. Or he can dwell on the belief that his lecturers were unfair or that his job leaves him little time to study. In this case, he is using strategy 2, reducing dissonance by adding consonant elements – those factors that can account for his poor grades and hence explain the discrepancy between his perceived intelligence and grades. Finally, he can use strategy 3 to change one of the dissonant elements. He can either improve his grades or revise his opinion of his own intelligence.

Induced compliance

Most of us believe that although we can induce someone to do something, getting someone to change an attitude is much harder. However, Festinger's theory of cognitive dissonance and supporting experimental evidence indicate otherwise. Under the right conditions, when people are coerced into doing something or are paid to do something, the act of **compliance** – simply engaging in a particular behaviour at someone else's request – may cause a change in their underlying attitudes.

Cognitive dissonance theory predicts that dissonance occurs when a person's behaviour has undesirable outcomes for self-esteem; there is a conflict between the person's belief in their own worth and the fact that they have done something that damages this belief. The person will then seek to justify the behaviour. For example, a poorly paid vacuum cleaner sales representative is likely to convince himself that the shoddy merchandise he sells is actually good. Otherwise, he must question why he works for a company that pays him poorly and requires him to lie to prospective customers about the quality of the product in order to make a sale. Conversely, an executive of one of the celebrity gossip magazines may know that the magazines she produces are sleazy, mindless drivel, but she is so well paid that she does not feel bad about producing them. Her high salary justifies her job and probably also provides her with enough self-esteem that she has decided that the public gets what it deserves anyway.

Festinger and Carlsmith (1959) verified this observation by having participants perform very boring tasks, such as putting spools on a tray, dumping them out, putting them on the tray again, dumping them out again, and so on. After the participants had spent an hour on exercises like this, the experimenter asked each participant whether they would help out in the study by trying to convince the next person that the task was interesting and enjoyable. Some participants received \$1 for helping out; others received \$20. Control participants were paid nothing. The experimenters predicted that participants who were paid only \$1

would perceive the task as being relatively interesting. They had been induced to lie to a 'fellow student' (actually, a confederate of the experimenters) for a paltry sum. Like the vacuum cleaner sales representative, they should convince themselves of the worth of the experiment to maintain their self-esteem. Poorly paid participants did in fact rate the task better than did those who were well paid (Figure 15.2). Clearly, our actions have an effect on our attitudes. When faced with inconsistency between our behaviour and our attitudes, we often change our attitudes to suit our behaviour.

Arousal and attitude change

Festinger's theory hypothesises that dissonance reduction is motivated by an aversive drive. A study by Croyle and Cooper (1983) obtained physiological evidence to support this hypothesis. The experimenters chose as their participants Princeton University students who disagreed with the assertion 'Alcohol use should be totally banned from the Princeton campus and eating clubs'. Each participant was induced to write an essay containing strong and forceful arguments in favour of the assertion or in opposition to it. While the participants were writing the essay, the experimenters measured the electrical conductance of their skin, which is known to be a good indicator of the physiological arousal that accompanies stress. Some participants were simply told to write the essay. Other participants were told that their participation was completely voluntary and that they were free to leave at any time; they even signed a form

Figure 15.2 Effects of induced compliance. People who received \$1 to lie about a boring task later indicated that they liked the task more than did people who received \$20.

Source: Based on data from Festinger, L. and Carlsmith, J.M., Cognitive consequences of forced compliance. *Journal of Abnormal and Social Psychology*, 1959, 58, 203–210.

emphasising the voluntary nature of the task. Of course, all participants felt social pressure to continue the study, and all of them did. Those who were simply told to write the essay should have felt less personal responsibility for what they wrote and would therefore be expected to experience less cognitive dissonance than those who believed that they had exercised free choice in deciding to participate.

Participants in the ‘free choice’ condition who had written essays contradicting their original opinions showed both a change in opinion and evidence of physiological arousal. Those participants who were simply told to write the essay or who wrote arguments that they had originally agreed with showed little sign of arousal or attitude change (Figure 15.3).

Attitudes and expenditures

Festinger’s theory of cognitive dissonance accounts for another relation between behaviour and attitudes: our tendency to value an item more if it costs us something. For example, some people buy extremely expensive brands of cosmetics even though the same ingredients are used in much cheaper brands. Presumably, they believe that if an

item costs more, it must work better. Following the same rationale, most animal shelters sell their stray animals to prospective pet owners, not only because the money helps defray their operating costs, but also because they assume that a purchased pet will be treated better than a free pet.

Aronson and Mills (1959) verified this phenomenon. The experimenters subjected female college students to varying degrees of embarrassment as a prerequisite for joining what was promised to be an interesting discussion about sexual behaviour. To produce slight embarrassment, they had the participants read aloud five sex-related words (such as prostitute, virgin and petting – remember that this research was conducted in the 1950s) to the experimenter, who was male. To produce more severe embarrassment, they had the women read aloud 12 obscene four-letter words and two sexually explicit passages of prose. The control group read nothing at all. The ‘interesting group discussion’ turned out to be a tape recording of a very dull conversation.

Festinger’s theory predicts that the women who had to go through an embarrassing ordeal in order to join the group would experience some cognitive dissonance. They had suffered an ordeal in order to take part in an interesting discussion that turned out actually to be very dull. These negative and positive experiences are inconsistent and dissonance arousing, and should make them view the ‘discussion’ more favourably so that their effort would not be perceived as having been completely without value. The results were as predicted: the participants who had been embarrassed the most rated the discussion more favourably than did the control participants or those who had experienced only slight embarrassment. We value things at least partly by how much they cost us. One controversial implication is that people might value social goods like education and national parks more highly if they personally paid (more) for them.

Figure 15.3 Physiological evidence for cognitive dissonance. Mean change in attitude towards the position advocated by the essay and mean frequency of skin conductance responses (a physiological index of arousal) in participants who argued for or against their own positions.

Source: Based on data from Croyle, R.T. and Cooper, J., Dissonance arousal: Physical evidence. *Journal of Personality and Social Psychology*, 1983, 45, 782–91.

Self-perception

Bem (1972) proposed an alternative to the theory of cognitive dissonance. Drawing on attribution theory, which we discussed earlier in this chapter, he defined **self-perception theory** in the following way:

Individuals come to ‘know’ their own attitudes, emotions, and other internal states partially by inferring them from observations of their own overt behaviour and/or the circumstances in which this behaviour occurs. Thus, to the extent that internal cues are weak, ambiguous, or uninterpretable, the individual is functionally in the same position as an outside observer, an observer who must necessarily rely on those same external cues to infer the individual’s inner states.

Bem noted that an observer who attempts to make judgements about someone's attitudes, emotions or other internal states must examine the person's behaviour for clues. For example, if you cannot ask someone why they are doing something, you must analyse the situation in which the behaviour occurs to try to determine the motivation. Bem suggested that people analyse their own internal states in a similar way, making attributions about the causes of their own behaviour.

You will recall the experiment by Festinger and Carlsmith (1959) in which students who were paid only \$1 later rated a boring task as more interesting than did those who were paid \$20. How does self-perception theory explain these results? Suppose that an observer watches a participant who has been paid \$1 to deliver a convincing speech to another student about how interesting a task was. Because being paid such a small sum is not a sufficient reason for calling a dull task interesting, the observer will probably conclude that the student actually enjoyed the task. Lacking good evidence for external causes, the observer will attribute the behaviour to a dispositional factor: interest in the task. Bem argued that the participant makes the same inference about themselves. Because the participant was not paid enough to tell a lie, they must have enjoyed the task. The principal advantage

of self-perception theory is that it makes fewer assumptions than does dissonance theory; it does not postulate a motivating aversive-drive state.

But as Croyle and Cooper's (1983) experiment on essay writing showed, some conflict situations do produce arousal. Perhaps self-perception and cognitive dissonance occur under different conditions, producing attitude changes for different reasons. One factor that may determine whether dissonance or self-perception processes come into play involves the idea that attitudes have ranges of acceptable behaviour. For example, a pacifist might agree with using force to protect a helpless child from attack but would not agree with using force to react to a personal insult. According to Fazio *et al.* (1977), a pacifist who used force to protect a child might change his attitudes through self-perception (the behaviour falls within the latitude of acceptable behaviours), whereas a pacifist who struck out in retaliation for an insult would experience dissonance (the behaviour falls outside the latitude of acceptable behaviours). Using a slightly different logic, Cooper and Fazio (1984) suggest that when counter-attitudinal behaviour has undesirable consequences, we go through an attributional/self-perception process where we decide whether the behaviour was voluntary. If it was, then we experience dissonance.

Chapter review

Social psychology

- Social psychology is the study of how the thoughts, feelings and behaviour of people are influenced by the actual, imagined or implied presence of other people.
- Social psychologists employ the scientific method – they formulate theories of human behaviour and test them using a wide range of empirical methods.
- Social psychology has its roots in late-nineteenth-century German folk psychology. By the 1920s, America had taken the lead and social psychology was a branch of general psychology. The Second World War gave impetus to a focus on groups and attitudes. This was gradually replaced from the mid-1960s by a focus on individual cognition and inference in its social context. Contemporary social psychology is very diverse, embracing a wide range of emphases on social cognition, groups, intergroup relations, close relationships and attitudes.

Social cognition and social knowledge

- Social cognition refers to the way we process and represent the social world and our place in it. Social cognition is governed by cognitive parsimony, but it is also motivated by our own goals.

- Impressions of people are strongly influenced by central traits, negative information and information that one encounters first (primacy effect).
- Our thoughts, feelings, perceptions and beliefs about the world are organised in mental frameworks, or schemas, which help us manage and synthesise information about our social world.
- Schemas can be tied closely to specific instances of a category (called exemplars) or they can be fuzzy abstractions of defining features (called prototypes).
- Schemas that are widely shared within a group, and are held about another group, are stereotypes.
- Schemas tend to be activated automatically once we have categorised a person, object or event.

Self and identity

- Our self-concept is based on schemas that organise and synthesise personal knowledge and feelings we have about ourselves.
- We often try to bring our behaviour, and thus our own self-conception, in line with how we would like to be, or we feel we ought to be.

- There are cultural and situational differences in the extent to which self-schemas are based on being an individual, a member of a group, or in a relationship with specific other people.
- The way we conceptualise ourselves is most strongly motivated by a desire for an evaluatively positive self-concept that contributes to a sense of positive self-esteem.

Social inference

- In making attributions about the causes of another person's behaviour, we consider the relative contributions of dispositional and situational factors.
- In some circumstances we may gain an understanding of what sort of person we are and how we feel, by trying to discover what the causes of our behaviour might be.
- In making attributions about others' behaviour we tend to overestimate the role of dispositional factors and underestimate the role of situational factors (the fundamental attribution error); however, we do the opposite for our own behaviour.
- Attributions also tend to be self-serving. We attribute our own and our groups' good behaviours internally and bad behaviours externally. We also tend to think bad things happen to bad people and good things to good people.
- In making inferences about people we tend to rely on cognitive short-cuts or heuristics, such as how available something is to memory, and how superficially representative something is of a category.

Attitudes and attitude change

- Attitudes have affective, cognitive and behavioural intention components and may be learned through mere exposure to the object of the attitude, classical conditioning processes and imitation.
- Attitudes are poor predictors of behaviour unless very specific attitudes and very specific behaviours are measured. Prediction is even better if attitudes towards behaviours are measured, and if normative support is strong and opportunity and resources to perform the behaviour are available.
- To understand explicit attempts to change a person's attitude, we must consider both the source of the intended persuasive message and the message itself.
- A message tends to be persuasive if its source is credible or attractive and if it is pitched correctly at its intended audience.
- There are at least two routes to persuasion. The central route involves careful consideration of the message, whereas the peripheral route involves superficial reliance on heuristics such as the attractiveness of the message source.
- Cognitive dissonance is an aversive state that occurs when our attitudes and behaviour are inconsistent. Resolution of dissonance often involves changing attitudes in line with behaviour.
- Our own observations of our behaviour and situation also influence attitude development.

Suggestions for further reading

Social psychology in general

Aronson, E. (2007) *The Social Animal* (7th edn). NY: Freeman
 Carr, S.C. (2003) *Social Psychology*. Australia: Wiley.
 Hogg, M.A. and Cooper, J. (eds) (2003) *Sage Handbook of Social Psychology*. London: Sage.
 Hogg, M.A. and Vaughan, G.M. (2005) *Social Psychology* (4th edn). London: Pearson Education.

Aronson's classic is a brilliant introduction to social psychology. The last three items are comprehensive texts which integrate European and North American research (Hogg et al.) and these territories and Australasia (Carr's is a lively book).

Self

Baumeister, R.F. (ed.) (1999) *The Self in Social Psychology*. Philadelphia: Psychology Press.

A set of key readings, presenting contemporary and classic published work.

Culture and social psychology

Smith, P.B., Bond, M.H. and Kagitcibasi, C. (2006) *Understanding Social Psychology Across Cultures*. London: Sage.

This is a completely up-to-date text on social psychological similarities and differences between cultures.

Social cognition and attitudes

Fiske, S.T. and Taylor, S.E. (2008) *Social Cognition: From brain to culture*. New York: McGraw-Hill.

Moskowitz, G.B. (2005) *Social Cognition: Understanding self and others*. New York: Guilford.

Tesser, A. and Schwartz, N. (eds) (2001) *Blackwell Handbook of Social Psychology: Intraindividual processes*. Oxford: Blackwell.

Some very good texts on social cognition. Fiske and Taylor's is a revision of an outstanding classic.

WHAT YOU SHOULD BE ABLE TO DO AFTER READING CHAPTER 16

- Understand how people are influenced by individuals, authority, group norms and minorities.
- Know what affects people’s performance of tasks in groups, and how groups make decisions and are influenced by leaders.
- Know why intergroup conflicts and prejudices are so difficult to change, and what underlies crowd behaviour and social movements.
- Understand some of the causes of human aggression, and what influences people’s inclination to help others.
- Understand why we like who we do, and the path taken by love and close relationships.
- Appreciate the role of language, speech and non-verbal communication in social life, and what factors influence how we communicate.

QUESTIONS TO THINK ABOUT

- If someone ordered you to do something that caused serious harm to another person, would you do it?
- How does the presence of an audience affect the way you perform?
- Is there such a thing as team spirit? If so, which psychological processes are involved?
- What makes a great leader? What would ten such leaders have in common?
- If you try hard to suppress your prejudices, do you think they will gradually disappear?
- Can contact between racial groups reduce racial prejudice?
- Are men more aggressive than women?
- What sort of person are you attracted to, and why?
- Does attraction lead to love or vice versa?
- ‘It’s not what you do; it’s the way that you do it.’ Is this true when considering communication between people?

Social influence

At the end of Chapter 15 we discussed attitude change. The social process responsible for attitude change is social influence. However, social influence is in fact a much wider topic because it also addresses changes in people's behaviour that are not associated with changed attitudes. Sometimes people simply do what people tell or ask them to do, without necessarily changing their underlying attitudes. A key distinction in the social influence literature is between **compliance** (a surface change in behaviour which is not associated with true underlying cognitive changes) and **conformity** (a deep-seated cognitive change, usually in response to the existence of self-defining group norms).

Compliance

Research on compliance focuses on the conditions under which people will go along with a request or do someone a favour. For example, how can you get someone to lend you some money, fix your car, pop down to the shops for you, fill out a questionnaire, and so forth? You simply want people to do what you request – you are not looking for deep-seated changes in their attitudes and values.

Ingratiation

One very effective method is **ingratiation**, which involves getting people to like you – flattery may not get you everywhere, but it is surprisingly effective. People are much more likely to agree to a request from someone they like or find attractive. One reason for this is that an attractive person, by association, makes the request appear more attractive. Advertisers regularly pay tribute to the effectiveness of association when they use attractive models and celebrities to endorse their products. For example, Smith and Engel (1968) showed two versions of an advertisement for a new car. One version included an attractive young woman and the other did not. When the participants subsequently rated the car, those who saw the advertisement with the attractive young woman rated the car as faster, more appealing, more expensive-looking and better designed.

Besides making products or opinions more attractive by being associated with them, attractive people are better able to get others to comply with their requests because people want to be liked by attractive people. People believe that being liked by attractive people makes them more desirable, too. Thus, people tend to emphasise their associations with attractive and important people. We have all encountered name-droppers who want us to think that they are part of a privileged circle of friends. This phenomenon is even demonstrated by fans of sports teams. Cialdini *et al.* (1976) found that students were more likely

to wear sweatshirts featuring their university name on the day after the university football team had won a game than after the team had lost. Also, Wann and Dolan (1994) have shown that spectators identify with, and are biased in favour of, fellow spectators who support the same team.

Although attractive people may influence our behaviour, it is possible that they may only influence our underlying attitudes when we do not consider the underlying message carefully. You will recall from the section on attitude change in Chapter 15 that, according to Petty and Cacioppo's (1986, 1996) **elaboration likelihood model**, people can process information either via a central or a peripheral route. Attractive people may influence us via the peripheral route, and can thus be less influential if we adopt central route processing.

Reciprocity

Another effective method for ensuring others will comply with your requests is first to do them a favour. This takes advantage of a powerful human expectation of **reciprocity** – the tendency to return favours others have done for us. When someone does something for us, we feel uncomfortable until we have discharged the debt. For example, if people invite us to their house for dinner, we feel obliged to return the favour in the near future. Owing a social debt to someone we do not like is especially distasteful. Often people will suffer in silence rather than ask for help from someone they dislike. Reciprocity is pervasive – every culture is known to have some form of the 'golden rule' (Cialdini, 1993). It establishes a basic guideline for behaviour in a wide range of situations, and its emergence in evolutionary history is considered to be crucial to the development of social life.

Reciprocity does not require that the 'favour' be initially requested or even wanted. The debt of obligation can be so strong that reciprocity can be exploited by people who want us to comply with their requests when we would otherwise not do so. For example, people trying to sell something often try to capitalise on the reciprocity rule by giving the potential customer a free sample. Once the person has accepted the 'gift', the sales representative tries to get them to return the favour by making a purchase. Many of us avoid accepting free samples because we dislike being manipulated into buying something we do not want.

Experiments conducted by social psychologists have confirmed the strength of reciprocity in human interactions. For example, Regan (1971) enlisted the participation of university students in an experiment that supposedly involved art appreciation. During a break in the experimental session, some participants were treated to a soft drink by another 'participant' (a confederate) or by the experimenter; others received nothing. After the experiment, the confederate asked each participant to purchase some raffle tickets he was selling. Compliance with the

request was measured by the number of tickets each participant bought. The participants treated to a soft drink by the confederate purchased the most raffle tickets.

Multiple requests

A third technique for gaining compliance involves the use of multiple requests. The focal request is either preceded by a smaller request that everyone will agree to (called foot-in-the-door), or preceded by a much larger request that everyone will refuse (door-in-the-face), or accompanied by all sorts of sweeteners (low-balling).

To investigate the **foot-in-the-door tactic**, Freedman and Fraser (1966) sent a person posing as a volunteer worker to call on homeowners in a residential California neighbourhood. The volunteer asked the homeowners to perform a small task: to accept a 3-inch-square sign saying 'Keep California Beautiful' or 'Be a Safe Driver' or to sign a petition supporting legislation favouring one of these goals. Almost everyone agreed. Two weeks later, the experimenters sent another person to ask these people whether they would be willing to have public service billboards erected in front of their houses. To give them an idea of precisely what was being requested, the 'volunteer worker' showed the homeowners a photograph of a house almost completely hidden by a huge, ugly, poorly lettered sign saying 'Drive Carefully'. Over 55 per cent of the people agreed to this obnoxious request. In contrast, only 17 per cent of householders who had not been contacted previously (and asked to accept the smaller sign) agreed to have such a billboard placed on their property.

The foot-in-the-door tactic works even better when the focal request is preceded by a graded series of smaller requests leading up to the focal request (Dolinski, 2000). So, if you wanted to persuade someone to go out with you, it might be useful to get them first to agree to study with you in the library, and once they say yes, say, 'How about going for coffee?', and then once they agree, pose the focal request of asking them to go out with you.

The foot-in-the-door tactic probably works because once people have committed themselves to a course of action they are loath then to change their mind. Commitment probably increases compliance for several reasons. First, the act of complying with a request in a particular category may change a person's self-image. Through the process of self-attribution, people who accept a small sign to support safe driving may come to regard themselves as public-spirited – what sensible person is not in favour of safe driving? Thus, when they hear the billboard request, they find it difficult to refuse. After all, they are public-spirited, so how can they say no? Saying no would imply that they did not have the courage of their convictions. Thus, this reason has at its root self-esteem. To maintain positive self-esteem, the person must say yes to the larger request.

Commitment may also increase compliance because the initial, smaller request changes people's perception of com-

pliance in general. Evidence supporting this suggestion was provided by Rittle (1981). While sitting in a waiting room before taking part in an experiment, some adult participants were approached by an 8-year-old child who was having trouble operating a vending machine. Later, while answering a series of questions designed to disguise the true nature of the experiment, they were asked to rate their perceptions of how unpleasant it might be to provide help to other people. After the participants had answered all the questions and the study was apparently over, the interviewer asked them whether they would volunteer between 30 minutes and 4 hours of their time to participate in a research project. Participants who had helped the child rated helping as less unpleasant and were more willing to participate in the research project than were people who had not helped the child (see Figure 16.1).

The second multiple request tactic, the **door-in-the-face**, is the opposite of the foot-in-the-door. Here, the focal request is preceded by a much larger request that no one is likely to comply with. Cialdini *et al.* (1975) tested this tactic by approaching students with a huge request: 'Would you serve as a voluntary counsellor at a youth offenders' centre two hours a week for the next two years?' Virtually no one agreed. However, when the researchers then asked for a considerably smaller request, 'Would you chaperone a group of these offenders on a two-hour trip to the zoo?', 50 per cent agreed. When the second request was presented alone, less than 17 per cent

Figure 16.1 The effect of commitment on compliance and perceptions of the potential unpleasantness of helping situations. Mean number of hours volunteered (compliance) and mean rating of potential unpleasantness of volunteering, for control participants and participants who first helped a child.

Source: Based on data from Rittle, R.H., Changes in helping behaviour: Self versus situational perceptions as mediators of the foot-in-the-door technique. *Personality and Social Psychology Bulletin*, 1981, 7, 431-37.

complied. For the tactic to be effective, the final request should come from the same person who made the initial request. According to Cialdini and associates, participants perceive the scaled-down request as a concession by the influencer, and consequently they feel pressure to reciprocate. If some other person were to make the second request, reciprocation would not be necessary.

The final multiple request tactic is called **low-balling**. The effectiveness of low-balling depends on people's disinclination to change their mind once they have already made a commitment. For example, some of you may have had dealings with car sales agents. You are shown a beautiful car that you fall in love with and the agent commits you to purchasing the car which includes CD-player, GPS, air-conditioning, sunroof, electric windows and so forth, as well as all the various dealer costs. The agent now goes to get the paperwork ratified by their boss and comes back with the disappointing news that many of the 'extras' are not included. A rational choice would now be to decline to buy the car. However, because you are committed to your decision you are actually very likely still to purchase the car.

The effectiveness of low-balling was experimentally demonstrated by Cialdini *et al.* (1978). They asked half their participants to be in an experiment that began at 7 a.m. The other half were asked first to commit themselves to participating in an experiment, and then were informed that it would start at 7 a.m. The latter group, in the low-balling situation, complied more often (56 per cent) than the control group (31 per cent), and also tended to keep their appointments.

Obedience

Research confirms that people tend to comply with the requests of people in authority and to be swayed by their persuasive arguments, and that such obedience is generally approved of by society. Obedience can be quite mindless. Cohen and Davis (1981) cite the example of a physician who prescribed ear-drops for a hospitalised patient with an ear infection. His order read 'place in R ear'. Unfortunately, he apparently did not put enough space between the abbreviation for right (R) and the word ear – the nurse delivered the ear drops rectally. Neither she nor the patient thought to question such treatment for an ear ache. Other research in the United States confirms that many medication errors occur because nurses overwhelmingly defer to doctors, even when the nurses have concerns about the wisdom or correctness of the doctors' directions (Lesar *et al.*, 1997).

The classic study of blind obedience is a series of experiments performed by Stanley Milgram (1963), who advertised for participants in local newspapers in order to obtain as representative a sample as possible. The participants served as 'teachers' in what they were told was a learning experiment. A confederate (a middle-aged account-

ant) serving as the 'learner' was strapped into a chair 'to prevent excessive movements when he was shocked', and electrodes were attached to his wrist. The participants were told that 'although the shocks can be extremely painful, they cause no permanent tissue damage'.

The participant was then brought to a separate room housing an apparatus having dials, buttons and a series of switches that supposedly delivered shocks ranging from 15 to 450 volts. The participant was instructed to use this apparatus to deliver shocks, in increments of 15 volts for each 'mistake', to the learner in the other room. Beneath the switches were descriptive labels ranging from 'Slight shock' to 'Danger: severe shock'.

The learner gave his answers by pressing the appropriate lever on the table in front of him. Each time he made an incorrect response, the experimenter told the participant to throw another switch and give a larger shock. At the 300-volt level, the learner pounded on the wall and then stopped responding to questions. The experimenter told the participant to consider a 'no answer' as an incorrect answer. At the 315-volt level, the learner pounded on the wall again. If the participant hesitated in delivering a shock, the experimenter said, 'Please go on'. If this admonition was not enough, the experimenter said, 'The experiment requires that you continue', then, 'It is absolutely essential that you continue', and finally, 'You have no other choice; you must go on'. The factor of interest was how long the participants would continue to administer shocks to the hapless victim. A majority of participants gave the learner what they believed to be the 450-volt shock, despite the fact that the learner pounded on the wall twice and then stopped responding altogether (see Figure 16.2).

In a later experiment, when the confederate was placed in the same room as the participant and his struggling and apparent pain could be observed, 37.5 per cent of the participants – over one-third – obeyed the order to administer further shocks (Milgram, 1974). Thirty per cent were even willing to hold his hand against a metal plate to force him to receive the shock.

Even the once most powerful man in the world feels the need to obey authority: G. W. Bush's handwritten note at the UN on 14 September 2005, asking if he can go to the lavatory.

Milgram's experiments indicate that a significant percentage of people will blindly follow the orders of authority figures, no matter what the effects are on other people. Most people find this surprising. They cannot believe that for such a large proportion of people the social pressure to conform to the experimenter's orders is stronger than the participant's own desire not to hurt someone else. As Ross (1977) points out, this misperception is an example of the **fundamental attribution error**. People tend to underestimate the effectiveness of situational factors and to overestimate the effectiveness of dispositional ones. Clearly, the tendency to obey an authority figure is amazingly strong. However, one factor that can dramatically reduce obedience is social support for non-compliance. In one of his studies, Milgram had two confederates work with the participant. When the confederates were obedient, so was the participant – obedience increased to 92.5 per cent. However, when the confederates were disobedient so was the participant – obedience dropped dramatically to 10 per cent.

Understandably, much of the attention given to Milgram's research focused on its considerable ethical implications (Elms, 1995). Many people, psychologists and non-psychologists alike, have attacked his research on the grounds that it involved deception and too much emotional strain on the participants. Indeed, Milgram's research helped prompt psychologists to strengthen ethical guidelines for conducting research with humans.

In his defence, however, it should be stressed that Milgram conducted an extensive debriefing at the end of each experimental session in which the true purpose of the experiment was explained to the participants. The participants were told that their behaviour was quite typical of the way most people responded to the situation posed by the experiment. In addition, the participants were later sent a detailed written report of the experimental procedure and a follow-up questionnaire asking them about their feelings regarding their participation. Eighty-four per cent of the participants said that they were glad to have participated in the experiment, and only 1.3 per cent indicated that they wished they had not participated.

An additional objection to Milgram's research is that people may have had to confront a disturbing aspect of their own behaviour – the self-realisation that they were capable of actions that they find reprehensible. Milgram replied that at least some of his participants considered their enhanced insight into their own behaviour to have been enough to justify their participation. Of course, Milgram could not guarantee that somebody, somewhere, who had participated in his research might not be deeply troubled by his participation. And therein lies another moral dilemma: to what extent is knowledge about behaviour, in general, and insight about one's own behaviour, in particular, to be avoided in case some people think that others might find this knowledge disturbing? That is not an easy question to answer and one that psychologists must grapple with each time they perform research such as that conducted by Milgram.

Cutting edge – Milgram and obedience to authority, 2007

Most psychologists thought it would never happen but, in 2007, a psychologist from Santa Clara did it. On 3 January 2007, the American current affairs programme, *Primetime*, featured a replication of Milgram's study, conducted by Jerry Burger. The programme was timely. Milgram's findings have been thought to explain aberrations ranging from the Holocaust of the Second World War, to the Mai Lai massacre, to the torture and humiliation that was allowed to fester at Abu Ghraib. For decades, psychologists and others have debated whether Milgram's findings were of their time or whether, in this multimedia age, they could transcend temporal bound-

aries. But no psychologist has replicated Milgram's study for over 30 years (Blass, 2000) because professional societies' guidelines on the ethical treatment of participants would prevent such experiments from being conducted (Elms, 1995).

However, Burger (2009) alighted on a solution. Most of controversy surrounding Milgram's studies focuses on his fifth experiment. This is where participants were asked to administer shocks from between 15 and 450 volts to an unseen person. At 150 volts, the participants heard the cries of protest from the victim and the victim's expressions of pain. At up to 300 volts, the victim yelled that he was in pain. After 330 volts,

Cutting edge – Continued

he fell silent. 65 per cent of people administered the shocks, at the experimenter’s instigation, at the maximum voltage. The point at which participants began to become reluctant to give the shock was 150 volts. When psychiatrists, students and members of the public are asked at what point they would stop, 150 volts is their threshold (Milgram, 1974). This is an important figure because of those who reached this level, 79 per cent were prepared to continue to 450 volts, the maximum.

Burger used this fact to inform his replication. The assumption would be that if participants were willing to deliver a shock at this level, it is highly likely that they would have administered a higher shock (regardless of whether they said they would not). Burger carefully screened his participants, making sure that they had seen a clinical psychologist beforehand and that there was no indication of vulnerability. Participants were also informed, three times, that they could withdraw at any point and still keep the money they were promised for participating. They were told that the learner had also been offered the opportunity to leave at any point. Participants were told immediately after the experiment that the learner had received no shock (a long time elapsed in Milgram’s study). In addition, the experimenter in Burger’s study was a clinical psychologist who was instructed to stop immediately if any unacceptable signs of distress were observed. Twenty-nine men and forty-one women participated. The experiment was run using an almost identical protocol to that in Milgram’s studies. In one condition, participants saw another confederate refuse the experimenter’s instructions.

Seventy per cent of participants were willing to go beyond the 150-volt limit and had to be prevented from doing so. Even when they saw a confederate refuse instructions they continued to deliver the shock, indicating that seeing others disobey did not inhibit the giving of punishment. There was no significant difference between men and women (Milgram’s studies recruited, largely, men). And while those who reported being highly empathetic expressed a reluctance to continue earlier than did those who were less empathetic, this empathy did not prevent them from physically continuing with the experiment and delivering the shocks.

It seems as if, almost 30 years after Milgram’s original experiment, people will behave in almost exactly the same way now as they did then. Of course, the jaded might ask whether we needed an experiment, Milgram’s experiment, to tell us that people are inclined to obey authority. ‘Of course not’, writes Blass (2009). ‘What he did teach us is just how strong this tendency is – so strong, in fact, that it can make us act in ways contrary to our moral principles . . . Milgram showed that it does not take evil or aberrant persons to carry out actions that are reprehensible and cruel’ (p. 40).

Public Announcement

**WE WILL PAY YOU \$4.00 FOR
ONE HOUR OF YOUR TIME**

Persons Needed for a Study of Memory

*We will pay five hundred New Haven men to help us complete a scientific study of memory and learning. The study is being done at Yale University.
*Each person who participates will be paid \$4.00 (plus 50c carfare) for approximately 1 hour's time. We need you for only one hour: there are no further obligations. You may choose the time you would like to come (evenings, weekdays, or weekends).

*No special training, education, or experience is needed. We want:

Factory workers	Businessmen	Construction workers
City employees	Clerks	Salespeople
Labors	Professional people	White-collar workers
Barbers	Telephone workers	Others

All persons must be between the ages of 20 and 50. High school and college students cannot be used.
*If you meet these qualifications, fill out the coupon below and mail it now to Professor Stanley Milgram, Department of Psychology, Yale University, New Haven. You will be notified later of the specific time and place of the study. We reserve the right to decline any application.
*You will be paid \$4.00 (plus 50c carfare) as soon as you arrive at the laboratory.

TO:
PROF. STANLEY MILGRAM, DEPARTMENT OF PSYCHOLOGY,
YALE UNIVERSITY, NEW HAVEN, CONN. I want to take part in
this study of memory and learning. I am between the ages of 20 and
50. I will be paid \$4.00 (plus 50c carfare) if I participate.

NAME (Please Print).....

ADDRESS

TELEPHONE NO. Best time to call you

The social psychology of attribution – An international perspective

People frequently talk of differences between the East and the West. Almost any psychological quirk in people from these two terrains can be attributed to one group having a ‘Western’ style of thinking or behaving and the other an ‘Eastern’ one. But is there any psychological evidence to support the cliché?

Interestingly, social psychology has provided some. Research on people’s perception of the causes of behaviour has found a striking result: people from the West, largely the

US, tend to explain others’ behaviour in terms of people’s characteristics, that is, they commit the fundamental attribution error. People from the East, on the other hand, such as East Asians, attribute people’s behaviour to situational factors (Lee *et al.*, 1996; Morris and Peng, 1994). In Morris and Peng’s study, for example, the researchers analysed American and Chinese newspaper reports of mass murder and compared how often each nation attributed the murderers’ actions

The social psychology of attribution – *Continued*

to personal or situational characteristics. The US journalists tended to focus on negative personality characteristics of the murderers; the Chinese journalists focused more on situational/contextual factors.

Research also shows that the West, at least those living in the North American part of it, tends to hold single individuals responsible for actions whereas East Asians hold groups or communities responsible (Chiu *et al.*, 2000; Menon *et al.*, 1999). Chui *et al.* asked people to determine who was responsible when a pharmacist dispensed the incorrect medicine. Americans believed it was the specific pharmacist; Chinese participants believed it was the pharmacy as a unit. Americans also believe there are fewer reasons for the causes of people's behaviour than do other Asian nations, such as Korea (Choi *et al.*, 2003).

In a recent study, European Americans and Asian Americans were asked to list their perceptions of consequences of various actions, including a shot in billiards and turning an area into a national park (Maddux and Yuki, 2006). When considering the consequences of taking a shot at bil-

liards, the Asian Americans thought that a single shot would have a much greater impact on subsequent shots than did the European Americans. Japanese participants also listed more indirect consequences of creating a national park.

When the groups had to consider the consequences of a social act such as firing someone or causing an accident, the Japanese thought that these events would affect more people than did the Americans. They also felt more responsible, felt worse and were more likely to apologise to those affected.

The authors make an interesting extrapolation from their findings. The crime rate in Japan may be lower because the Japanese perceive their acts as affecting more people. The Japanese are also the only people to suffer from the culture-dependent psychological disorder, *taijin kyofusho* – an extreme fear of hurting or offending others and of being harshly judged by others. 'For East Asians,' the authors suggest, 'a sense of interdependence with others may extend farther outward in a temporal and physical manner, leading to a heightened sense of responsibility' (p. 680).

Conformity

Compliance and obedience produce changes in people's behaviour, but in general such changes do not correspond to a change in people's attitudes or other internal cognitive structures. These deeper changes are more likely to be wrought by group influence where we conform to what we perceive to be group norms (Turner, 1991).

Norms

People, particularly in individualistic Western societies, often think that they are not very influenced by norms and conventions. Indeed, conforming is often viewed as undesirable, as an indication of a weak personality, a lack of individual autonomy, and so forth. In reality, almost everything we think and do is, to varying degrees, grounded in social norms and conventions. Language itself is a normative way of communicating and representing the world to ourselves and others. If people did not agree on how to construct sentences or on what sounds to use to refer to what objects, then communication would be impossible. What we eat, when we eat, what side of the road we drive on, how we behave in restaurants – these are all normative behaviours.

Norms (in statistics) can take the form of explicit rules that are enforced by legislation and sanctions (for example, societal norms to do with private property, pollution and aggression), or they can be the implicit, unobserved, taken-for-granted background to everyday life (Garfinkel, 1967).

Garfinkel believed that these latter, implicit, norms and social regularities are hidden because they are so commonplace and integral to everyday life. They account for much behaviour that is often labelled native, instinctive and innate. Garfinkel coined the term **ethno-methodology** to describe the way that ordinary people (hence 'ethno') make sense of and maintain the normative regularities of the social order. Garfinkel believed that because these ethno-methods are usually tacit they are most easily noticed or brought to attention when they are violated. To demonstrate this point, Garfinkel had students act at home for 15 minutes as if they were boarders – that is, be polite, speak formally, and only speak when spoken to. Their families reacted with astonishment, bewilderment, shock, embarrassment and anger, backed up with charges of selfishness, nastiness, rudeness and lack of consideration. An implicit norm for familial interaction was revealed, and its violation provoked a strong reaction. The existence of an implicit norm is often revealed only when it is violated.

One of the earliest and most influential studies of how group norms emerge and then influence us was conducted by Sherif (1936). Sherif was able to show empirically how norms can arise out of social interaction, and then how these norms exert influence on behaviour. Sherif's study was based on a perceptual illusion, originally discovered by astronomers, called the **autokinetic effect**: a small stationary pin-point of light, when projected in an otherwise completely darkened room, appears to move. The illusion is so strong that even if someone is aware of the effect, the apparent movement often persists.

Sherif first placed participants in the room individually and asked each of them how far the light was moving at different times. The answers were quite variable; one person might see the light move 6 cm on average, whereas another might see it move an average of 300 cm. Next, Sherif had groups of three people observe the light together and call out their judgements of movement one after the other. Finally, the participants would again observe the light individually. The most interesting result of the study was that when people made their judgements together they very rapidly converged on a narrow range of judgements that was pretty close to the average of their individual judgements, and their subsequent individual judgements also fell within this narrow range. The group had established what Sherif referred to as a collective frame of reference – a group norm. Even when tested by themselves on a subsequent day, the group members still conformed to this frame of reference.

MacNeil and Sherif (1976) were able to show that even an arbitrary norm can have the same effect. They had a group with only one true participant and three confederates – the confederates made very extreme judgements that produced an extreme norm. MacNeil and Sherif gradually replaced all the confederates with real participants whose individual autokinetic judgements were nowhere near as extreme as the group norm – and yet, they still conformed tightly to the norm.

Sherif's autokinetic findings are not too surprising if we consider that the participants found themselves in an uncertain situation. It makes sense to use others' opinions or judgements as a frame of reference when you are not sure what is going on. But just how strongly do group norms influence individual behaviour when the situation is unambiguous – when we are certain that we perceive things as they really are? The answer to this question was provided in a series of elegant studies conducted by Asch (1951, 1952, 1955).

Majority influence

Asch's studies were less to do with the emergence of norms and more to do with how a numerical majority can influence a single person. Asch asked several groups of seven to nine students to estimate the lengths of lines presented on a screen. A sample line was shown at the left, and the participants were to choose which of the three lines to the right matched it (Figure 16.3). The participants gave their answers orally. In fact, there was only one true subject in each group; all the other participants were confederates of the experimenter. The seating was arranged so that the true subject answered last. On 12 of the 18 trials the confederates made unanimously incorrect responses. When this happened, about 25 per cent of true subjects remained unaffected, but the rest conformed to the erroneous majority on at least one trial. Five per cent conformed to all the incorrect judgements. Overall conformity occurred 33 per

Some people, like this protesting Greek student, believe so passionately in a point of view that they are prepared to go to great lengths to disobey (this is a work of art; the blood is paint).

cent of the time when it could have occurred. Under control conditions, when the confederates responded accurately, fewer than 1 per cent of the true subjects' estimations were errors – the task was quite unambiguous.

Group pressure did not affect the participants' perceptions; it affected their behaviour. That is, the participants went along with the group decision even though the choice still looked wrong to them – and even though the other people were complete strangers. When they were questioned later, they said that they had started doubting their own eyesight or had thought that perhaps they had misunderstood the instructions. The participants who did not conform felt uncomfortable about disagreeing with the other members of the group. The Asch effect shows how strong the tendency to conform can be. Faced with a simple, unambiguous task while in a group of strangers who showed no signs of disapproval when the participant disagreed with them, the vast majority of participants nev-

Figure 16.3 An example of the stimuli used by Asch (1951).

ertheless ignored their own judgements and agreed with the obviously incorrect choice made by the other people.

Presumably, people conformed because they thought that the other members of the group might ridicule them, or at least secretly think badly of them, if they did not. If this is true then conformity should entirely disappear if participants could give their responses privately, without the other members of the group knowing what they had done. To investigate this, Deutsch and Gerard (1955) conducted an Asch-type study where participants gave their responses privately in cubicles. Conformity dropped but certainly did not disappear – it occurred at a rate of 23 per cent.

Subsequent conformity research sought to discover factors that would reduce conformity. Probably the most important influence on conformity was found to be the unanimity of the erroneous majority. Asch's original experiment employed a unanimous erroneous majority to obtain a conformity rate of 33 per cent. However, Asch also found that a correct supporter (i.e. a member of the majority who always gave the correct answer – and thus agreed with and supported the true participant) reduced conformity from 33 per cent to 5.5 per cent. Other experiments have confirmed that conformity is greatly reduced if the majority is not unanimous (Allen, 1975).

However, support itself may not be the crucial factor in reducing conformity. Any sort of lack of unanimity among the majority seems to be effective. For example, Asch found that a dissenter who was even more incorrect than the majority was equally effective. Allen and Levine (1971) conducted an experiment in which participants who were asked to make visual judgements were provided with a supporter who had normal vision, or a supporter who wore such thick glasses as to raise serious doubts about his ability to see anything at all, let alone accurately judge lines. In the absence of any support, participants conformed 97 per cent of the time. The 'competent' supporter reduced conformity to 36 per cent, but most surprising was that the 'incompetent' supporter reduced conformity as well, to 64 per cent.

The process of conformity

Why do people conform? Or rather, what is the process by which people conform? There are at least three reasons why people conform (Turner, 1991). The first is that people like to think their perceptions and attitudes are accurate and valid. So, if people are uncertain or find that others disagree with them, they may think they are wrong and feel a need to change their perceptions and attitudes in line with those of other people. This form of social influence is called **informational influence** (Deutsch and Gerard, 1955). It would have been present in the autokinetic studies, but not the Asch studies.

The second reason why people conform is that people like to be liked and approved of by others and therefore do not like to stand out as different, particularly when in

the physical presence of other people. This form of social influence is called **normative influence** (Deutsch and Gerard, 1955). It would have been present in both the autokinetic studies and the Asch studies, but not in the Deutsch and Gerard study.

The third reason why people conform is that they feel a sense of belonging with the group defined by the norm – this is a process of **referent informational influence** (Turner, 1991), which is associated with social identity processes (Turner *et al.*, 1987; Hogg and Abrams, 1988). Group norms map out the defining attributes of a group. Thus, when people identify with the group they use the norms of the group to define themselves as group members. The process is fairly automatic – the group's norms are cognitively represented as a prototype (a fuzzy set of features that define the in-group and distinguish it from out-groups). When people categorise themselves as group members, they assimilate self to the relevant prototype and thus their behaviour is transformed so that it conforms to the prototype/norms. In the Sherif and Asch situations, other people's behaviour becomes a self-defining norm that is internalised to regulate one's own behaviour as a group member. Abrams *et al.* (1990) found that conformity in both the Sherif and the Asch paradigms was reduced when the source of influence was categorised as an out-group rather than an in-group.

The Stanford Prison experiment

On a par with the ethical vortex that is Milgram's obedience experiments is Phillip Zimbardo's Stanford Prison experiment, another of social psychology's ground-breaking studies (Zimbardo, 1982). Zimbardo's involvement was motivated by several reported examples of guard brutality in US prisons. He sought to discover whether bad prison guards were inherently bad or were shaped by the situation in which they found themselves. In the original study, Zimbardo had the Palo Alto police arrest students, for various misdemeanours, assign them prisoner numbers and lock them up in a mocked-up real-life prison cell in a basement at Stanford University. Every attempt was made to ensure the authenticity of the prison environment (you can find our more details here: www.prisonexp.org). The students were randomly assigned to playing prisoners or guards. They knew the situation was not real but, as Zimbardo himself has noted, 'No one expected what happened'. The experiment was meant to run for 14 days; it was stopped after less than a week. The researchers expected the prisoners to sit around, behind bars, reading books and playing guitars. But the prisoners began to rebel. On the second morning, they began protesting vocally and physically. It was at this point that the atmosphere changed. The guards became increasingly brutal, as if they were determined to demonstrate who had the real power in this context (remember that both groups

were students). As the prisoners became increasingly humiliated, the guards' behaviour worsened. Faced with this authoritarian onslaught, the prisoners became increasingly compliant. This simply made the guards more sadistic. You can see how the guards' behaviour changed, and changed dramatically, in these quotes from one of the students who played a guard.

Diary entry, before the experiment

As I am a pacifist and non-aggressive individual, I cannot foresee a time when I might maltreat other living things.

Day 3 of the study

This was my first chance to exercise the kind of manipulative power that I really like.

Day 5 of the study

I harass Sarge, who continues to stubbornly over-respond to commands. I have singled him out for special abuse both because he begs for it and because I simply don't like him.

Now, imagine if these were real prisoners and real guards, and maltreatment of prisoners was either condoned or not seen. What do you think would be likely to happen? The BBC 're-created' the experiments in 2003, not entirely to Zimbardo's satisfaction (see his interview in Cohen, 2004). But a real-life illustration emerged a few years ago with the revelation of the treatment of prisoners at the Iraqi prison, Abu Ghraib.

Minority influence

Conformity research tends to focus on the way that a numerical majority influences the attitudes and behaviour

A still from the original Stanford Prison Experience.

Source: Philip G. Zimbardo, Phd.

of a minority. A valid question arises then as to whether a minority can influence the majority – what facilitates **minority influence**. After all, everyday experience tells us that people do not always conform to majorities. Sometimes a minority can be persuasive. Indeed social change – from new trends and fashions to social movements and political revolutions – would not be possible if active minorities could not have influence over the masses (Moscovici, 1976). Asch (1952) looked at this in one of his studies. He had 16 naive participants facing one confederate who gave incorrect answers. The participants found the confederate's behaviour ludicrous, and openly ridiculed him and laughed at him. Even the experimenter found the situation so bizarre that he could not contain his mirth and ended up laughing at the poor confederate. Clearly, in this context a minority was pretty ineffectual.

But in the Asch paradigm, who really is the majority and who the minority? Moscovici and Faucheux (1972) make the point that in a standard Asch experiment the hapless lone participant is faced by a small group of people who actually behave extremely bizarrely – in the real world, no one would make the judgements that the confederates make in the experiment. In reality, the majority is a minority, and the studies actually show how a minority viewpoint can be persuasive. This clever insight raises the question of how minorities are influential.

Because minorities have to combat a pervasive consensus that often has the support of a powerful elite, they need to adopt particular behavioural styles in order to be effective (Mugny, 1982). Minorities need to challenge the dominant consensus by providing an alternative viewpoint that is strongly consensual among minority members and has marked consistency across time. A consistent minority (1) disrupts the majority norm and thus produces uncertainty and doubt; (2) draws attention to itself as an entity; (3) conveys the existence of an alternative coherent point of view; (4) demonstrates certainty in, and unshakeable commitment to, its point of view; and (5) shows that the only solution to the conflict that has arisen is espousal of the minority viewpoint.

Minorities are also more effective if they are seen to have made significant personal or material sacrifices for their cause, to be acting out of principle rather than from ulterior motives, and to have some flexibility around their core message. There is also some evidence that minorities may be more effective if they are viewed by the majority as being a relevant in-group. This is usually difficult to bring about because, by definition, the majority protects itself by emphasising the out-group status of the minority. It can work, however, if the minority is able to establish its legitimate in-group credentials before it espouses a minority viewpoint (Crano and Alvaro, 1998) – in effect behaving like a wolf in sheep's clothing.

A consistent, but not rigid or inflexible, minority has what is called 'latent influence' that produces a conver-

sion effect. Majority members cogitate about the minority position, but still conform to the majority position, until at a later point they suddenly appear to be converted to the minority's position and switch their allegiance and change their behaviour. This distinction, between the majority having relatively surface influence and the minority having a deeper latent influence leading to conversion, resembles to some extent the distinction made by social cognition and attitude researchers between peripheral and central route processing (Petty and Cacioppo, 1986) that we discussed in Chapter 15.

Moscovici and Personnaz (1980) conducted an intriguing experiment to test the conversion and latent influence ideas. Participants called out the colour of a series of blue slides, which varied only in intensity, after they had heard a confederate who was described as either a member of the majority (82 per cent of people) or a member of a minority (18 per cent of people) describe the slide as green. Moscovici and Personnaz also had participants describe the chromatic after-image they saw when the slide had been removed – participants did not realise that the after-image of blue is yellow, and of green is purple. Participants exposed to majority influence (the confederate who was a member of the majority) showed a tendency to call the blue slides green, but their after-image was unaffected – it remained yellow, indicating that although they may have complied with the majority they certainly had not changed what they actually saw. Participants exposed to minority influence, however, continued to call the slides blue, but remarkably their after-image had shifted towards purple, and the effect had become a little stronger when they were tested individually at a later stage. Although they had not changed their surface behaviour, there was a deeper latent change in their perception as a consequence of minority influence.

People in groups

Human beings are unmistakably social creatures: a great deal of our lives is spent in the company of others. By itself, this is not an especially profound observation, but it leads to some interesting implications, particularly for social psychologists. We do not merely occupy physical space with other people. We affiliate psychologically and form groups with each other. A **group** is a collection of individuals who have a shared definition of who they are and what they should think, feel and do – people in the same group generally have common interests and goals. Groups are very diverse in size, form and longevity – they include ethnic groups, nations, organisations, departments, teams, clubs and even

families. However, by the definition above, not all aggregations of people are groups in a psychological sense – a crowd of people shopping or some people standing at a bus stop are unlikely to be a group.

People aggregate, affiliate, or form groups for all sorts of reasons. One set of reasons is very instrumental. Being in a group provides protection and allows people to do things that they cannot do alone. For example, it is probably better to walk down dangerous back streets in a crowd rather than alone, and a community can put up a barn more quickly than a lone individual. There are, however, some more basic psychological reasons for joining groups. A group of people with similar attitudes and behaviours to your own provides a wonderfully comforting sense of self-validation. Groups can reduce anxiety (Schachter, 1959), provide confirmation of the validity of one's perceptions (Festinger, 1954), and reduce uncertainty about one's self and one's place in the world (Hogg, 2000).

Baumeister and Leary (1995) believe that the need to belong is one of the most fundamental of all human motives. They may well be right. Williams (2001) has shown in a series of vivid experiments that simply being ignored or excluded from social interaction can have quite profound effects. Indeed, many societies use ostracism or shunning as a potent punishment. In Williams's studies, a naive participant ostensibly waiting with two other people (actually experimental confederates) for an experiment to begin is excluded by the confederates from a spontaneous game of passing a ball that they have found in the room. The participant showed signs of genuine distress – fidgeting, disengagement, displacement activities and so forth.

In 2007, the UK saw its first 'run' on a bank. Within hours of rumours of the extent of the bank's debt, Northern Rock's customers began queuing to withdraw their money. Some claimed that such images fuelled greater panic and exacerbated the bank's problems.

The treatment of marginal group members and deviants

Many of the groups we are in, our in-groups, provide the psychological environment for the self and are therefore fundamental, or even primary, to our sense of who we are (Allport, 1954; Yzerbyt *et al.*, 2000). They matter psychologically so much to us that we can be inordinately concerned and upset if we feel marginalised or rejected by the group, and we can go to great lengths to protect the integrity of the group by treating deviant members harshly. For example, people are much more willing to derogate a deviant member of the in-group than a similarly deviant member of an out-group – a phenomenon known as the ‘black sheep effect’ (Marques *et al.*, 1988). Moreover, this effect is particularly strong when people identify strongly with their group (Branscombe *et al.*, 1993).

Marques *et al.* (2001) proposed that this effect reflects the operation of ‘subjective group dynamics’, whereby people try, psychologically, to sustain the sense of validity of their in-group’s norms. In one experiment, Abrams *et al.* (2000) asked psychology students to evaluate normative or deviant group members who were either psychology students (in-group) or customs officers (out-group) who made statements about the UK’s policy on asylum seekers. The norm for psychology students was to leave the existing policy unchanged, whereas the norm for customs officers was to advocate tighter restrictions. Two types of deviant were presented in each group. The anti-norm psychologist and anti-norm customs officer actually both expressed an identical (slightly restrictive) attitude which tended towards the views of the opposing group. Evaluations of these anti-norm members showed the classic black sheep effect. The out-group deviant was preferred over the in-group deviant. However, when the deviants expressed extreme positions that exaggerated the norm of their own group (i.e. a very restrictive customs officer and a very lenient psychologist) they were evaluated much more negatively, and positively, respectively. This pattern of results is shown in Figure 16.4.

The opposing reactions to the anti-norm and pro-norm deviants shows that people may be more concerned to ensure that they maintain the difference between in-group and out-group norms than to ensure that all members of their group conform. Equally important is that people do not necessarily reject out-group members more than in-group members. They may favour out-group members who lend apparent support to the validity of in-group norms. Other research (Yzerbyt *et al.*, 1999; Hutchison and Abrams, 2003) shows that group members who identify more highly are likely to reject an anti-norm deviant from the stereotypical image of the group. All of this suggests that people are strongly motivated to sustain the idea that their in-group is a coherent entity.

Figure 16.4 Favourability towards anti-norm and pro-norm deviants relative to normative members of the in-group and out-group.

Which is more important – the individual or the group?

There is evidence that people may store information about the individual and collective self in separate cognitive ‘baskets’ (Trafimow *et al.*, 1991), that is, when people think of their personal qualities they are unlikely also to think about their group memberships, and vice versa. This means it is possible to test whether the individual or collective self has primacy in terms of people’s motivation. Despite evidence that people will defend their collective in-group norms, some researchers argue that the individual self-concept provides the most powerful motivational force for behaviour. Gaertner *et al.* (2002) proposed that the individual self has primacy both because the individual self is the unit of natural selection and because attributes of the self seem to remain stable over time, and changes occur only slowly over the lifespan, presumably because people defend their individual self against threatening feedback, and they selectively accept or pursue information that confirms their self-image as an individual.

A further possibility is that either the individual or collective self may have primacy, depending on the context. For example, Markus and Wurf (1987) assume that the self is defined by a ‘working self-concept’, which draws on the relevant attributes in relation to the current situation. More radically, Turner *et al.*’s (1987) self-categorisation theory holds that the context and situation have a very strong effect on how the self is defined. In particular, self is defined in terms of a social category to which one belongs relative to a category to which one does not belong within a situation. For example, at a football match people define themselves primarily in terms of which team they support (Cialdini *et al.*, 1976), whereas

when taking part in an election they define themselves in terms of which party they support.

Gaertner and Insko (2000) showed that participants would allocate more money to the in-group than an out-group only if they believed their personal earnings could be influenced by other in-group members. In another set of studies Gaertner *et al.* (1999) showed that people whose individual self was threatened considered the threat to be more severe, felt more negative and angry and derogated the source of the threat more than did those who experienced a threat to the collective self. For example, in their experiment participants anticipated playing a game with an individual partner (dyad condition) or joined two others to play against another three-person group. Participants rated their initial feelings of anger, and then after completing an initial comprehension task, participants received positive or insulting feedback from the opposing person/team that they 'did well/seems to know what is going on', or 'did not do well, must be a little slow'. Participants then rated their feelings of anger again. Figure 16.5 shows that participants felt angrier when their individual self was insulted than when their collective self was insulted.

To compare evidence for these different views, Gaertner *et al.* (2002) conducted a meta-analysis (statistical summary across a series of different studies) to examine how people respond to threats to the individual and collective self, and how they respond to opportunities to enhance the self. In these experiments threats and enhancements were manipulated either by directing negative or positive feedback or linking positive or negative information to the individual or collective self. Across 37 different items of research evidence, Gaertner *et al.* found that people responded more strongly to both threats and enhancements of the individual self than to comparable threats to the collective self or the contextual self.

Social facilitation

You saw in the above discussion of social influence that the behaviour of other people has a powerful effect on our behaviour. Studies have shown that the mere presence of other people can affect a person's behaviour. Triplett (1897) published the first experimental study of **social facilitation** – the enhancement of a person's performance by the presence of other people. He had people perform simple tasks, such as turning the crank of a fishing reel. He found that his participants turned the crank faster and for longer if other people were present. Although many other studies found the same effect, some investigators reported just the opposite effect. If the task was difficult and complex, the presence of an audience impaired the participants' performance. We're all probably familiar with the sound of audience laughter accompanying a sitcom on television. More often than not, this laughter is real not canned and we know that – despite what people might say – people laugh more and find the comedy funnier if they watch or listen to the material with audience laughter present (Martin and Gray, 1996).

Zajonc (1965) has suggested an explanation for social facilitation. He claims that the presence of people who are watching a performer (or of people whom the performer perceives as watching) raises that person's arousal level and produces 'drive'. The increase in arousal has the effect of increasing the probability of performing dominant responses: responses that are best learned and most likely to occur in a particular situation. When the task is simple, the dominant response is generally the correct one (by definition an easy task is one which you get right all the time), so an audience improves performance. When the task is difficult the dominant response is generally not the correct one (by definition a difficult task is one which you get wrong all the time), so an audience impairs performance.

Subsequent experiments have supported Zajonc's explanation. For example, Martens (1969) tested the prediction that the presence of a group increases a person's level of arousal or drive. While participants performed a complex motor task alone or in the presence of ten people, the experimenter determined physiological arousal by measuring the amount of sweat present on the participants' palms. The presence of an audience produced a clear-cut effect: the participants who performed in front of other people had sweatier palms.

Markus (1978) tested the effects of an audience on task performance. She had student participants get undressed and then dress up in either their own clothes (an easy task where the dominant response is to get it right) or in unfamiliar clothing involving a special lab coat and special shoes (a difficult task where the dominant response is to make mistakes). Some participants did this alone whereas others did this while being watched.

Relative to those who did the task alone, those who were being watched were faster on the easy task and slower on the difficult task – clear support for social facilitation.

Zajonc (1965) believed that the mere presence of other people produces arousal and drive. Baron (1986) proposed an alternative view. He argued that people are distracting and that trying to concentrate on a task while being distracted causes arousal and drive. There is some support for this idea. Any form of distraction, for example loud noise, produces social facilitation effects – improved performance of easy tasks and degraded performance of difficult tasks. Baron has also suggested that perhaps the notion of arousal or drive is unnecessary. People have a limited capacity for attention. In order to perform a task successfully you need to attend to a range of cues and procedures. The presence of other people is an additional tax on attention, which people combat by narrowing their attention onto the task cues and procedures. Difficult tasks require more attention than easy tasks, and thus narrowing of attention causes you to fail to attend to some important cues – task performance deteriorates. Easy tasks require less attention, so narrowing of attention actually causes you to attend more to the task than you ordinarily would – task performance improves.

A final perspective on how being in the presence of other people affects task performance builds on the idea that people make you self-aware (Carver and Scheier, 1981; Higgins, 1987; see also the section on ‘Self awareness’ in Chapter 15). Being self-aware motivates people to try to bring their actual self (their actual task performance) into line with their ideal self (how they would like or feel they ought to perform the task). Where the discrepancy is small, the additional motivation improves performance, but where the discrepancy is large and insurmountable, people tend to give up trying and task performance deteriorates.

Social loafing

Working together on a task, rather than merely being watched by others or simply being in the presence of others, can have additional effects: the presence of a group sometimes results in a decrease in effort, or **social loafing**. Thus, a group is often less than the sum of its individual members. Many years ago, Ringelmann (1913) measured the effort that people made when pulling a rope in a mock tug-of-war contest against a device that measured the exerted force. Presumably, the force exerted by eight people pulling together in a simple task would be at least the sum of their individual efforts or even somewhat greater than the sum because of social facilitation. However, Ringelmann found that the total force exerted was only about half what would be predicted by the simple combination of individual efforts. The participants exerted less force when they worked in a group.

The reduced performance could be due to at least two reasons. The people pulling on the rope could have distracted each other or interfered in other ways, or the people pulling the rope could simply have tried less hard – this is a distinction between **coordination losses** and **motivation losses** (Steiner, 1972). To tease these two possibilities apart, Ingham *et al.* (1974) replicated Ringelmann’s study, but with two experimental conditions: one in which real groups of varying size pulled on a rope, and the other involving pseudo-groups with only one true participant and a number of confederates. The confederates were instructed only to pretend to pull on the rope while making realistic grunts to indicate exertion. The true participant was in the first position and so did not know that the confederates, who were behind, were not actually pulling. Participants in pseudo-groups pulled less strongly than participants pulling on their own. Because there was no coordination, there can be no loss due to poor coordination; the decrement can be attributed only to a loss of motivation. In real groups, there was an additional decrement in individual performance that can be attributed to coordination loss.

Scores of more recent studies have confirmed these results and have extended them to other behaviours, such as clapping, shouting, cheering and brainstorming (Williams *et al.*, 2003). Formally defined, loafing is ‘a reduction in individual effort when working on a collective task (in which one’s outputs are pooled with those of other group members) compared to when working either alone or coactively’ (Williams *et al.*, 1993, p. 131).

Several variables have been found to influence the tendency to loaf. One of the most important of them is identifiability. Williams *et al.* (1981) asked participants to shout as loud as they could individually or in groups. Participants who were told that the equipment could measure only the total group effort shouted less loudly than those who were told that the equipment could measure individual efforts. The latter did not loaf – they shouted just as loudly in groups as they did alone. These results suggest that a person’s efforts in a group activity are affected by whether other people can observe their individual efforts.

Another variable that determines whether social facilitation or social loafing occurs is individual responsibility. If a person’s efforts are duplicated by those of another person (and if their individual efforts are not identifiable), the person is likely to exert sub-maximum effort. Harkins and Petty (1982) had participants work in groups of four on a task that required them to report whenever a dot appeared in a particular quadrant of a video screen. In one condition, each participant watched an individual quadrant and was solely responsible for detecting dots that appeared there. In the other condition, all four participants watched the same quadrant; thus, the responsibility for detecting dots was shared. Participants did not loaf when they were responsible for their own quadrants.

In a review of the social loafing literature, Karau and Williams (1993) noted that two variables – sex and culture – appear to moderate people's tendency to loaf. Although all people in different cultures are susceptible to social loafing, the effect is smaller for women than for men and for people living in Eastern cultures than for those living in Western cultures. Karau and Williams offer a reasonable explanation for this finding: both women and people living in Eastern cultures tend to be more group- or collectively-oriented in their thinking and behaviour than are men and people living in Western cultures. That is, women and people living in Eastern cultures tend to place greater importance on participating in group activities, which partially buffers them from social loafing effects.

Although research tends to show that loafing is the rule in groups, there are some studies which show that groups sometimes motivate people to work harder than they do alone. For example, Zaccaro (1984) had male and female participants construct 'moon tents' out of sheets of paper in two- or four-person co-active groups. The usual loafing effect emerged. However, other participants who believed they were competing against an out-group, and for whom the attractiveness and social relevance of the task was accentuated, behaved quite differently. The loafing effect was reversed: individuals performed at a higher rate in the larger group. This effect may represent **social compensation**, in which people work harder collectively than co-actively in order to compensate for anticipated loafing by others on important tasks or in important groups.

Why do people loaf? There are many reasons. For example, people are often anxious about having their performance evaluated, and so when their individual performance cannot be identified, they can avoid the possibility of evaluation by simply doing less. When their performance can be evaluated they are motivated to work harder in order to avoid an unfavourable evaluation. Another reason why people loaf may be because they feel that in a group they are dispensable – their effort is not really necessary to the group's overall performance because so many others are making a contribution.

Karau and Williams (1993; Williams *et al.*, 2003) have proposed an integrative model they call the **collective effort model**. It states that people will work hard on a collective task only to the degree that they expect their efforts to be instrumental in leading to outcomes that they value personally. Thus loafing will occur if people view the outcomes of the group performance or collective task as trivial or inconsistent with their own desires. Valued outcomes can be objective, say pay and rewards, or subjective such as personal satisfaction and feelings of growth, belonging or enjoyment. Even if people do value the outcomes, they will still loaf if they do not believe that their own efforts can help achieve those outcomes.

The collective effort model identifies a number of factors that moderate loafing. Because people work harder

on collective tasks when they expect their effort to be instrumental in obtaining valued outcomes, loafing will be reduced when people: (1) believe their collective inputs can be evaluated; (2) work in smaller rather than larger groups; (3) view their contributions to the collective task as unique or important rather than redundant or trivial; (4) work on tasks that are meaningful, high in personal involvement, important to respected others, or intrinsically interesting; (5) work in cohesive groups or in situations that activate a salient group identity; (6) expect their co-workers to perform poorly; and (7) have a dispositional tendency to value collective outcomes.

Suppose that you have been asked by your psychology lecturer to organise a small group of class members to prepare a presentation. As the leader of the group, what steps might you take to prevent the individual members of your group from becoming social loafers?

Group decision-making

One of the most significant tasks that people perform in groups is decision-making. Group decision-making usually involves discussion that transforms a diversity of opinions into a single group decision.

Because it can be useful to predict what decision a group will come to from an initial distribution of diverse views (for example, juries, parliament, summits and other committees), research has identified a small number of explicit or implicit decision-making rules that groups can adopt, called **social decision schemes** (Davis, 1973). These are:

- 1 unanimity (discussion pressurises deviants to conform);
- 2 majority wins (discussion confirms the majority position, which is then adopted as the group position);
- 3 truth wins (discussion reveals the position that is demonstrably correct);
- 4 two-thirds majority (unless there is a two-thirds majority, the group is unable to reach a decision); and
- 5 first shift (the group ultimately adopts a decision consistent with the direction of the first shift in opinion shown by any member of the group).

If you know the decision rule that is being adopted, and you know the initial distribution of positions, then you can predict the group decision with a respectable degree of accuracy (Stasser and Dietz-Uhler, 2001).

Group decision-making involves social interaction, and so is subject to a range of effects that do not impact on individual decision-making, e.g. social facilitation and social loafing may affect the decision-making process. Here we will discuss four group decision-making phenomena that have been the subject of research: brainstorming, group remembering, group polarisation and groupthink.

Cutting edge – Creativity and brainstorming

One model of group interaction and creative thinking suggests that creativity is improved if you add new individuals, with differing views, to the group. Nemeth and Ormiston (2007) tested this by having three people (psychology undergraduates) brainstorm on a given issue then move on to a completely new group or remain in the original brainstorming group. The participants discussed issues such as 'How to decrease traffic congestion in the San Francisco Bay area' and

'How to increase tourism in the San Francisco Bay area'. The ideas generated were coded and judged for creativity.

When people remained in the original brainstorming group, participants felt more comfortable and perceived the group to be creative, but were actually no more creative. When membership changed, participants felt less comfortable but the number of creative ideas generated increased.

Brainstorming

Brainstorming is a group decision-making process that involves generating as many ideas as possible as quickly as possible (Osborn, 1957). Group members are told not to be inhibited or concerned about quality (simply to say whatever comes to mind), to be non-critical, and to build on others' ideas when possible. This process is intended to facilitate creative thinking and thus make the group more creative. Popular opinion is so convinced that brainstorming works that the activity is widely used in business organisations and advertising agencies. However, scientific research on brainstorming paints a rather different picture. According to a review by Stroebe and Diehl (1994), individual creativity and productivity are actually reduced, primarily due to interference effects from contending with others generating ideas at the same time as one is trying to generate one's own ideas. This is what Steiner (1972) would classify as a coordination loss. Brainstorming is effective, however, if it is engaged in electronically rather than face-to-face, and if the brainstorming group is very heterogeneous in its membership.

Group remembering

For groups to make decisions they need to marshal a substantial amount of material that is stored in memory. Do groups facilitate or impede memory? Research shows that groups are better than individuals at recalling simple information – such as names of performers or capital cities (Clark and Stephenson, 1995). This is because the group can pool unshared information and can recognise what is true and what is false. However, in more complex memory tasks, like recalling a police interrogation, the group's memory tends to be a creative reconstruction rather than regurgitation of facts. Group remembering is often a constructive process, characterised by negotiation of an agreed joint account of some part of experience. Some individuals' memories will contribute to the developing consensus while others' will not. In this way the group shapes a version of the truth that gains its subjective veracity from the degree of consensus. The group in

effect constructs a version of the truth that guides individuals about what to store as a true memory and what to discard as an incorrect memory.

Another way to look at group remembering is to focus not on what a group recalls, but on how a group stores information. Groups tend to have **transactive memory** structures (Moreland *et al.*, 1996). Within the group, different people specialise in remembering different things, but through interaction (transactions) all members of the group remember who is the memory specialist in different domains. Transactive memory has clear advantages in dealing with remembering large amounts of information. However, there are pitfalls. In the context of organisations, if someone leaves then their memory domain disappears and it can take a while for someone else to occupy that domain. The other side of the coin is that new members of organisations may take some time to learn the transactive memory structure of the organisation. In both cases, group processes are disrupted. Disruption can be minimised by making sure that people occupying important memory domains have 'understudies', and that new members are formally taught the transactive memory structure of the organisation.

Group polarisation

We often think of committees and other small decision-making groups as being cautious and conservative in making decisions. Indeed this is often the case – such groups arrive at group decisions that smooth out and average individual variability, which is precisely what one would expect from Sherif's (1936) research on group norms, described above. So, the social psychology community was most interested in Stoner's research (1961) – Stoner found that a group would actually make a more risky decision than the average of the positions held by the group members if the members themselves already leaned towards such a decision. Group discussion produced a risky shift.

Subsequent research has shown this phenomenon to be part of a more general tendency for a group decision to be more extreme than the mean of its members' positions, in the direction favoured by the mean – a phenomenon called

group polarisation (Moscovici and Zavalloni, 1969). If the group leans towards taking a risk, group discussion will produce a more risky decision, if it leans towards caution then the group decision will be more cautious; if it leans towards joining the single European currency the decision will strongly favour joining; if it leans against joining it will be even more opposed; and so forth.

One important consequence of group polarisation is attitude change. For example, suppose that you join a local environmental group because you have a desire to protect the environment. After attending several meetings and discussing environmental issues with other group members, you may find that your pro-environment attitude has become even stronger: you are more of an environmentalist than you thought you were. The fact that group discussion can effect attitude change so powerfully has been documented in many psychology experiments. For example, Myers and Bishop (1970) found that the initial level of racial prejudice voiced by groups was altered through group discussion. Discussion caused the group with an initially low level of prejudice to become even less prejudiced and discussion caused the group with an initially high level of prejudice to become even more prejudiced.

What causes group discussion to lead to polarisation? Although several explanations have been offered, three seem the most plausible: those concerning informational and normative influence (Isenberg, 1986), and social identity processes (Turner *et al.*, 1989). Informational influence involves learning new information germane to the decision to be made. When you are in a group that is already slanted towards one decision, group discussion will bring to light new information that supports your position but that you have not heard before. This supportive novel information will strengthen commitment to your position, and across the members of the group this will encourage the group to endorse a more extreme decision.

Normative influence involves comparison of one's individual views with that of the group. Just as we discussed in the earlier section on conformity, people strive for social approval and do not like to stand out from the crowd. Discussion reveals what appears to be the socially desirable position, and thus members of the group strive to be seen by the other members of the group to be adhering to the 'popular' position. In this way the group becomes more extreme and is able to endorse a more extreme decision.

Social identity processes involve people in the group constructing a group norm to define their membership in the decision-making group and then conforming to that norm. If the group's mean initial position is relatively extreme, this implies that people who are not in the group (or who are in a specific out-group) are less extreme. In order to distinguish the group from 'other people', the in-group norm is perceptually polarised away from 'most other people'. The process of self-categorisa-

tion and depersonalisation associated with group identification (Turner *et al.*, 1987) causes people to conform to the polarised norm and thus endorse a polarised group decision. Research has supported this analysis by showing that group polarisation occurs only if people perceive the extreme mean to be a group norm rather than merely an aggregate of positions, and if they identify with the group defined by the norm (Mackie, 1986; Turner *et al.*, 1989; Abrams *et al.*, 1990).

Groupthink

Irving Janis has studied a related phenomenon that sometimes occurs in group decision-making – **groupthink**, the tendency to avoid dissent in the attempt to achieve group consensus (Janis, 1972, 1982). He developed the notion of groupthink after studying the poor decision-making that led President John F. Kennedy to order the ill-fated attempt to overthrow the Castro regime in Cuba in 1961. The decision to embark on the Bay of Pigs invasion was made by Kennedy and a small group of advisers. After studying the conditions that led to this decision and other important group decisions that altered the course of twentieth-century history (such as the 1941 Japanese attack on Pearl Harbor), Janis proposed his theory of groupthink.

The theory specifies the conditions necessary for groupthink as well as its symptoms and consequences (see Figure 16.6). The conditions that foster groupthink include a stressful situation in which the stakes are very high, a cohesive group of people who already tend to think alike and who are isolated from others who could offer criticism of the decision, and a strong group leader who makes their position well known to the group. In the Bay of Pigs example, the overthrow of one of America's arch-enemies was at stake, Kennedy's group of advisers were like-minded regarding the invasion and met in secret, and Kennedy was a forceful and charismatic leader who made his intentions to invade Cuba known to the group.

Janis also notes five symptoms of groupthink, all of which were present during the decision to invade Cuba: (1) group members share the illusion that their decision is sound, moral and right – in a word, invulnerable; (2) dissent from the leader's views are discouraged, further supporting the illusion that the group's decision is the right one; (3) instead of assessing the strengths and weaknesses of the decision, group members rationalise their decision, looking only for reasons that support it; (4) group members are closed-minded – they are not willing to listen to alternative suggestions and ideas; and (5) self-appointed 'mindguards' exist within the group who actively discourage dissent from the group norm.

Combined, these symptoms lead to flawed decision-making. They contribute to the tendency to conduct only incomplete or no research on the issue about which a decision is being made, to fail to examine alternative

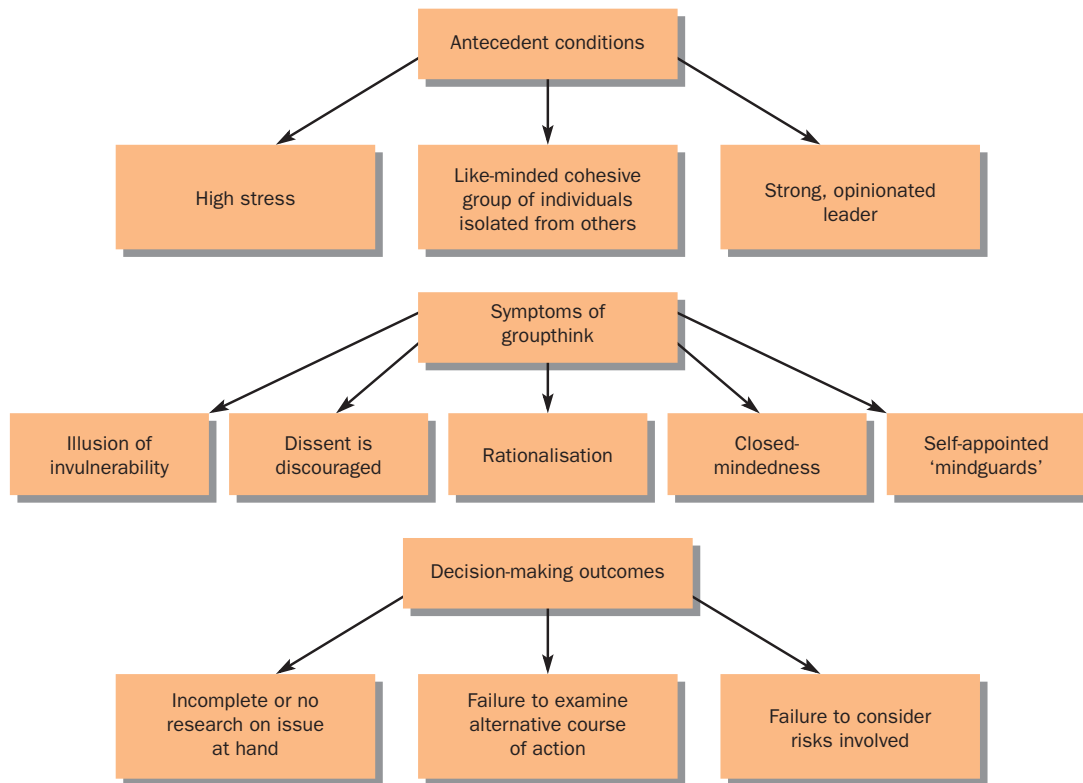

Figure 16.6 A summary of Janis's conception of groupthink.

courses of action specified by the decision, and finally, to fail to consider potential risks inherent in the decision.

Janis argues that groupthink may be avoided by taking several precautions: (1) criticism by group members should be encouraged; (2) relevant input should be sought from appropriate people who are not members of the group; (3) the group should be broken down into sub-groups in which different ideas and opinions are generated and developed; and (4) the group leader should not overstate their position

on the matter and should be on guard for rationalisation, closed-mindedness and illusions of invulnerability. An unlikely last word on this topic goes to former US President Ronald Reagan. He perceptively understood the dangers of groupthink: 'You risk becoming isolated. People tell you about what you want to hear and are reluctant to tell you about somebody who might not be pulling his weight or doing something hurtful to your administration. Not many people close to you are willing to say: "You're wrong".'

Psychology in action – The social psychology of drunkenness

How does alcohol affect your behaviour? Is it any different when you are alone or in a group? Are groups more risky or dangerous when they are drinking? Research into the effects of alcohol shows that individuals take more risks when they have been drinking. They are likely to be sexually irresponsible, aggressive, emotional, and to drive dangerously. Why?

According to Steele and Joseph's (1990) 'alcohol myopia' model, alcohol makes social behaviour more extreme because it blocks response conflicts by reducing cognitive constraints on affective preferences. Fromme *et al.* (1997) argued that drinkers maintain relatively automatic expectation of positive outcomes but they do not engage in systematic processing that is needed to evaluate potential negative outcomes. As a

result, people become riskier in their choices. Research on groups suggests that people also change the way they view risks and social relationships when they make decisions in groups (Janis, 1972).

Curiously, almost all of the research into these effects of alcohol examines only the behaviour of individuals. This is surprising given that such a large proportion of alcohol consumption happens in social settings, often in groups of three or more people.

Abrams *et al.* (2006) investigated whether moderate alcohol intake affected students' attraction to risk. Half of the students consumed enough alcohol to bring them to the legal limit for driving in the UK and USA (roughly 2 pints of beer or 4 glasses

Psychology in action – Continued

of wine). The other students consumed a placebo that tasted like alcohol but contained almost none. In one condition students were asked to complete tasks alone. In another condition students completed the same tasks together in groups of four. Members were asked to rate how attractive a series of 16 bets was to them and were told that they would be expected to spend some of their participation payment on these bets.

If *group polarisation* occurred, the group consensus should be more extreme than the average initial tendency of their individual members (Moscovici and Zavalloni, 1969). Given that alcohol myopia should make individuals risky, group polarisation should make them riskier still, so that the effect of alcohol is larger for groups than individuals. The group might also exhibit *deindividuation*, where group members become less self-conscious and less inhibited than individuals (Diener, 1980). Being in a group and drinking could add together to increase riskiness. A third possibility, *group monitoring*, argues that by sharing information, groups are often able to solve problems more reliably than their individual members (Laughlin and Ellis, 1986). The group monitoring hypothesis states that even when moderately intoxicated, group members will be able to attend to one another suffi-

ciently to be reminded that perspectives other than their own should be considered during decision-making. This mutual monitoring within the group may compensate for the effects of alcohol on individuals' riskiness. Alcohol would make individuals but not groups riskier if group monitoring occurs.

Abrams and colleagues found the results supported the group monitoring hypothesis. Individuals found the bets significantly more attractive if they had consumed alcohol than if they were sober. However, when students were in groups, alcohol made no difference to the attractiveness of the bets. Adding further support to the group monitoring explanation is that whereas individuals completed the tasks more quickly after drinking alcohol (suggesting they were paying less attention), groups were significantly slower if they had been drinking alcohol. This fits with the idea that the groups were devoting time to monitoring and discussing their decisions.

Most people's drinking is likely to be moderate and relaxed social drinking, perhaps in the context of an informal meeting, or a drink after work. Under these circumstances it seems that groups might be able to compensate for the negative effects of alcohol on individuals' attentional capacities and loss of inhibition.

Leadership

Our discussion of groupthink has identified the important role of leaders in group decision-making. Indeed, it is very difficult to envisage groups without leaders. Almost all groups are structured into one or more people who have greater influence and take the lead, and others who are more influenced and act as followers. Leadership is endemic to group processes.

One approach to leadership focuses on the way that particular leadership styles are suited to different leadership situations – these are called **contingency theories** because they argue that the effectiveness of a particular style is contingent on situational factors. The best known of these is Fiedler's (1965) contingency theory. Fiedler believed that people differ in their leadership styles – some people are task-oriented and others relationship-oriented. Task-oriented leaders are authoritarian, value group success, and derive self-esteem from task accomplishment rather than being liked by the group; relationship-oriented leaders are relaxed, friendly, non-directive and sociable, and gain self-esteem from happy and harmonious group relations. Fiedler also believed that leadership situations could be classified in terms of what he called situational control. At one extreme were situations in which leaders had legitimate authority, good leader–member relations

and the task was well structured; at the other extreme, legitimacy was low, leader–member relations poor and the task poorly structured. Fiedler predicted that relationship-oriented leaders were more effective than task-oriented leaders except if situational control was either very high or very low, when task-oriented leaders would be more effective. There is general support for this analysis, except that critics have suggested that it is too static a view of leadership, and that it underplays the fact that leadership is very much a group process that involves the relationship between leaders and followers.

Leader–follower relations are a more central focus of **transactional theories of leadership**. For example, Hollander (1958) argues that for leaders to be effective they need to develop a relationship with the rest of the group that allows them to be innovative and to exert influence over the group. Hollander suggests that leaders need to accumulate what he calls idiosyncrasy credits. This can be done by (1) initially conforming closely to established group norms, (2) ensuring that the group feels it has democratically elected you as the leader, (3) making sure that you are seen to have the competence to fulfil the group's objectives, and (4) being seen to identify with the group, its ideals and its aspirations.

Another transactional model of leadership is **leader–member exchange theory** (Graen and Uhl-Bien, 1995). To

be effective, leaders need to establish very different individualised exchange relationships with different members of the group. However, in doing this, leaders need to be careful to treat all members with respect as valued group members, and not to create destructive internal divisions by showing too much preference for some members over others.

A development of transactional models of leadership focuses on **transformational leadership** (Bass, 1998). Transformational leaders' transactions with followers are characterised by charisma, inspirational motivation, intellectual stimulation and individualised consideration, which motivate followers to work for group goals that transcend immediate self-interest. Transformational leaders are those who respond positively to change and who actively induce change. Great leaders often do seem to behave in this way but critics worry that too much emphasis is now being placed on charisma as a personality attribute.

A different approach to the explanation of leadership has been proposed by social identity theorists (Hogg, 2001; Hogg and van Knippenberg, 2003). In groups, people tend to rest their evaluation and endorsement of leaders on the extent to which leaders match schemas they have of good leadership. However, where people identify

strongly with a group that is important to self-definition, people's evaluations of their leaders are increasingly influenced by how prototypical of the group the leader is perceived to be.

There are many implications of this idea. For example, in very cohesive and salient groups with which people identify strongly, poor leaders (those who do not match effective leadership schemas) may prevail simply because they are highly prototypical of the group. Leaders are also presumably aware that they can increase their leadership effectiveness of such groups by being seen to be prototypical. They will engage in a rhetoric of prototypicality in which they talk up their own prototypicality (Reicher and Hopkins, 1996). Leaders of cohesive groups may behave differently as a function of how prototypical they are (van Knippenberg and van Knippenberg, 2003). Leaders who are highly prototypical are often aware that their prototypicality is not in question – they are thus able to be innovative and non-conformist. The prototypicality of less prototypical leaders still needs to be established – these leaders need to be much more conformist and thus less able to be innovative.

Negotiation, teamwork and leadership – An international perspective

From selling detergent to securing peace in Northern Ireland or the Middle East, the ability to negotiate with others is an important social skill. The outcome of a transaction or interaction can turn on not only how well you negotiate, but on how you work as a team and the leadership you show. A recent review by Gelfand *et al.* (2007) summarises how these three characteristics vary across nations and how this variation affects decisions.

Research on negotiation has shown that, in the US, people are more likely to show self-serving biases and make internal attributions about other negotiators' behaviour (Gelfand and Christakopoulou, 1999). North Americans are more likely to see conflicts as being about winning or violating an individual's rights (Gelfand *et al.* 2001), to share information directly with their colleagues during negotiation, and achieve high goals that both parties want to attain (Adair *et al.*, 2001). They are more likely to make concessions at the end of the negotiation than at the beginning (Hendon *et al.*, 2003), and are most satisfied with a negotiation when their economic gains have been maximised (Ma *et al.*, 2002).

Japanese negotiators, in contrast, see conflicts as a violation of duty but also as an opportunity to compromise (Gelfand *et al.*, 2001). The Chinese are more susceptible to the influence of fellow negotiators than are Americans (Liv *et al.*, 2005), and the Japanese, Russians and participants from Hong Kong are more likely to seek out information during a negotiation through a pattern of offers (Adair *et al.*, 2001).

Unlike US negotiators, Asian negotiators are more likely to make generous concessions early on in an exchange and gradually reduce these concessions as the negotiation goes on (Hendon *et al.*, 2003). Unlike Americans, Estonians see a successful negotiation ending when both parties are the recipients of equivalent outcomes (Ma *et al.*, 2002).

The ways in which teams operate and are perceived also differ across cultures. For example, Americans view their team less favourably if they – as individuals – do well but the team performs poorly. You don't see such an interpretation in Chinese participants (Chen *et al.*, 1998). Taiwanese participants view their teams more negatively if membership changes often (compared with Australian participants, who don't) (Harrison *et al.*, 2000). Individuals from collectivistic cultures are more likely to view teams as 'entities' and as 'acting as one' (Chiu *et al.*, 2000). In Japan, indirect personal ties between group members is important for engendering trust amongst the team; in the US, this trust is fostered by team participants belonging to some shared membership category, such as the school they went to (Yuki *et al.*, 2005). Teams of people from collectivistic cultures cooperate better and are more successful (Eby and Dobbins, 1997).

What if the team is made up of people from different cultures? The research suggests that these teams show considerable evidence of ethnocentrism and strong in-group biases (Cramton and Hinds, 2005; Von Glinow, 2004). When

Negotiation, teamwork and leadership – *Continued*

the team leaders prevent communication breakdown, however, multicultural teams perform as well as monocultural teams (Ayoko *et al.*, 2002). A person's culture/nation becomes important in team negotiations when either very few or very many members share the same background (Randel, 2003). Here, performance is worse than in more homogeneous groups (Thomas, 1999). Over time, however, Harrison *et al.* (2002) have found that this performance improves, presumably because team members have begun to familiarise themselves with each other and have learned about each other's behaviour. Also, the more heterogeneous the team, the better the performance (compared with moderately varied teams) (Earley and Mosakowski, 2000).

Finally, we all know of leaders who seem capable of persuading others and of turning the minds of people who appear to hold entrenched, immutable opinions – Bill Clinton intervening to negotiate with the violently opposed political factions in Northern Ireland; Tony Blair persuading Bill Clinton to release ground troops in Kosovo which, ultimately, put an end to Milosevic's ethnic cleansing; Bob Geldof persuading a few popstars to sing a tune and then subsequently persuading millions to help feed the millions of starving in Africa and, more recently, persuade the eight richest nations in the world to tackle poverty in developing countries. (Of course, there are those whose persuasion is not as honourable or which leads

to outcomes that are not as positive – such as those who can persuade young men that crashing a plane into a building or detonating a bomb on a tube train is a good idea or, more historically, Jim Jones, leader of the People's Temple – a Californian cult – who in 1978 ordered almost 800 people to commit suicide.)

Is there any trait that leaders such as this share? In individualistic cultures there is a tendency for leaders to use coercive power to achieve aims whereas in collectivistic cultures, the tendency is to use expert power. According to the Global Leadership and Organizational Behaviour Effectiveness Project (cleverly acronymed as GLOBE) which looked at 17,000 middle managers in 62 cultures, two traits stand out in good leaders: being charismatic and being a team-player (House *et al.*, 2004). The best senior managers were described as innovative, visionary and courageous; those at a lower level were described as being attentive to subordinates and were good at team building.

Gelfand *et al.* (2007) note that charisma varies across nations. They cite the example given by Den Hartog and Verbarg (1997). They found that a strong, ululating voice was described as enthusiastic in Latin American cultures, and therefore a vehicle for charisma, whereas a monotonous tone was described as worthy of respect and self-control in Asian cultures, a uniformity that was considered charismatic.

Crowds and social movements

Crowds are clearly group events; however, they seem to be somewhat different from other group phenomena we have discussed. We have all seen media coverage of football riots, and of crowd aggression in, for example, the Middle East and Northern Ireland, and many of us may have been involved in protests or demonstrations that have turned ugly. We are also familiar with vivid literary accounts of the great riots and demonstrations associated with the French and Russian revolutions. Crowds tend to be volatile, unruly and often violent. They are, of course, not always like this – the crowds attending the funeral of Queen Elizabeth, the Queen Mother, in London in 2002 or those outside the Vatican hearing the Papal address, were certainly not. However, research on crowds has traditionally focused on the antisocial and violent portrayal of crowds. The assumption is that, sometimes, just being part of a crowd can be sufficient to transform our otherwise civil behaviour into unruly, violent acts.

Many social psychologists explain these acts in terms of **deindividuation**, in which one loses one's sense of individuality and personal responsibility. In collective settings, people 'blend' into the crowd,

achieving a sense of anonymity that causes them to assume less responsibility for their actions (Diener, 1980). Consider a study of empathy towards strangers conducted by Zimbardo (1970). In one condition, young women were easily identifiable: they wore name tags and were called by their names. In another condition, a different group of young women were not so easily identifiable: they wore large coats and hoods without name tags and were never referred to by their names. The two groups of women were given chances to administer electric shocks to a stranger, who was actually a confederate of Zimbardo's. The young women who were unidentifiable gave nearly twice as many electric shocks to the stranger as did the young women whose identities were known. Thus, the amount of aggression Zimbardo observed in his participants was strongly correlated with the extent to which their identities were known, reinforcing the idea that antisocial behaviour observed in some groups is due to the loss of personal identity of its individual members.

People in crowds are not always antisocial, and crowds themselves are not always aggressive. Deindividuation may not be an automatic consequence of crowds, or it may be a process that is less mechanically tied to antisocial behaviour. Taylor *et al.* (1994) characterise deindividuation as a

process wherein one's personal identity – one's sense of self – is replaced by identification with the group's values and goals (see also Reicher *et al.*, 1995).

This idea has been more fully explored in terms of social identity theory, which we discussed earlier in this chapter. Reicher (1987, 2001) suggests that crowds are events where people from the same group, and thus with a common social identity, come together to achieve goals (which may or may not involve violence). The strong sense of common social identity ensures that people are highly attuned to the appropriate group norm, and thus conform tightly to it. There is no loss of identity or responsibility, no deindividuation, rather a change of identity. For Reicher, crowds are not fickle or irrational. They are group events in which there are clear limits to acceptable behaviour – limits set by the identity of the crowd. Local conditions and goals will influence how the crowd's social identity expresses itself within these limits. For example, Stott and colleagues have analysed the role of police behaviour in situations when football fans become violent, such as the 1998 World Cup Final, and conclude that the more heavy-handed the police are in their approach to policing the more violent and antagonistic the fans will be (e.g. Stott and Adang, 2004; Stott *et al.*, 2001).

This rational model of crowds links crowd action to various forms of social protest that may be part of a social movement. The key question in the study of social protest is what causes individual discontents or grievances to be transformed into collective action: how and why do sympathisers become mobilised as activists or participants? Klandermans (1997) argues that this involves the relationship between individual attitudes and behaviour (see Chapter 15). Sympathisers hold, by definition, sympathetic attitudes towards an issue yet these attitudes do not translate into behaviour. Participation also resembles a social dilemma (see below). Protest is generally for a social good (such as equality) or against a social ill (for example, pollution), and as success benefits everyone irrespective of participation but failure harms participants more, it is tempting to 'free ride' – to remain a sympathiser rather than become a participant.

When crowds go wrong: football hooliganism

Since the early 1970s European, but particularly English, football has become strongly associated with hooliganism. Football 'hooliganism' involves groups of people behaving in the same way. It is also a set of behaviours which is often associated in the popular mind with crowd behaviour, the popular image of a riot or other violent and antisocial collective event. Popular hysteria tends to characterise football hooliganism in terms of the familiar stereotypical image of football fans on the rampage (Murphy *et al.*, 1990).

Deindividuation theories offer a group-oriented analysis of this phenomenon. A football match is a crowd context where people feel anonymous and unidentifiable; they lose their sense of individual identity and thus no longer feel that it is necessary to act in socially acceptable ways. This perspective assumes that people are fundamentally antisocial and aggressive, and that the only reason people do not ordinarily act in this way is that they are usually identifiable in a society whose norms strongly proscribe such behaviour. Hooliganism is primitive unsocialised behaviour which lies deep in all our psyches, and which is released in crowd settings like a football match. Although recognising the group context of hooliganism, this analysis is also rather individualistic. The crowd releases individual aggressive instincts – and in fact any (non-group) context that makes one feel deindividuated may have the same effect (for example, darkness, or clothing which conceals who we are). One problem with this analysis is that it cannot easily explain why most people at football matches do not indulge in hooliganism. Perhaps they are not deindividuated – but why? Perhaps they are deindividuated, but deindividuation does not inevitably produce hooliganism, in which case alternative or additional processes must operate to produce hooliganism.

A different, more genuinely group-oriented analysis of football hooliganism is provided by Marsh *et al.* (1978). According to their analysis, violence by football fans is actually orchestrated far away from the stadium and long before a given match. What might appear to be a motley crowd of supporters on match day can actually consist of several distinct groups of fans with different status. By participating in ritualised aggression over a period of time, a faithful follower can be 'promoted' into a higher group and can continue to pursue a 'career structure'. Rival fans who follow their group's rules quite carefully can avoid real physical harm to themselves or others. For example, chasing the opposition after a match ('seeing them off') need not necessarily end in violence since part of the agreed code is not actually to catch anyone. Seen in this light, football hooliganism is a kind of staged production and is not the example of an uncontrollable mob sometimes depicted by the media. When real violence does take place it tends to be both unusual and attributable to particular individuals.

Football hooliganism can also be understood in more broadly societal terms. For example, Murphy *et al.* (1990) described how football arose in Britain as an essentially working-class sport, and that by the 1950s working-class values to do with masculine aggression had already become associated with the game. Attempts by the government (seen as middle class) to control this aspect of the sport can backfire because these attempts merely enhance class solidarity and encourage increased violence that generalises beyond matches. This sort of explanation points towards an analysis in terms of intergroup relations and

subcultural norms that prescribe and legitimate aggression. Fans derive a sense of who they are – a sense of identity – from being part of a group of supporters. Some people, particularly those with few other valued sources of identity, identify more strongly than others. The attitudinal, dress and behavioural norms of the group are strongly adhered to, particularly in situations where the group is very salient, for example, at or around a match when supporters of opposing teams are present in the stadium, in the streets and on public transport. The actual norms of the groups reflect the historical origins of the sport and the intrinsically competitive and masculine nature of the game. Football hooliganism is largely a display of controlled aggression and machismo that reflects strong identification with group norms (this sort of group-oriented analysis owes much to social identity theory).

Protestors marching after the riots in Paris of October/ November 2005, which led to debates on integration and discrimination in France, and to what extent French of North African descent could have a French national identity.

Intergroup relations and prejudice

Our discussion of social protest leads neatly into this next topic. Social protest involves one group of people protesting against another group – often a minority group protesting against the government. It is a manifestation of intergroup relations. Sherif (1962, p. 5) has provided a classic definition of intergroup relations:

Intergroup relations refer to relations between two or more groups and their respective members. Whenever individuals belonging to one group interact, collectively or individually, with another group or its members in terms of their group identifications we have an instance of intergroup behaviour.

Relations between groups vary enormously from being relatively harmonious to being massively destructive, but almost always they tend to be characterised by some degree of competitive orientation that seeks to maintain the groups as distinctive entities. Because the extreme and harmful aspect of intergroup behaviour is so damaging (it includes war and genocide), research has tended to focus on that aspect and in particular on intergroup conflict and on the attitudinal aspect of hostile intergroup relations – prejudice.

Intergroup behaviour

Intergroup behaviour tends to be competitive and ethnocentric, that is, people tend to view all attributes of their group as being better than all attributes of any out-group they compare themselves with.

Realistic conflict and interdependence

One explanation of why and how this happens was developed on the basis of a series of three famous field experiments conducted by Sherif and his colleagues in 1949, 1953 and 1954 at summer camps for young boys in the United States (see Sherif, 1966). The participants, 11-year-old boys, were randomly assigned to one of two cabins that were isolated from each other. Friends were split up to be in different cabins. During the first week, the boys in each cabin spent their time together as a group, fishing, hiking, swimming, and otherwise enjoying themselves. The boys formed two cohesive groups, which they named the Rattlers and the Eagles. They became attached to their groups and strongly identified with them.

Next, the experimenters arranged a series of formal competitive events between the two groups. The best team was to win a trophy for the group and individual prizes for its members. As the competition progressed, the boys began taunting and insulting each other. Then the Eagles burned the Rattlers' flag, and in retaliation, the Rattlers broke into the Eagles' cabin and scattered or stole their rivals' belongings. Although further physical conflict was prevented by the experimenters, the two groups continued to abuse each other verbally and seemed to have developed a genuine hatred for each other – stereotypes and prejudices developed and were expressed verbally and physically.

Finally, in one of the studies the experimenters arranged for the boys to work together in order to accomplish shared goals that both groups valued but neither group could accomplish alone. The experimenters sabotaged the water supply for the camp and had the boys fix it; they had the boys repair a truck that had broken down; and they induced the boys to pool their money to rent a movie. After the boys worked on cooperative ventures, rather than competitive ones, the level of intergroup conflict diminished markedly.

To explain the results of these studies, Sherif developed **realistic conflict theory**. Sherif argued that the way people behave towards one another is strongly influenced by people's goals and their perception of the goal relations between people. When people have a common goal that requires interdependent action for its achievement, then people cooperate to help one another to achieve the goal, and this produces a sense of solidarity and oneness that underpins group formation. This is what happened in the first stage of the studies. When two groups have mutually exclusive goals, in other words when only one group can achieve the goal at the expense of the other group, then the groups compete and hinder each other from achieving their goal. This spawns mutual dislike, conflict and hostility. This is what happened in the second stage of the studies. When two groups have a common goal that cannot be achieved by one group alone (called a superordinate goal), then the two groups cooperate to help one another to achieve the goal. This reduces hostility and generates more positive intergroup attitudes. This is what happened in the final stage of the studies.

Frustrated goals and relative deprivation

A key feature of realistic conflict theory is the argument that intergroup conflict rests on competitive goals that cause each group to impede or frustrate each other's attempts to achieve their goals. Collective goal frustration may contribute to hostile intergroup relations. This idea has its roots in Dollard *et al.*'s (1939) **frustration–aggression hypothesis**. When people's goals are frustrated they can feel a sense of anger (technically called an 'instigation to aggress') that can be dissipated only by aggression, often not directed at the cause of the frustration but at a scapegoat that is weak and vulnerable. According to Berkowitz (1962), frustration is most likely to translate into collective aggression against an out-group when the instigation to aggress is associated with other generally aversive conditions, there are aggressive cues in the environment, and people are in the presence of others who are acting aggressively.

Generally, conflict between groups arises when a group has an acute feeling of being deprived. **Relative deprivation** can be most acute when a period of rising expectations (how things ought to be) and rising achievements (how things are) comes to an abrupt end because achievements suddenly drop off. This J-curve hypothesis (Davies, 1969) has been used to explain large-scale intergroup conflicts, for example, the French and Russian revolutions, and the rise of anti-Semitism in Europe after the economic crash of 1929.

Although relative deprivation can be based on diachronic (over time) comparisons between one's circumstances now and how they used to be, Runciman (1966) suggests that synchronic (here and now) self–other com-

parisons are much more immediate and powerful. These comparisons can be between one's self and individual others (interpersonal comparisons) or between one's own group and another group (intergroup comparisons). The former generates a sense of **egoistic relative deprivation** that is associated with stress, depression and demotivation. It is the latter that generates a sense of **fraternalistic relative deprivation** that is associated with collective protest, intergroup conflict, prejudice and so forth (Vanneman and Pettigrew, 1972).

There are at least three conditions that seem to amplify the impact of fraternalistic deprivation on competitive intergroup behaviour: (1) people need to identify strongly with their group (Abrams, 1990); (2) people need to feel that their deprived state relative to another group rests not only on an unjust distribution of resources (distributive injustice), but also on unjust procedures (procedural injustice) (Tyler and Smith, 1998); and (3) there is a perception of real intergroup conflict over scarce resources (see our discussion of realistic conflict theory, above).

Social identity

Although competitive goals and a sense of relative deprivation certainly do encourage conflict and hostile intergroup attitudes and behaviour, there is also substantial evidence that the mere existence of social categories or groups can be sufficient to provide the framework for this behaviour. Tajfel *et al.* (1971) conducted an experiment in which school students were randomly assigned to groups (ostensibly on the basis of preferences for paintings by the artists Klee and Kandinsky, who were unknown to the students). The participants did not interact and did not know who was in their group or who was in the other group. Nevertheless they subsequently discriminated against the out-group by repeatedly allocating less money to the out-group than their own group (even though they personally did not benefit financially from this allocation). This paradigm, the **minimal group paradigm**, and variants of it, have been used many hundreds of times over the last 35 years or so to replicate this effect – people who are categorised on a minimal, trivial, and often random basis tend to show a competitive and discriminatory orientation towards an out-group.

It should be noted that minimal social categorisation can sometimes not produce discrimination. Experimental participants need to feel they belong to the minimal group, and this sense of belonging or identification is enhanced where people feel uncertain about themselves and their place in the social context (Hogg, 2000). Also, discrimination can disappear when participants, rather than allocating rewards, are asked to allocate punishments or withhold rewards – called the positive–negative asymmetry effect (Mummendey and Otten, 1998).

The initial minimal group finding was an important catalyst for the development, originally by Tajfel and then by Turner and his associates, of **social identity theory** (Tajfel and Turner, 1986; Turner *et al.*, 1987; Hogg and Abrams, 1988; Hogg, 2006 – see also the section in Chapter 15 on self and identity). According to social identity theory, group and intergroup behaviour is associated with social identity (self-definition in terms of the defining attributes of an in-group), not personal identity (self-definition in terms of idiosyncratic traits or close interpersonal relationships). People cognitively represent social groups in terms of a fuzzy set of attributes (called a prototype) that simultaneously captures in-group similarities and intergroup differences. Prototypes are catered to specific contexts in order to maximise entitativity – the property of a group that makes it a distinct entity with sharp boundaries and clear consensual defining attributes. Self-inclusive social categories with high entitativity and clear prescriptive prototypes are very effective at reducing self-conceptual, attitudinal and behavioural uncertainty (Hogg, 2000).

When a particular intergroup categorisation seems best to account for what is going on in a particular situation it then becomes psychologically salient, that is, people categorise themselves and others in terms of the categorisation. Social categorisation causes people to view others and themselves not as unique individuals, but in terms of the relevant in-group or out-group prototype – a process called **depersonalisation** because perception is based on group membership and group attributes not individuality and personal attributes. Depersonalisation explains why, in intergroup contexts, we tend to see out-group members stereotypically, why we conform to in-group norms relating to perceptions, feelings, attitudes and behaviours, and why we tend to accentuate intergroup differences and intragroup similarities on all available and relevant dimensions of comparison. This cognitive aspect of social identity theory is called **self-categorisation theory** (Turner *et al.*, 1987).

Because groups define and evaluate who we are, it is important that the groups we belong to have attributes that we consider to be evaluatively positive. Intergroup behaviour is a struggle for positive distinctiveness for our own group relative to relevant out-groups. This furnishes a favourable social identity, and this in turn contributes to an underlying sense of self-esteem. The struggle for positive social identity can be framed in terms of a struggle for status, with dominant groups protecting their high-status position of advantage and privilege, and subordinate groups striving to rectify their lower-status position and associated disadvantage. According to social identity theory, the form that this struggle takes depends upon people's perceptions of the nature of status relations between groups (Ellemers, 1993; Tajfel and Turner,

1986). The focus is largely on how lower-status groups respond to their social position.

Where status relations are considered legitimate but the boundaries between groups are believed to be permeable, members of lower-status groups pursue social mobility – they disidentify from their group and try to gain admittance for themselves and their immediate family to the higher-status group. This is almost always unsuccessful. It leaves people with a marginal social identity – rejected by their in-group and not accepted by the out-group. Where status relations are considered to be relatively legitimate and highly stable and boundaries are impermeable, lower-status group members pursue a strategy of social creativity. They try to improve their social identity by seeking a redefinition of in-group properties – different, more positive attributes and a re-evaluation of existing properties. They also focus on comparisons with groups who are even lower in status than their own. Finally, where people recognise the illegitimacy of their lower-status position, feel that status relations are unstable, and can envisage ways to achieve a change in status relations, they engage in direct social competition. They go head-to-head with the higher-status groups – this can take the form of democratic political action, social protest, or revolution and war.

The social identity analysis of intergroup behaviour has gathered substantial support as an account of the dynamics of intergroup behaviour. For example, regarding the role of **self-esteem**, Hunter *et al.* (1996) studied the intergroup relationship between Catholic and Protestant 16-year-olds in Northern Ireland. Participants first completed some measures of self-esteem and then evaluated the two groups. Self-esteem was then measured again. Among those who expressed in-group bias when they evaluated the groups (favouring their own group over the other), self-esteem was raised on dimensions such as honesty, academic ability and physical appearance.

Regarding the motivational role of uncertainty reduction, a series of experiments has shown that discrimination in the minimal group paradigm occurs only if people are categorised under conditions of subjective uncertainty that causes them to identify with the minimal group (Hogg, 2000). Regarding intergroup conflict, there is an entire literature in the area of language and social psychology which shows that ethnolinguistic groups (ethnic groups for whom language is a defining feature) thrive or perish depending on perceptions of the stability, legitimacy and permeability of status relations, exactly as predicted by social identity theory (Giles and Johnson, 1987). Finally, there is evidence that in-group prototypes do enhance entitativity and that people conform to such norms when they identify with their group (Abrams *et al.*, 1990), and that this is associated with out-group stereotyping (Oakes *et al.*, 1993; Leyens *et al.*, 1994).

Ostracism

Research by Zadro *et al.* (2005) shows that people can feel worse when they are the target of ostracism (being excluded and ignored in the presence of others) than the target of a verbal dispute. Furthermore, those who are the source of the behaviour actually feel better when they ostracise you than when they target you with verbal dispute.

To demonstrate this, Zadro and colleagues conducted three role-playing experiments in which they constructed a mock train ride in the laboratory – three rows, one right behind the other, of three chairs. To further cue the ‘train ride’ aspect there were some of the usual signs found in trains, such as ‘no smoking’ and ‘do not place your feet on the seats’. Student participants were randomly assigned the role of target or source – targets sat in the middle of rows and sources sat at the ends.

The scenario was described as one in which they were travelling home by train and the sources were cross with the target because he or she had not invited them to a party. In the ostracism condition the sources were told to express their anger by talking to one another across the target but ignoring the target. In the dispute condition they were told to express their anger by directly arguing with the target. The role-play lasted about five minutes, after which participants completed a questionnaire indicating how they felt – more specifically, to what extent they felt the four basic needs of belonging, control, self-esteem and meaningful existence were being met.

The results of the first study, with 35 students, showed that targets of ostracism felt all four needs were less satisfied than did targets of dispute – they felt less belonging, less control, lower self-esteem, and less meaningful existence. Sources who used ostracism felt greater control than did sources who used dispute. The second study, with 57 participants, was virtually identical with some minor changes to increase the realism of the role-play. Once again targets of ostracism felt all four needs were less satisfied than did targets of dispute. The final study,

with 138 participants, used a slightly different scenario – the target had refused to provide notes for the sources to catch up on a class they had missed – but was the same in other respects. Yet again, targets of ostracism felt all four needs were less satisfied than did targets of dispute – but here the difference was significant only on belonging and meaningful existence. In addition, sources of ostracism felt greater belonging and more superiority than did sources of dispute. This last study also had a control condition in which the target was explicitly included by the sources – as one would expect, inclusion caused both targets and sources to feel their needs were being better satisfied than did ostracism or dispute.

These studies by Zadro *et al.* (2005) are part of an extensive programme of research by Williams and his associates on the psychological effects of ostracism (Williams, 2001). These studies have used some very vivid paradigms – for example, in one paradigm a participant ostensibly waiting with two others for an experiment is initially included in a ball-tossing game and then excluded (e.g. Williams and Sommer, 1997). The ball-tossing paradigm has been adapted for a web-based experiment on cyber-ostracism (Williams *et al.*, 2000).

Prejudice

Intergroup attitudes are a core component of intergroup behaviour. Attitudes toward the out-group tend to be shared among the in-group members, and tend to devalue the out-group relative to the in-group – they are stereotypes and are a defining feature of prejudice. Indeed, **prejudice** can be defined as a shared attitude, generally negative, towards a social out-group, and thus towards members of that group purely on the basis of their membership in that group (see Chapter 11 for some discussion of the development of prejudice). Some of the most pernicious prejudices are those based on people’s race, ethnicity, religion, age, sex, sexual orientation, and mental and physical health. But people have a remarkable ability

Cutting edge – Being left out in the cold

Research on ostracism shows that having one’s existence ignored or denied by others is one of the most aversive situations that people can face – underscoring the fundamentally social nature of human existence and the way that our sense of self and of reality is grounded in social recognition. We feel isolated. What is astonishing is that this isolation can also make us feel, literally, cold. Zhong and Leonardelli (2008) found that when people were asked to recall an experience in which they felt socially isolated, they estimated the tempera-

ture of the room to be lower than did those who recalled an experience in which they were socially included. In a follow-up study, they manipulated exclusion directly. Participants played an online game of pass the ball with three other players. What the participants did not know is that some of them would not have the ball passed to them. They would be excluded. Those who were excluded found the room colder and expressed a greater desire for warm food and drink than did those who were included.

to be prejudiced against almost any group you care to mention – powerfully illustrated by the 2006 Oscar-winning film *Crash*. Like other attitudes, prejudices have a cognitive component. In this case the cognitive component is, as discussed in the social cognition section of Chapter 15, a stereotype or schema – a set of interrelated (and shared) beliefs about members of the group that influences perception once we categorise someone as being a member of the group. Again, like other attitudes, there is no guarantee that prejudice will be expressed as behaviour, but when it is, that behaviour is called **discrimination**.

Theories of prejudice

Because prejudice is repugnant and can have such appalling effects, such as genocide, prejudice is often traced to individual differences and personality attributes. One of the most widely promulgated theories of prejudice is the **authoritarian personality** (Adorno *et al.*, 1950). Children who are brought up in families where their parents use harsh disciplinarian methods to secure love and dependence develop a love–hate relationship with their parents, which is unendurably stressful. The stress is resolved by idealising their parents and all authority figures and redirecting their hatred onto weaker others. This resolution becomes a deep-seated and immutable personality syndrome, authoritarianism, which frames relations for the rest of the person's life. It predisposes people to be prejudiced. Another personality explanation has been proposed by Rokeach (1948), who argues that some people, for whatever reason, have a general cognitive style that is rigid and dogmatic. These people are predisposed to be prejudiced because they strive for a rigidly stratified social world, are resistant to belief change in the light of contradictory evidence, and are inclined to ground their beliefs in authority and orthodox belief systems.

An individual differences explanation of prejudice, called **social dominance theory**, has been proposed by Pratto *et al.* (1994). They describe a relatively sophisticated, but nonetheless 'individual differences', analysis of exploitative power-based intergroup relations. People who desire their own group to be dominant and superior to out-groups have a high social dominance orientation that encourages them to reject egalitarian ideologies, and to accept myths that legitimise hierarchy and discrimination. These kinds of people are more inclined to be prejudiced than are people who have a low social dominance orientation.

Critics of personality and individual differences explanations of prejudice (Pettigrew, 1958; Billig, 1976) note that prejudice is not a sporadic individual matter, but rather it is a collective behaviour engaged in by large numbers of people in a relatively coordinated and highly targeted manner. They also provide evidence that personality is actually a poor predictor of prejudice, and that the

nature of intergroup relations is a better predictor. In general, most social psychologists now believe that prejudice is a part of intergroup behaviour and therefore needs to be understood as part of a theory of intergroup behaviour. Although prejudice, stereotypes and discrimination are expressed by individuals, they are genuinely intergroup phenomena: individuals are prejudiced because they belong to groups that have developed certain relations with one another that are characterised by unequal status and advantage, and by conflict and hatred (Brown, 1995).

Cognitive processes in prejudice

We have already seen one way in which cognitive processes are involved in prejudice – the categorisation of people into in-group and out-group seems to lay the groundwork for intergroup behaviour and possible prejudice. It may do this because it affects self-conception: it encourages people to view themselves as group members and think of themselves in terms of social identity, which can be considered a type of self-schema. Social categorisation causes people to view out-group members in terms of stereotypes, and to behave in ways that favour the in-group and maintain the distinctiveness of in-group identity.

Another cognitive process that is involved in stereotyping and prejudice is illusory correlation. Recall from Chapter 15 that the availability heuristic involves people assuming that distinctive, easily imagined items occur more frequently. This phenomenon probably explains why people overestimate the rate of violent crime (because an act of violence is a frightening, distinctive event) and overestimate the relative numbers of violent crimes committed by members of minority groups (because members of minority groups tend to be more conspicuous). This tendency is an example of an **illusory correlation** – the perception of an apparent relation between two distinctive elements that does not actually exist or is enormously exaggerated (Hamilton and Gifford, 1976).

Another fallacy that promotes stereotyping is the **illusion of out-group homogeneity**. People tend to assume that members of other groups are much more similar than are members of their own group (Linville, 1982). This tendency is even seen between the sexes: women tend to perceive men as being more alike than women are, and men do the opposite (Park and Rothbart, 1982). The same is true for young people and old people (Linville *et al.*, 1989). However, this effect can sometimes be reversed so that people think their own group is more homogeneous than the out-group. Simon and Brown (1987) suggest that one situation in which this can happen is when the in-group is a minority group in terms of status. The reason for this is that solidarity and thus homogeneity may have a special value for minorities.

Under-representation of women in academia – An international perspective

Although women make up approximately half of the student population, and in the UK and the Netherlands constitute the clear majority of psychology students, women are less well represented further up the academic ladder: faculty staff. According to one study, the proportion of women academic staff in universities around the world never exceeds 25 per cent (Lie *et al.*, 1994).

The further up the ladder we progress, the fewer women there are – even in liberal Western democracies. For example, Osborn (1998) found that the percentage of full-time women professors, across all disciplines, in 13 out of 16 European countries was 10 per cent or less; in North America, the figure was 13 per cent and in Australia, 14 per cent. Why? One reason might be that women are less committed to work because of competing commitments associated with child-rearing. Another reason is that employers have a gender stereotypical view of women employees that makes women appear less committed and therefore more of an employment risk.

Ellemers *et al.* (2004) tested these hypotheses in a study of students undertaking Ph.D. research at universities in the Netherlands and in Italy. In the Dutch study, the researchers found no differences between men and women Ph.D. students in terms of measured work commitment or work satisfaction, although the women themselves reported spending more time on household tasks than work. However, when staff from the same university were asked to judge these students, women doctoral students were perceived as being less committed than men students, even by women staff.

These findings were replicated in the Italian sample (although the women students reported greater team-oriented commitment). However, the biased judgement of women staff was even greater than in the Dutch sample, suggesting that the most stereotypical views of women are actually held by women.

Stigma and disadvantage

One of the principal problems with prejudice is that it stigmatises and disadvantages entire groups of people: ‘Stigmatised individuals possess (or are believed to possess) some attribute, or characteristic, that conveys a social identity that is devalued in a particular social context’ (Crocker *et al.*, 1998, p. 505). The targets of prejudice and discrimination are members of stigmatised groups, and thus they are stigmatised individuals. Stigma persists for a number of reasons.

An fMRI study of stigma suggests that our unstated prejudices might be revealed by our brain activation. Krendl *et al.* (2006) asked 22 men to make explicit (do you like this person?) or implicit (is this a man or a woman?) judgements about people with well-established stigma (obesity, unattractiveness, transexuality, etc). Areas of the brain normally activated by negative emotional stimuli, as well as regions involved in control and inhibition, were activated. However, when the most negatively perceived faces were judged in the implicit condition, activation was much greater in the amygdala and prefrontal cortex. Perhaps as one increased (in the amygdala), the other area responded to inhibit its activation.

A relatively positive sense of self can be gained by comparing others unfavourably with oneself. Stigma can legitimise inequalities of status and resource distribution

that favour a dominant group – such groups are certainly going to ensure that the stigma remains in place, because it serves a system justification function (Jost and Hunyadi, 2002). Finally, people may need to stigmatise groups that have different world views from their own, because if one did not degrade and discredit out-groups in this way then the frail sense of certainty in, and controllability of, life that one gains from one’s own world view would be shattered (Solomon *et al.*, 1991).

Members of stigmatised groups can experience **attributional ambiguity**. They can continually read prejudice and discrimination into innocuous behaviours and even into behaviours favouring them: Was I served first at the bar because I am black and the bartender was trying to conceal her hidden prejudice? Members of stigmatised groups can also suffer depressed self-esteem, self-worth and efficacy that can reduce motivation. For example, because stigmatised groups know exactly the negative stereotypes that others have of them, they experience what Steele *et al.* (2002) have called **stereotype threat**. Stigmatised individuals are aware that others may judge and treat them stereotypically, and thus, on tasks that really matter to them, they worry that through their behaviour they may even confirm the stereotypes. These concerns not only increase anxiety, but can also impair task performance. For example, an academically ambitious West Indian Briton, aware of

Cutting edge – Shoot me, I’m black

The social psychology literature is bursting with studies demonstrating prejudice against black people, as well as other similarly stigmatised groups. Researchers at the universities of Colorado and Chicago have now found that making stereotypes about people accessible influences a person’s decision to shoot those individuals during a videogame (Correll *et al.*, 2007).

In the experiment, participants had to press a key indicating ‘shoot’ if they saw a person with a gun in the game they were playing. If the person was not carrying a gun, they were to press a key indicating ‘don’t shoot’. Half of the characters in the game were white, half were black. Before playing the

game, people were asked to read newspaper articles in which armed robberies committed by either black or white felons were reported.

People who read about the black criminals were significantly more likely to shoot black targets in the videogame – regardless of whether these targets were armed or unarmed – than white (even armed) targets. So, by making stereotypical information accessible (the link between black people and violence), the researchers found that people’s tendency to engage in stereotype-driven behaviour increased.

stereotypes of intellectual inferiority, may be extremely anxious when answering a question in class – she would be worried that the slightest mistake would be interpreted stereotypically. This anxiety may actually impact adversely on behaviour.

In general, however, although some stigmatised individuals are vulnerable to low self-esteem, diminished life satisfaction and, in some cases, depression, most members of stigmatised groups are able to weather the assaults and maintain a positive self-image (Crocker and Major, 1989). There are many ways in which people can do this. One way is to deny personal disadvantage. For instance, Crosby (1982) has identified the ‘paradox of the contented female worker’. Women workers compare their salaries and working conditions with those of other women, which narrows the potential for recognising much larger sex-based inequalities in pay and conditions (Major, 1994).

Stereotype threat

Why do some groups in society underperform in particular areas – for example, academic underachievement of African-Americans, and mathematical and scientific underachievement of women? Coining the term ‘stereotype threat’, Steele and his colleagues argue that underachievement is a psychological response to stereotypes that characterise one’s in-group (e.g. women) as inferior to a relevant outgroup (men) on a specific task (maths) in a specific domain (school) (Steele *et al.*, 2002). The negative stereotype is a cognitive and emotional burden that impedes performance and paradoxically actually produces an effect consistent with the negative expectation. Stereotype threat has two repercussions: anxiety about confirming the stereotype and thus being judged as possessing the negative attribute, and disen-

agement with the task and the domain. These two effects lead to underachievement (Steele, 1997; Aronson *et al.*, 1999).

Much of the original research had been conducted with African-American students in the American schooling system. For example, African-American students have been found to perform less well than their white counterparts in testing situations where negative stereotypes about African-Americans are relevant (Steele and Aronson, 1995). This may be due to the potential recognition that failure could confirm a negative stereotype of their in-group (and, by extension, the self). The stereotype threat effect has been investigated with different stigmatised groups and in several domains including white men’s maths ability when compared to Asian-American men (traditionally associated with higher maths ability; Aronson *et al.*, 1999) and children from low socio-economic backgrounds in academic testing situations (Croizet and Claire, 1998).

A principal aim of social psychological research into stereotype threat has been to discover what psychological variables (at both the social and individual levels) affect individuals’ vulnerability to this effect. Some basic processes and issues have been identified, for example:

- 1 **Domain identification.** Stereotype threat only occurs in individuals for whom performing well in a given domain is important (Steele, 1997). Aronson *et al.* (1999) measured white male students’ identification with maths and then asked them to complete a maths test either in the context of the stereotype that Asians are superior at maths (stereotype threat condition) or not (control condition). Performance on the maths test was significantly worse in the stereotype threat condition, but only for participants who identified highly with the maths domain (even when controlling for previous standardised aptitude test (SAT) scores).

Interestingly, this study not only provides evidence for domain-specific identification but also demonstrates that stereotype threat can affect traditionally non-stigmatised groups (American white male students).

- 2 *Cognitive load.* It is possible that the stereotype threat effect is more pronounced when people are under high cognitive load as there is an extra pressure to disconfirm negative stereotypes. Spencer *et al.* (1999) examined this possibility in two experimental studies of high-achieving male and female American university students. Women are believed to experience stereotype threat in maths-related domains. Participants in the first study did a maths test that was either easy or difficult. There was no difference in the performance of male and female students on the easy test, but females performed significantly worse on the difficult test. The increased cognitive load of stereotype threat impeded performance on a task that also demanded greater cognitive capacity. In a second study, Spencer *et al.* showed that this gender difference in performance on the difficult test was accentuated when the test was explicitly introduced in terms of gender differences in maths ability. This finding lends further credibility to the idea that performance differences do indeed result from stereotype threat rather than from real differences between males' and females' maths ability.
- 3 *Self-categorisation with the stereotyped group.* Research suggests that priming the social identity of the stigmatised group will automatically prime the negative stereotype and in turn affect performance in a stereotype consistent manner. One study clearly demonstrates this effect in the maths performance of Asian-American women (Shih *et al.*, 1999). In contrast to the negative connotations of being female in the maths domain, Shih *et al.* reasoned that Asian-American identity is associated with a positive stereotype of maths ability. Indeed, female Asian-Americans who were primed with their Asian-American identity significantly outperformed participants who were primed instead with their gender identity ('women').
- 4 *Individual level of identification with the stereotyped group.* Schmader (2002) demonstrated that the degree to which a person identifies with a relevant category also affects how strongly the stereotype influences their performance. White American students completed a maths test in either a gender-relevant domain or a gender-irrelevant domain. In the gender-irrelevant domain there was no difference between men's and women's performances on the test. However, in the gender-relevant domain, only the female participants who identified

highly with their gender underperformed compared with males. Thus, vulnerability to stereotype threat seems to depend on whether people see themselves as representative of the stereotyped category.

Given the deleterious consequences of stereotype threat, is it possible to train people to combat or overcome stereotype threat? Aronson *et al.* (2002) conducted an intervention study to trial a method of helping students resist their responses to stereotype threat. African-American and Caucasian male and female undergraduates participated in a laboratory study ostensibly concerning a penpal mentoring system for younger students. They were randomly divided into three groups. A battery of attitude change techniques were used to teach them and help them internalise the idea that intelligence is malleable (intervention-specific group) or that people have different intelligence orientations (intervention-only group – in case intervention alone boosts performance). The third group was a no-intervention control. The results showed that several weeks after the lab session the students in the intervention-specific group (where the negative stereotype was challenged) reported greater academic identification and enjoyment and higher grades compared with the other intervention style and the control group. This was particularly the case for African-American students whose academic performance and identification were depressed as a reaction to stereotype threat in the other conditions. It is interesting to note that there were no differences between groups on stereotype threat scores *per se*, suggesting that the specific intervention changed the participants' responses to stereotype threat and not their perceptions of it.

Modern forms of prejudice

Prejudice can express itself in many different ways. We are all familiar with what has been called old-fashioned prejudice – name-calling, abuse, persecution, assault and discrimination. This kind of expression of prejudice is now illegal and socially censured in all Western democratic societies, and so it is rarely encountered. Not surprisingly, research on racism in the United States shows a dramatic reduction in expressed anti-black attitudes since the 1930s (Devine and Elliot, 1995).

However, it may not be so much that prejudice is vanishing but that it is changing its form. This new form of prejudice (the research focuses mainly on racism), has a number of different names – aversive racism, modern racism, symbolic racism, regressive racism or ambivalent racism (Gaertner and Dovidio, 1986; Hilton and von Hippel, 1996). However, the general idea is that people

now experience a conflict between deep-seated emotional antipathy towards racial out-groups, and modern egalitarian values that exert pressure to behave in a non-prejudiced manner. The resolution of this conflict, which produces **modern racism** or subtle forms of racism, is achieved by avoidance and denial of racism – separate lives, avoidance of the topic of race, denial of being prejudiced, denial of racial disadvantage, and thus opposition to affirmative action or other measures to address racial disadvantage. Although this analysis is mainly focused on racism in the USA, it can also apply to sexism (Swim *et al.*, 1995), and to racial attitudes in Europe (Pettigrew and Meertens, 1995).

Modern forms of prejudice can, by definition, be very difficult to detect, because people try to conceal their prejudices. To detect prejudice, researchers need to be ingenious in designing unobtrusive and indirect measures. Many different methods have been devised (Crosby *et al.*, 1980). For example, social cognition research shows that stereotypes can be automatically generated by categorisation, and categorisation can automatically arise from category primes (an accent, a face, a costume) (Bargh, 1989).

Another powerful unobtrusive measure of prejudice is to analyse the subtext of what people say. Racism can very subtly and quite unintentionally be embedded in the words we use, the way we express ourselves, and the way we communicate with and about racial out-groups (Potter and Wetherell, 1987, Edwards, 1997). For example, van Dijk (1987) found evidence of prejudice from a detailed analysis of spontaneous everyday talk among whites in the Netherlands and in southern California about other races (blacks, East Indians, North Africans, Hispanics, Asians). One hundred and eighty free-format interviews conducted between 1980 and 1985 were qualitatively analysed to show how racism is embedded in and reproduced by everyday discourse. People can use particular forms of language to communicate their prejudiced attitudes in ways that disarm the charge of being a racist. A common example is the disclaimer ‘I’m not racist, but . . .’ that can precede a clearly racist comment.

A more cognitive index of language and prejudice is the **linguistic intergroup bias** effect (Maass, 1999). Maass discovered that people tend to use concrete language that simply describes events when talking about positive out-group (and negative in-group) characteristics, but use much more general and abstract terms that relate to enduring traits when talking about negative out-group (and positive in-group) characteristics. In this way we can detect negative out-group attitudes: people start to become abstract and general when talking about their prejudices.

Can we reduce prejudice?

How can prejudice and intergroup conflict be reduced? Research suggests that propaganda, public service advertising and formal education have a limited effect – these methods are effective in conveying official societal expectations, but then, of course, they fail if they are conducted against a background of powerful and entrenched day-to-day informal endorsement of prejudice. So, are there any techniques that work and, if so, how?

On a larger scale, a popular view about how to reduce prejudice is the **contact hypothesis**: if people from different races could just get to know one another through coming together to interact then prejudice would disappear (Allport, 1954). Although this idea has immediate appeal, and indeed it was part of the scientific justification for the racial desegregation of the American schooling system in the 1950s, it is fraught with problems. For intergroup contact to work, people have to come together for prolonged equal-status, meaningful interaction that is pleasant and capable of changing stereotypes of entire groups not just attitudes towards the individuals with whom one interacts. Contact can often produce interracial friendships, but it rarely changes racial stereotypes. More often than not, contact can confirm and accentuate intergroup perceptions and further entrench stereotypes. There is often so much anxiety associated with intergroup encounters that groups avoid contact or find contact unpleasant and attribute this to the out-group (Stephan and Stephan, 2000).

Nevertheless, contact between members of different groups may promote positive attitudes. Indeed, a recent statistical survey of 515 studies of the effects of contact concluded that, all things being equal, contact does promote more positive intergroup relationships (Pettigrew and Tropp, 2006).

Contact may foster good interpersonal relationships (‘decategorisation’ of group members; Brewer and Miller, 1984), or it may foster a sense of common membership in a superordinate ingroup (‘recategorisation’; Gaertner *et al.*, 1993), or it may allow the recognition of positive features of other groups while preserving a sense of in-group distinctiveness (mutual positive differentiation; Hewstone, 1996). Dovidio *et al.* (1997) asked sets of six participants to work first as two three-person groups. These groups then interacted and participants judged one another. Half of the participants were then encouraged to think of themselves as one larger (six-person) category. These recategorised participants were less likely to show evaluative preferences for their own sub-group, or to show a preference for self-disclosing to and helping members of their own sub-group.

Other research by S. C. Wright *et al.* (1997) has shown that that intergroup attitudes can improve if people witness or have knowledge of rewarding intergroup friendships between others – if my friend John has close out-group friends then maybe the out-group isn’t quite as bad as I thought. Pettigrew (1998) concluded that friendship across group boundaries is an important way that contact allows people to learn about out-groups and to feel less anxious about future interaction with other members of these groups. This makes it more likely that people will generalise their positive feelings about an out-group friend to the out-group as a whole. Similar conclusions were reached by Brown and Hewstone (2005), who also emphasise the way that contact can influence emotions and feelings, and trust between groups, which in turn can promote more positive intergroup relationships.

Prejudices are intergroup psychological mechanisms for protecting and enhancing our self-image and our material well-being. Not surprisingly, threats to racial or cultural identity are unlikely to reduce prejudice. Thus, nations that try to assimilate ethnic minorities threaten those minorities and cause them to react to protect themselves, which in turn threatens the dominant majority and fuels prejudice. One strategy that does seem to help is pluralism or multiculturalism – a social policy that recognises cultural diversity within the confines of a common superordinate national identity (Hornsey and Hogg, 2000).

Many people are unaware of their stereotypes and preconceptions about members of other groups because, as noted in the social cognition section of Chapter 15, stereotypes are automatically linked to categories (Bargh, 1989). Although making people aware of their stereotypes can persuade people that their beliefs are unjustified, this can backfire if people then try too hard to suppress their stereotypes. In one study, participants were shown a picture of a skinhead and then wrote a passage about a day in the life of that person (Macrae *et al.*, 1994). Half of the participants were instructed not to rely on stereotypes. Consistent with the instructions, participants in the no-stereotype condition used less stereotypical descriptions.

Next, participants were shown a picture of a second skinhead and were asked to write about a day in his life, but without suppression instructions. In this second stage, those who had been given the suppression instructions previously now showed a substantially increased use of stereotypical descriptions (see Table 16.1).

In a further experiment, compared with those in a control condition, participants who had first been in a suppress condition subsequently chose to sit further away from a chair they thought would be occupied by a skinhead. Macrae *et al.* reasoned that the effort involved in suppressing the stereotype actually makes the content of the stereotype more accessible. Thus, once a person is no longer actively suppressing the stereotype this content

Table 16.1 Ratings of passage stereotypically as a function of task instruction in Macrae *et al.*, Experiment 1

Passage	Instruction	
	Suppress stereotype	Control

becomes ‘hyperaccessible’ (Wegner and Erber, 1992), resulting in a stereotype rebound effect (see also Plant and Devine, 2001).

The knack would seem to be to get people to have insight into their stereotypes – to understand them and see through them rather than merely to suppress them. The best solution may be to teach people to become less cognitively lazy and to take the time to reflect about their biases. For example, Langer *et al.* (1985) gave a group of children specific training in thinking about the problems of people with disabilities. They thought about such problems as the ways that a person with disabilities might drive a car and the reasons why a blind person might make a good newscaster. After this training, they were found to be more willing to go on a picnic with a person with disabilities than were children who did not receive the training. They were also more likely to see the specific consequences of particular disabilities rather than to view people with disabilities as ‘less fit’. For example, they were likely to choose a blind child as a partner in a game of pin the tail on the donkey because they realised that the child would be likely to perform even better than a sighted child. Thus, at the individual level, people can learn to recognise their biases and to overcome their prejudices.

Devine (1989) proposed that even when a person has knowledge of a stereotype that is automatically linked to a category membership, the explicit application of a stereotype is a controllable process. It seems that people who are high and people who are low in prejudice towards a particular group may both share the same knowledge of the stereotype but low-prejudiced people may suppress or control the stereotype. However, the connection between categorising a person and applying a stereotype turns out to be complex. Lepore and Brown (1997) found that white British people’s stereotypes of West Indians were similar regardless of whether participants were high or low scorers on a measure of prejudice.

The important message from this research is that even though people may share knowledge of a stereotype, they apply the stereotype differently when a categorisation is activated. That is, high-prejudiced people seem more likely

to apply the negative aspects of the stereotype automatically, whereas low-prejudiced people are more likely to apply the positive aspects of the stereotype automatically.

What happens when a stereotype is activated directly at the same time as the category? For example, images conveyed by the music press often involve extreme representations of aggressive blacks (for example, rappers), or highly feminised and sexual images of women. It seems likely that such stereotypical images might override people's initial levels of prejudice. In line with this idea, Lepore and Brown (1997) found that when they primed participants with negative stereotype content (rather than just category labels) people who scored higher or lower on the prejudice scale were affected by the prime in the same way. Both sets of participants rated the target more negatively following the prime than when no prime was used. Thus, when the stereotype is activated directly, low- and high-prejudiced people apply negative stereotypical traits more readily.

With practice, stereotypes can be overcome: that is, when people either choose to, or are requested to, resist stereotypes over a period of time, the automatic associations they make with a particular category can be altered. A study by Kawakami *et al.* (2000) showed how people might be trained to avoid stereotyping. Participants were presented with a set of pictures and words. Half the participants were asked to say 'yes' if the word and picture were congruent (for example, a picture of a black person and a word that fits the stereotype of black people), and 'no' if they were incongruent (black person with a white stereotype word). The other half of the participants were in a stereotype negation condition. They were asked to say 'no' when the word and picture were congruent, and 'yes' when they were incongruent. This manipulation weakened the automatic linkage between the categorisation of the picture as black or white and the stereotype content associated with it. In the 'yes' condition but not the 'no' condition, participants categorised black and white faces faster when they were preceded by stereotype-consistent words.

The question is: how do low-prejudiced people sustain their low levels of prejudice in the face of pervasive social stereotypes? Monteith *et al.* (2002) argue that low-prejudiced people are especially sensitive to 'cues for control'. In essence, when automatic stereotype activation results in a reaction that is inconsistent with the way we think we should respond, this results in a negative sense of self – a sense of guilt or unease. This activates a behavioural inhibition system which ensures that behaviour matches the standards one sets for oneself. Over time, people learn that certain situational or other cues give advance warning that an undesired response is likely (for example, if race is mentioned in a conversation you might be alerted to the possibility that you could say something prejudicial).

Monteith *et al.* argued that when low-prejudiced individuals see images of black people linked with stereotypical content (for example, the statement 'this person spends a lot of time on the streets') this evokes guilt about the stereotypical association, and this in turn acts as a well-established cue for control.

In Monteith *et al.*'s research, participants who had completed measures of prejudice earlier in the year were asked to engage simultaneously in what they believed were two separate tasks. The first task was to decide whether pictures (of black and white people) had been presented before in the original format or as a mirror image. The second task was to decide what categories would best fit people described by a series of sentences (for example, the description 'this person has to do a lot of reading' fits the category 'college student'). Monteith *et al.* reasoned that if a picture of a black person happened to be presented in conjunction with a black stereotype description then this would constitute a cue for control among low-prejudiced people. Indeed, when these participants were presented with this combination of stimuli their decision times slowed down, relative to trials when the same sentences were paired with white faces. In contrast, participants who were high in prejudice were not expected to try to control their reactions, and in fact they responded with equal speed regardless of whether the black stereotypical sentences were paired with white or black faces. See Figure 16.7.

Various methods are available by which we could reduce prejudice but many of them rely on the consistent and motivated involvement of the prejudiced. With this involvement, the techniques might work. But this section provokes many questions. For example, how is it that we sometimes make important errors when we make judge-

Figure 16.7 Reaction times as a function of race of photo and participant type.

ments about other people? Why do we have immediate, ‘gut’ reactions to people and events, and what are the advantages and pitfalls?

Think about the amount of contact you have with people who are ethnically different from yourself. Maybe you live in a diverse neighbourhood or have gone on holiday to countries which are ethnically quite different from your own. In what ways do you think this may have changed (or not changed) your images of other ethnic groups as a whole? When have these encounters resulted in more positive attitudes to that group and when have your attitudes become more negative?

Finally, if you were hired by an organisation to design and implement a strategy to reduce harmful ethnic prejudice among employees within the organisation, what would your strategy comprise?

Aggression and helping behaviour

Aggression

Human **aggression** is often considered to be an innate component of our biological inheritance, a behaviour which is a necessary part of the evolutionary process that ensures survival of the fittest (Lorenz, 1966). Chapter 13 described some of the basic functions of aggression. The ability to hurt others may well have these roots; however, social psychologists tend to be more interested in discovering situational factors that encourage or inhibit aggression and explain the huge diversity of human aggression (Baron and Richardson, 1994).

Many factors can cause aggression. When important goals are frustrated, people can feel angry and express this as aggression, particularly when there is an available target for aggression without fear of retaliation, and when the person who is frustrated has few other coping mechanisms available. According to social learning theory (Bandura, 1977), aggression can be learned by simply observing other people being reinforced for behaving aggressively. Aggression can also become more likely in a given situation if a person who has a tendency to respond aggressively is aroused, even if the arousal has nothing to do with anger (it could be arousal from a gym workout, a film, a sexual encounter).

People with a type A personality or elevated testosterone levels are also more likely to be aggressive. Testosterone is the male hormone, so, not surprisingly males tend to be more physically aggressive than females, but the hormonal cause can be very difficult to dissociate from the fact that men are typically socialised to be more aggressive than are females. There is little difference in verbal aggression between males and females (Harris,

1992). There is also evidence that disinhibition, caused perhaps by deindividuation, which we described earlier in this chapter, can increase the probability of aggression. Aggression, in the form of assaults in Minneapolis, has even been shown to increase with increasing temperature, peaking at around 25° C and then dropping off as it gets even hotter (Cohn and Rotton, 1997).

There are many paths to aggression – not surprisingly, aggression is an enduring problem for society. Consider the following scenario. A male with a type A personality and elevated testosterone is driving home in a hurry from the gym in traffic where people are successfully cutting in. He is in a large car with dark windows and the CD on full blast. What do you think might happen if you were driving rather slowly in front of him, or took rather a long time to pull away from the traffic lights?

Alcohol and aggression

Alcohol consumption is often associated with aggression. Research suggests that alcohol makes people more prone to social influence while at the same time less able to think through the consequences of their actions for themselves or others. Together this facilitates aggression when people drink in groups in societies that glorify aggression (Bushman and Cooper, 1990). Causal links are complex. For example, perhaps aggressive people like to go drinking in groups, and they would be aggressive even if they had not been drinking? However, controlled studies have shown that people who had consumed alcohol were more likely to act aggressively when encouraged by a confederate than were those who had consumed a placebo.

Media violence and aggression

Many people believe that the mass media, particularly films and television, have much to do with aggression. There is no denying that these media portray a great deal of aggression and in the majority of cases the aggression brings rewards to the aggressor – violence seems to pay. **Social learning theory** makes the clear prediction that much of the aggression in our society is caused or amplified by excessive violence on television and in films. However, research is inconclusive about the causal links (Phillips, 1986): perhaps aggressive people watch or pay more attention to media aggression, whereas non-aggressive people either do not watch media aggression or simply do not pay much attention to it. Similar arguments hold for the evidence that violent pornography is associated with more aggressive attitudes and behaviours towards women: perhaps misogynistic attitudes encourage men to view violent pornography rather than vice versa.

Prosocial and helping behaviour

Aggression is generally regarded as antisocial and undesirable. The flip side of this kind of behaviour is **prosocial behaviour** and behaviour oriented towards helping others. Just as aggression may have an evolutionary dimension, so does prosocial behaviour – cooperative helping behaviour among people is the foundation of human endeavour, and so it would be expected that over millions of years predispositions to behave in this way would have a selective advantage (Wilson, 1978). But again, as with the study of aggression, social psychologists are more concerned to identify situational factors that encourage people to behave prosocially and to help other people.

Cooperation and social dilemmas

Despite the possibility of an evolutionary advantage to cooperative prosocial behaviour, people are remarkably uncooperative. One popular research paradigm involves the **prisoner's dilemma** (Rapoport, 1976), which you read about in Chapter 3. In one variant, two obviously guilty suspects are questioned separately by detectives who have only enough evidence to convict them of a lesser offence. The suspects are separately offered a chance to confess, knowing that if one confesses but the other does not, the confessor will be granted immunity and the confession will be used to convict the other of the more serious offence. If both confess, each will receive a moderate sentence. If neither confesses, each will receive a very light sentence. The prisoners are faced by a dilemma as to whether to trust one another in order to obtain the best joint pay-off. Although mutual non-confession produces the best joint outcome, mutual suspicion and lack of trust almost always encourage both to confess. This finding has been replicated in hundreds of prisoner's dilemma experiments, using a variety of experimental conditions and pay-off matrices (Dawes, 1991).

Many other **social dilemmas** involve a number of individuals or groups exploiting a limited resource (Kerr and Park, 2001) under conditions where, if everyone cooperates, an optimal solution for all is reached, but if everyone competes then everyone loses. These are called **commons dilemmas** because they are modelled on the 'tragedy of the commons'. English towns used to have common pasture on which people were free to graze their cattle. If all used it in moderation it would replenish itself and continually benefit them all. Imagine, however, 100 farmers surrounding a common that could support only 100 cows. If each grazed one cow, the common would be maximally utilised and minimally taxed. One farmer, however, might reason that if they grazed an additional cow, output would be doubled, minus a very small cost due to overgrazing – a cost borne equally by all 100 farmers. So this farmer adds

a second cow. If all 100 farmers reasoned in this way they would rapidly destroy the common, thus producing the tragedy of the commons. The commons dilemma is an example of a replenishable resource dilemma. The commons is a renewable resource that will continually support many people provided that all people show restraint in 'harvesting' the resource. Many of the world's most pressing environmental and conservation problems are replenishable resource dilemmas – for example, rainforests and the world's population of ocean fish are renewable resources if harvested appropriately.

Another type of social dilemma is called a public goods dilemma. Public goods, such as public health, national parks, clean air, and road networks are provided for everyone. Because public goods are available to all, people are tempted to use them without contributing to their maintenance.

Experimental research on social dilemmas finds that when self-interest is pitted against the collective good, the usual outcome is competition and resource destruction even when appeals are made to cooperative and altruistic norms (Kerr, 1992). People can, however, act more cooperatively when they identify with the common good (Brewer and Kramer, 1986). In other words, when people derive their social identity from the entire group that has access to the resource, self-interest becomes subordinate to the common good (de Cremer and van Vugt, 1999). However, the same research indicates that when different groups, rather than individuals, have access to a public good, then the ensuing intergroup competition ensures ethnocentric actions which are far more destructive than mere self-interest. International competition over limited resources such as rainforests, whales and wetlands tragically accelerates their disappearance.

Another way in which social dilemmas can be resolved is by putting in place various structural solutions. These include a range of measures such as limiting the number of people accessing the resource (via permits), limiting the amount of the resource that people can take (via quotas), handing over management of the resource to an individual (a leader) or a single group, facilitating free communication among those accessing the resource, and shifting the pay-off to favour cooperation over competition. The problem with structural solutions is that they require an enlightened and powerful authority to implement measures, manage the bureaucracy and police violations. This can be hard to bring about (Rutte and Wilke, 1984).

Bystander intervention

People sometimes find themselves in a situation where they witness an emergency where someone needs their help. When are people most likely to help and why?

In 1964 in New York City, a woman named Kitty Genovese was chased and repeatedly stabbed by an assailant, who took 35 minutes to kill her. The woman's screams apparently went unheeded by at least 38 people who watched from their windows. No one, it seemed, tried to stop the attacker; no one even made a quick, anonymous telephone call to the police. When the bystanders were questioned later, they could not explain their inaction. 'I just don't know,' they said.

As you can imagine, people were shocked by the bystanders' response to the Genovese murder. Commentators said that the apparent indifference of the bystanders demonstrated that American society, espe-

cially in urban areas, had become cold and apathetic. Experiments performed by social psychologists suggest that this explanation is wrong – people in cities are not generally indifferent to the needs of other people. The fact that Kitty Genovese's attack went unreported is not remarkable because 38 people were present; it is precisely because so many people were present that the attack was not reported. Recent research, however, including a detailed review of the case suggests that this picture is not as clear-cut as it has usually been portrayed in textbooks. The Controversies in Psychological Science section reveals some remarkable facts about the case and undermines some persistent myths.

Controversies in Psychological Science – What did Kitty Genovese's witnesses really witness?

The issue

Kitty Genovese is one of the most well-known women not only in social psychology, but in psychology in general. The horrific ordeal she went through gave rise to a theory of social behaviour and intervention and sparked a series of now-famous experiments on the bystander effect, described in the text. It was identified as a 'signal crime' – one that issued a warning about the breakdown in society's collective moral fabric (Innes, 2004). But was this research based on an enormous series of false premises? According to a review of the evidence by Manning *et al.* (2007), it was.

The evidence

These are the facts of Kitty Genovese's murder and the response to it:

In the early morning of 13 March 1964, Kitty Genovese was sexually assaulted and then murdered in the Kew Gardens district of Queens in New York. According to almost all textbooks you will read which report the case, 38 people witnessed the assault and murder at some point from a nearby building but did nothing to intervene or alert the police. Curiously, although the case was reported in the local paper the next day, reference to the 38 witnesses only appeared in a newspaper, *The New York Times*, two weeks later, on 27 March – '38 who saw murder didn't call the police,' the story boldly surmised and went on: 'Apathy at stabbing of Queens woman shocks inspector.'

However, research by a local historian and lawyer, Joseph de May Jnr, began to cast doubt on this interpretation. He found that:

- not all of the 38 alleged witnesses were eyewitnesses – some only heard noise from the assault;

- the police were called immediately;
- despite reports that witnesses had seen Kitty Genovese for 30 minutes, this was impossible because, given the geography and chronology of the assault, she could only have been visible for a few seconds;
- Kitty Genovese was still alive when the police arrived – she was not seen being murdered.

The story then becomes even more intriguing because no list of the 38 witnesses has ever been made available and the three witnesses in court said that their first glimpse of what transpired could not lead them to believe that what they were witnessing was a murder (Manning *et al.*, 2007). According to the District Attorney, only half a dozen people were found who saw something of relevance. None actually saw the stabbing and one reported shouting at the assailant. This scared him off. After this first attack, Kitty Genovese made her way around the corner of the building and tried to make her way to the entrance of her flat. She would have been out of sight of most witnesses. At the site of the second attack, the stairwell of 92–96 Austin Street, only one person could have seen what happened.

Despite reports to the contrary, some residents did try to contact the police. An affidavit sworn by a 15-year-old boy stated that his father called the police. At the appeal of the murderer in 1995, several of the residents stated that they had tried to call the police but were unsuccessful. There was no '911' service at that time and calls to the local police station were not always welcome. There were regular reports of trouble at a nearby bar and police found the constant aggravation troublesome. This bar had closed earlier than usual on the night of Genovese's murder. One resident was even reported to have telephoned another resident, called the police and went to Genovese's side.

Controversies in Psychological Science – Continued

Conclusion

What does this curious collection of facts demonstrate? First, it clearly demonstrates that you should never believe what you read in the papers. The hoo-ha over the YK2 Millennium Bug and other spurious fears, many of which are detailed in Nick Davies's *Flat Earth News* (2008), and the Controversies in Psychological Science section in Chapter 2, provides further evidence in support of the recommendation. Misreporting, however, is alive and well. Recall the supposition, guesswork,

accusations and rumour that surrounded Portugal resident Robert Murat and the media's assumption of his involvement of the kidnapping of Madeleine McCann in 2007. Second, far from sounding the death knell of the responsible citizen and the intervening bystander, it appears to show that citizen intervention was in reasonably good health.

The case of Kitty Genovese may, in Manning *et al.*'s words, be 'a stubborn and intractable urban myth'. It illustrates explicitly the value of evaluating everything you read, including this CiPS section.

Darley and Latané have extensively studied the phenomenon of **bystander intervention** – the actions of people witnessing a situation in which someone appears to require assistance. Their experiments have shown that in such situations the presence of other people who are doing nothing inhibits others from giving aid. For example, Darley and Latané (1968) staged an 'emergency' during a psychology experiment. Each participant participated in a discussion about personal problems associated with college life with one, two or five other people by means of an intercom. The experimenter explained that the participants would sit in individual rooms so that they would be anonymous and hence would be more likely to speak frankly. The experimenter would not listen in but would get their reactions later in a questionnaire. Actually, only one participant was present; the other voices were simply tape recordings. During the discussion, one of the people, who had previously said that he sometimes had seizures, apparently had one. His speech became incoherent and he stammered out a request for help.

Almost all participants left the room to help the victim when they were the only witness to the seizure. However, when there appeared to be other witnesses, the participants were much less likely to try to help. In addition, those who did try to help reacted more slowly if other people were thought to be present (see Figure 16.8).

Darley and Latané reported that the participants who did not respond were not indifferent to the plight of their fellow student. Indeed, when the experimenter entered the room, they usually appeared nervous and emotionally aroused, and they asked whether someone was helping the victim. The experimenters did not receive the impression that the participants had decided not to act; rather, they were still in conflict, trying to decide whether they should do something.

Thus, it seems that whether bystanders will intervene in a particular circumstance depends in part on how they perceive the situation. Latané and Darley (1970) have proposed a model describing a sequence of steps bystanders face when confronted with a potential emergency:

- 1 The event must come to their attention or be noticed.
- 2 They must assume some responsibility for helping the victim.
- 3 The possible courses of action must be considered and compared.
- 4 Finally, they must actually implement the chosen course of action.

Of course, this sequence takes place rapidly and without much awareness on the bystander's part, as is true of many situations to which we respond daily.

Unfortunately, at least from the perspective of the victim, obstacles may arise at any stage in this decision-making process, which make it unlikely that a bystander

Figure 16.8 Bystander intervention. Percentage of participants attempting to help as a function of the number of other people the participants believed to be present.

Source: Based on data from Darley, J.M. and Latané, B., Bystander intervention in emergencies: Diffusion of responsibility. *Journal of Personality and Social Psychology*, 1968, 8, 377–83.

will intervene. In many cases, the bystander who is aware that others are available to help may not feel any personal responsibility to do so, a phenomenon called **diffusion of responsibility**. This factor is considered to be responsible for the finding that help is less likely to be offered when there are several bystanders present. In addition, the bystander may not feel competent to intervene or may be fearful of doing so; consequently, no action is taken. Shotland and Heinold (1985) staged an accident in which a person seemed to be bleeding. Bystanders who had received training in first-aid treatment were much more likely to come to the victim's aid, and they did so whether or not bystanders were present. Because they knew how to recognise an emergency and knew what to do, they were less likely to fear doing the wrong thing.

In life-saving and first-aid classes, people are taught to take control in emergency situations. For example, in a situation in which a person appears to be drowning, they assign onlookers specific responsibilities, such as calling emergency services, fetching rescue equipment, and so on. To what extent does taking control in this manner enhance bystander intervention? What effect might it have on the onlookers' tendency towards diffusion of responsibility?

Attraction and relationships

One of the most pervasive and immediate aspects of social life is our interpersonal relationships. It is, therefore, no accident that soap operas and celebrity magazines have a huge following, and they focus almost exclusively on close relationships – friendships, enmities, family life, romance and so forth. For most of us, much of our day-to-day happiness or misery rests on how our personal relationships are faring.

Interpersonal attraction

One of the key features of our interpersonal relationships is whether we like someone or not, and whether they like us – **interpersonal attraction**.

Many factors determine interpersonal attraction. Some factors are characteristics of the individuals themselves; others are determined by the socially reinforcing aspects of the environment. Interpersonal attraction is an important aspect of more enduring and closer relationships, such as friendships; however, the bases of attraction can change as one moves through different stages of a relationship (Duck, 1992). Physical appearance and attitudinal similarity can be very important in the initial stages of a relationship, whereas deeper personality similarities and complementarities of needs may become more important later on.

Physical appearance

Despite such maxims as 'Beauty is in the eye of the beholder', 'Never judge a book by its cover', and 'Beauty is only skin-deep', research confirms that we tend to like physically attractive people more than physically less attractive people (Langlois *et al.*, 2000). Social reinforcement provides a likely explanation for this phenomenon. Someone who is seen in the company of an attractive person and is obviously favoured by this person is likely to be well regarded by other people.

Walster *et al.* (1966) studied the effects of physical appearance at a dance at which university students were paired by a computer. Midway through the evening, the experimenters asked the participants to rate the attraction they felt towards their partners and to say whether they thought they would like to see them in the future. For both sexes, the only characteristic that correlated with attraction was physical appearance. Intelligence, grades and personality variables had no significant effect.

When people first meet someone who is good-looking, they rate the person as probably holding attitudes similar to their own and tend to assume that they have a good personality, a successful marriage and high occupational status (Dion *et al.*, 1972). In fact, physically attractive people usually do possess many of these characteristics, probably because they receive favourable treatment from society (Hatfield and Sprecher, 1986).

However, among same-sex heterosexual individuals, physical appearance may have its drawbacks, especially if members of the other sex are involved. For example, consider a study in which females were shown photos of the same woman dressed either casually or provocatively and either talking or not talking to a man in the presence of his female companion (Baenninger *et al.*, 1993). The female participants rated the 'other woman' in the photos more negatively when she was provocatively dressed than when she was casually dressed. Thus, we seem to take into account the particular circumstances under which we meet another person – their sex and the other people who may be present – when making judgements about that person and their attractiveness.

Proximity

Not surprisingly, the mere physical proximity of one person to another is a potent facilitator of attraction (Sprecher, 1998). Festinger *et al.* (1950) found that the likelihood of friendships between people who lived in an apartment house was related to the distance between the apartments in which they lived: the closer the apartments, the more likely the friendship was. People were also unlikely to have friends who lived on a different floor unless their apartments were next to a stairway, where they would meet people going up or down the stairs.

Proximity enhances familiarity, and familiarity has been shown to increase liking. We tend to grow to like things that become familiar to us over repeated exposure. Repetition generally increases our preference for a stimulus. This phenomenon applies to people as well. Even in the brief time it takes to participate in an experiment, familiarity affects interpersonal attraction. Saegert *et al.* (1973) had female university students participate in an experiment supposedly involving the sense of taste. Groups of two students (all were participants; no confederates this time) entered booths, where they tasted and rated various liquids. The movements of the participants from booth to booth were choreographed so that pairs of women were together from zero to ten times. Afterwards, the participants rated their attraction to each of the other people in the experiment. The amount of attraction the participants felt towards a given person was directly related to the number of interactions they had had – the more interactions, the more attracted they were to those persons (see Figure 16.9). And as you saw in Chapter 13, those who smile more are liked more.

Reciprocity

Liking follows the reciprocity principle – we tend to like those who like us. Dittes and Kelley (1956) led students in small discussion groups to believe, by way of anonymous written evaluations (actually written by the experimenters), that other group members either liked or disliked them. Results showed that students who believed they were liked were more attracted to the group than were those who believed they were disliked. More recently, Sprecher (1998) found reciprocal liking to be one of the major determinants of interpersonal attraction.

However, people with low or high self-esteem respond differently. People with high self-esteem base their liking for others less strongly than do people with low self-esteem on whether other people like them. In addition, we tend to like others who grow to like us, and dislike those who initially like us and then cool off on us – this is called the **gain-loss hypothesis** (Aronson and Linder, 1965). There are two possible explanations for this effect. When rejection changes to acceptance, the anxiety over rejection is reduced so that we experience the pleasure of being liked. Alternatively, it is possible that we regard those who like us from the beginning as indiscriminating, and this reduces the value of their praise. Those who dislike us to begin with but then re-evaluate as they get to know us better are discerning people, so their praise is worth more.

Similarity and need complementarity

Another factor that influences interpersonal attraction is similarity – similarity in looks, interests and attitudes. Couples tend to be similar in attractiveness. In fact, couples

Figure 16.9 Familiarity, exposure and attraction. The rated likeability of a fellow participant as a function of number of interactions.

Source: Based on data from Saegert, S.C., Swap, W. and Zajonc, R.B., Exposure, context, and interpersonal attraction. *Journal of Personality and Social Psychology*, 1973, 25, 234–42.

who are mismatched in this respect are the most likely to break up (White, 1980). Although we might think that people would seek the most attractive partners that they could find, people tend to fear rejection and ridicule. Men especially tend to be afraid of approaching attractive women for this reason (Bernstein *et al.*, 1983).

Couples (and groups of friends) also tend to hold similar opinions. Presumably, a person who shares our opinions is likely to approve of us when we express them. Also, having friends who have similar opinions guarantees that our opinions are likely to find a consensus; we will not often find ourselves in the unpleasant position of saying something that invites disapproval from other people. Byrne (1971) confirmed, in a series of laboratory experiments, the important role of attitude similarity in relationships. The results were so reliable and consistent that Byrne formulated a '**law of attraction**': attraction towards a person bears a linear relationship to the proportion of attitudes associated with the person. The more that other people agree with you, the more reinforcing they are and the greater your attraction to them. For example, if you suddenly discover that someone you are going out with likes the same obscure rock group as you, your liking for that person will suddenly increase.

Similarity of attitudes is not the only factor determining the strength of interpersonal attraction. Other kinds of similarity are also important, such as age, occupational status and ethnic background. Friends tend to have similar backgrounds as well as similar attitudes. In addition,

liking can sometimes rest on dissimilarity. Winch (1958) suggested that under some circumstances, particularly in more developed relationships, people seek others who have different qualities from ourselves and who can thus best satisfy our needs – we pursue **need complementarity**.

Loving

The relationships we have with others are generally marked by two different kinds of emotion: **liking**, a feeling of personal regard, intimacy and esteem towards another person, and **loving**, a combination of liking and a deep sense of attachment to another person. Loving someone does not necessarily entail romance. You may have several close friends whom you love dearly yet have no desire to be involved with romantically.

Romantic love, also called **passionate love**, is an emotionally intense desire for sexual union with another person (Hatfield, 1988). Feeling romantic love generally involves experiencing five closely intertwined elements: a desire for intimacy with another, feeling passion for that person, being preoccupied with thoughts of that person, developing feelings of emotional dependence on that person, and feeling wonderful if that person feels romantic love towards you and dejected if not.

‘Falling in love’ and ‘being in love’ are common expressions that people use to describe their passionate desires for one another. Passionate love may occur at almost any time during the life cycle, although people involved in long-term cohabitation or marriages seem to experience a qualitatively different kind of love. The partners may still make passionate love to one another, but passion is no longer the defining characteristic of the relationship. This kind of love is called **companionate love** and is characterised by a deep, enduring affection and caring for another. Companionate love is also marked by a mutual sense of commitment, or a strong desire to maintain the relationship. How passionate love develops into companionate love is an unanswered question, although it is likely that the sort of intimacy that punctuates romantic love is still a major force in the relationship. An important feature of intimacy is self-disclosure, or the ability to share deeply private feelings and thoughts with another. Indeed, part of loving another is feeling comfortable sharing deeply personal aspects of yourself with that person.

Sternberg (1988b) has developed a theory of how intimacy, passion and commitment may combine to produce liking and several different forms of love (see Table 16.2). According to this theory, liking involves only intimacy, infatuation involves only passion, and empty love involves only commitment. Combining any two of these elements produces still other kinds of love. Romantic love entails both intimacy and passion but no commitment. Companionate love

Table 16.2 Sternberg’s theory of love

According to Sternberg, love is based on different combinations of intimacy, passion and commitment. These elements may combine to form eight different kinds of relationship

	Intimacy	Passion	Commitment
Non-love			
Liking	*****		
Infatuated love		*****	
Empty love		*****	
Romantic love	*****	*****	
Companionate love	*****		*****
Fatuous love		*****	*****
Consummate love	*****	*****	*****

***** indicates that the element is present in the relationship; a blank space indicates that the element is absent or is present only in low quantities

Source: After Sternberg, R.J., *The Triangle of Love*. New York: Basic Books, 1988.

entails both intimacy and commitment but no passion. Fatuous love (a kind of love marked by complacency in the relationship) entails both passion and commitment but no intimacy. The highest form of love, consummate love, contains all three elements.

Sternberg’s theory is descriptive. It characterises different kinds of love but it does not explain the origins of love. What function has love served in the evolution of our species? The answer can be summed up very succinctly: procreation and child-rearing. Although love of any kind for another person is not a necessary requirement for sexual intercourse, a man and a woman who love each other passionately are more likely to have sex than are a man and a woman who do not. And if their union produces a child, then love serves another function – it increases the likelihood that both parents will share in the responsibilities of child-rearing. Our capacity for loving, then, contributes in very practical ways to the continued existence of our species.

Is Sternberg’s theory of love an accurate account of your own experience with different kinds of love? Are there kinds of love that you have experienced that are not included in his theory?

Maintaining and ending relationships

Research on the maintenance of relationships has mainly dealt with heterosexual marriages in Western societies. Marital satisfaction seems to rest on companionate love and role complementarity, coupled with a sense of security and a shared search for new excitements and stimulation.

Commitment, the desire or intention to continue in the relationship, is crucial. Highly committed partners have a greater chance of staying together (Adams and Jones,

1997), and the very idea of subjectively committing oneself to a relationship can be more important than the conditions that led to commitment (Berscheid and Reis, 1998). Commitment has also been linked to the level of marital satisfaction, pro-relationship behaviour and trust. Two longitudinal studies by Wieselquist *et al.* (1999) revealed that commitment-inspired acts, such as accommodation and willingness to sacrifice, are good indicators of someone's pro-relationship motives. This is a cyclical model: such acts in turn elicit the partner's trust and reciprocal commitment and subsequent dependence on the relationship.

Adams and Jones (1997) pinpointed three factors that contribute to an ongoing relationship: (1) personal dedication (positive attraction to a particular partner and relationship); (2) moral commitment (a sense of obligation, religious duty or social responsibility, as controlled by a person's values and moral principles); and (3) constraint commitment (factors that make it costly to leave a relationship, such as lack of attractive alternatives, and various social, financial or legal investments in the relationship). More informally, relationship maintenance depends on people's feelings that: (1) they want to continue the relationship; (2) they ought to continue it; (3) they must continue it.

The end of a relationship is heralded by four factors (Levinger, 1980): (1) a new life seems to be the only solution; (2) alternative partners are available; (3) there is an expectation that the relationship will fail; and (4) there is a lack of commitment to a continuing relationship. Rusbult and Zembrodt (1983) believe that once deterioration is identified, it can be responded to in any of four ways. A partner can take a passive stance and show loyalty by waiting for an improvement to occur, or neglect, by allowing the deterioration to continue. Alternatively, a partner can take an active stance and show 'voice' behaviour, by working at improving the relationship, or exit behaviour, by choosing to end the relationship.

Duck (1992) describes a **relationship dissolution model** of four phases that partners pass through when a breakup occurs. There is an intrapsychic phase that involves brooding and some needling of the partner. The next phase is the dyadic phase. The pair will discuss the relationship, identify problems and make attributions of blame. The third phase is the social phase. In saying that the relationship is near an end, the partners may negotiate with friends, both as a means of social support for an uncertain future and for reassurance of being right. The social network will probably take sides, pronounce on guilt and blame and, like a court, sanction the dissolution. The final grave-dressing phase involves elaborating an acceptable account of the relationship that preserves one's reputation for reliability in future relationships. This 'grave-dressing' activity seeks a socially acceptable version of the life and death of the relationship.

Attraction is usually seen as a positive thing, but to what extent is it likely to be an advantage or a problem if people within a workplace (classroom, office, military unit) are attracted to one another? How likely is this to happen, and why?

Communicating and language

In many ways, communication is the essence of human social life, and the use of language to communicate is almost exclusively a human quality. People communicate both using language and non-verbally, and in recent years computer-mediated communication has become an entire new dimension of communication.

Speech and language

Spoken language communicates information in many different ways. First of all, what we actually say communicates information – if a person says, 'It's very hot in this room', then that tells you something about temperature. Sometimes, however, what we mean may not be evident in what we say. There is often a hidden subtext to language and the meaning of what we say can only be found by a detailed analysis of the entire discourse or text – what we say, to whom, and in what immediate and broader social context. You saw in Chapter 10 how context is important when revealing sex differences in communication.

Computer-mediated communication

In the past, people communicated with one another by speaking face-to-face, and if that was not possible by writing letters. Text communication has been with us for thousands of years, but its form and function has dramatically and very suddenly altered with the advent of computer-mediated communication (CMC). In the developed world we now conduct our business and personal relationships overwhelmingly by email, instant messaging, texting, in chat rooms, and so forth. Things have changed so quickly that research on CMC is in its infancy – as yet relatively fragmented, unprogrammable, and atheoretical (Hollingshead, 2001). The study of CMC recruits what we know about non-verbal communication and group processes. From research so far there are at least four general findings:

- 1 CMC restricts non-verbal communication channels and other accompaniments to spoken language (stress, pitch, speed, tone pauses), called paralanguage. This has relatively little effect on communication between

strangers, but it has a detrimental effect on interaction between people who have a closer relationship. Some non-verbal and paralanguage cues can, however, be introduced into CMC by emphasis, for example ‘YES!!!’, or by means of emoticons such as the sideways ‘smiley’ :-).

- 2 CMC can suppress the amount of information that is exchanged, which in turn can lead to poorer communicative outcomes. Generally, procedural aspects of group discussion that improve information exchange and group decisions in face-to-face settings may not have the same effect in computer-mediated settings.
- 3 CMC has a ‘participation equalisation effect’ that evens out many of the status effects that occur in face-to-face communicative contexts. People may feel less inhibited because they are less identifiable and may be deindividuated (Postmes *et al.*, 1998). However, the effect does depend on how completely identity and status markers are concealed by the electronic medium (Postmes *et al.*, 2001; Sassenberg and Boos, 2003). For example, emails often have a signature that clearly indicates the identity and status of the communicator.
- 4 Although, on balance, CMC initially hinders interaction and group performance, over time people adapt quite successfully to their mode of communication (Walther, 1996). Indeed, in many ways people gradually respond to CMC as if it was not computer-mediated. For example, Williams *et al.* (2000) found that when people are ignored in email interactions or chat rooms, they can interpret it as ostracism (called cyberostracism) and can react much as they would in face-to-face settings.

One interesting line of research on CMC focuses on sex differences. Do men and women use the medium differently? After all, men and women do differ in how they communicate non-verbally when interacting with each other. Thompson and Murachver (2001) investigated students’ email messages, and found clear sex differences even when the sex of the target person was unknown to the sender. The differences were small, but when used in combination allowed quite accurate classification of a male or a female sender. Here are some differences. Female students used more intensive adverbs (for example ‘it was *really* good’), hedges (‘it was *sort of* interesting’), emotive references (‘I was *upset*’) and provided more personal information (for example, where they worked). On the other hand, male students were more insulting (for example, ‘you were stupid to take that course’) and offered more opinions (‘the protest was worthwhile’). Perhaps with your own knowledge of sex-stereotypical behaviour these findings do not surprise you.

Non-verbal communication

Verbal communication is accompanied by a smorgasbord of non-verbal cues that are richly communicative (DePaulo and Friedman, 1998). **Non-verbal communication** provides information about feelings and intentions (for example, non-verbal cues are often reliable indicators of whether someone likes you). It also can be used to regulate interactions (non-verbal cues can signal the approaching end of an utterance, or that someone else wishes to speak), to express intimacy (touching and mutual eye contact), to establish dominance or control (non-verbal threats), and to facilitate goal attainment (for example, pointing).

Cutting edge – What’s in a name?

The British sitcom character, Hyacinth Bucket in *Keeping Up Appearances*, was so snobbishly offended by her surname, she adopted the phonological moniker, ‘Bouquet’. Hilarity ensued as people would read her name as Bucket only for the character to disdainfully and brusquely upbraid them for their mispronunciation. People with the surname Pratt must have a difficult life. Some names appear guaranteed to produce a stereotypical response.

But is there any good evidence that your name influences people’s reactions to you? Researchers in management at the Universities of California and Yale suggest that there is. They have found that, astonishingly, students whose names begin with the letters A or B achieved a higher grade point average (GPA, the American system of combining and averaging scores for end-of-school performance) than did those whose names

began with C or D (Nelson and Simmons, 2007). If the students liked their initials, the effects were even more pronounced, i.e. if they liked the letters A and B, they were even more likely to have a high GPA. The inference is that those letters were associated with better and poorer grades, respectively. Those students with C/D names moved onto graduate schools of poorer quality and reputation than did those with A/B names.

These data are correlational. But when the researchers set up a study to see whether name actually influenced task performance, they found that participants solved fewer anagrams when a consolation prize shared their first initial than when it didn’t.

So, if your name is Adam Boulton, you’re blessed. But where this leaves Celine Dion is anyone’s guess.

People tend to have less control over non-verbal than verbal communication, and people are often unaware that they are sending or receiving non-verbal cues. Non-verbal sensitivity improves with age, is more advanced among successful people, and is compromised among people with various psychopathologies. Women are generally more adept than men at detecting and sending non-verbal communications; however, they differ less in conscious awareness of precisely what information has been communicated by which non-verbal channel, and they are worse than men at recognising covert messages such as discrepant or deceptive communications (Hall, 1984). These differences are probably due to child-rearing strategies that encourage girls more than boys to be emotionally expressive and attentive.

Because the eyes are often considered to be the windows of the soul, eye contact, now technically called **gaze**, communicates an enormous amount of information (Kleinke, 1986). For example, people gaze more at people they like, and lower-status people gaze more at higher-status people than vice versa except when a higher-status person wants to exert control over a lower-status person. Because white adults tend to gaze more when listening than when speaking, a speaker who increases gaze signals that they are about to stop speaking, and a listener who reduces gaze indicates that they are about to start speaking.

More general facial expressions are a rich indicator of people's feelings. Research shows that facial expressions are universal indicators of six basic emotions: happiness, surprise, sadness, fear, disgust and anger (Ekman, 1982). There are, however, strong cultural differences in the expression of emotion – for example, the expression of emotion is encouraged in Mediterranean cultures but discouraged in Asian cultures (Gallois, 1993).

The body itself is a means of communication, via postures and gestures. For example, postures can communicate liking – people who like one another tend to lean forward, maintain a relaxed posture and face one another. It can also communicate status – higher-status individuals adopt a relaxed, open posture, with arms and legs asymmetrically positioned and a backward lean to the body, whereas lower-status individuals adopt a more rigid, closed and upright posture, with arms close to the body and feet together (Mehrabian, 1972). Gestures are more straightforward – pointing at one's chest refers to self, beckoning with an upturned finger invites someone to approach, and so forth.

Touching means different things depending on the type of touch, the context within which the touch occurs, who touches whom, and what the relationship is between the interactants (Jones and Yarbrough, 1985). For example, touching can communicate liking, control, playfulness, and so forth. The prevalence and acceptability of touching varies markedly between cultures – northern Europeans hardly touch at all, whereas Latin Americans touch a

great deal. Jourard (1966) observed people in cafés, and noted, in a one-hour period, no touching at all in London and 180 touches in Puerto Rico.

Finally, how close people position themselves relative to other people, **interpersonal distance**, communicates intimacy and liking. Hall (1966) has identified four interpersonal distance zones: intimate (up to 0.50 m), personal (0.5–1.25 m), social (1.25–4 m) and public (4–8 m). Clearly, if you want to become intimate with someone you will stand close, and if that person would rather not be that intimate they will move away.

Speech style

Language also communicates information by the way we say things – the language, accent, or **speech style** we use. For example, just saying 'Hello' conveys entirely different information if it is said in French or English, with an American or South African accent, in a lively, cheerful manner or a flat, depressed manner. Language contains **social markers** that convey information about the context, the person who is speaking, and the person who is being spoken to (Scherer and Giles, 1979). Social markers tell us, for example, about someone's mood or health, the formality of the situation, and the social category membership of the interactants – their age, sex, socio-economic status, ethnicity, and so forth.

The study of social category markers, particularly ethnicity markers, shows that language use and speech style in particular contexts are influenced to a significant extent by the relative social standing of identities that are cued by language and speech style, and that even second language proficiency is influenced in this way.

Because language is often an integral aspect of ethnic identity, indeed many groups effectively define themselves through their language (called **ethnolinguistic groups**), intergroup dynamics that affect whether a group thrives or not can also impact language. Languages can thrive, revive or die. The key variable here is **subjective ethnolinguistic vitality**, which refers to people's overall perception of the status of their language, how much support it has from society and social institutions, how many people speak the language and whether numbers are increasing or decreasing (Harwood *et al.*, 1994). High vitality encourages continued use of the language and thus ensures its survival and the survival of the ethnolinguistic group itself as a distinct entity in society. Low vitality is associated with declining use of the ethnic language, its gradual disappearance, and often the disappearance of the ethnolinguistic group as a distinct entity: that is, there is language death or language suicide. This analysis has been used to help understand the French language revival in Quebec over the past 30 years (Bourhis, 1984), and the loss of Japanese culture and language by third-generation Japanese in Brazil (Kanazawa and Loveday, 1988).

Because language is so tied up with identity, identity dynamics may impact one's motivation to become proficient in a second language. Many societies are multilingual with a dominant language – for example, in Britain English is the dominant language, but there are large numbers of people for whom Urdu or Hindi are their native tongue. What influences whether these people acquire native-like rather than classroom proficiency in English? According to Giles and Byrne (1982), it is all a matter of motivation, which hinges on the perception of whether or not native-like proficiency adds something of value to one's identity or subtracts from one's identity (Sachdev and Wright, 1996).

Low ethnic identification, low subjective vitality and a belief that one can 'pass' linguistically into the dominant group, coupled with a large number of other potential identities of which many are high status, are conditions that motivate the individual to acquire native-like mastery in the second language. Proficiency in the second language is considered economically and culturally useful; it is additive to one's identity. Realisation of this motivation will be facilitated or inhibited by the extent to which one is made to feel confident or anxious about using the second language in specific contexts. The converse set of sociopsychological conditions motivates people to acquire only classroom proficiency. Through fear of assimilation, the second language is considered subtractive in that it may attract in-group hostility and accusations of ethnic betrayal. Intelligence and aptitude will also affect proficiency.

How one speaks says much about one's status in society, and so it is not surprising to discover that we can change our speech style in different contexts to address issues of status – we can do this deliberately, but to a great extent this is an automatic process. **Speech accommodation theory** (Giles, 1984) describes the type of accommodation that occurs as a function of the social

orientation that two speakers have towards one another. Where an interpersonal orientation exists, such as that between two friends, bilateral speech convergence occurs. Higher-status speakers shift their accent or speech style 'downwards' towards that of lower-status speakers, who in turn shift 'upwards'. Convergence increases interpersonal speech style similarity and thus enhances interpersonal approval and liking, particularly if the convergence behaviour is clearly intentional.

Where an intergroup orientation exists between the speakers, accommodation depends on the perceived nature of the relations between the two groups. If the lower-status group has low subjective vitality coupled with a belief in social mobility (i.e. that one can pass, linguistically, into the higher-status group), there is unilateral upward convergence on the part of the lower-status speaker and unilateral speech divergence on the part of the higher-status speaker. In intergroup contexts, divergence achieves psycholinguistic distinctiveness: it differentiates the speaker's in-group on linguistic grounds from the out-group. Where an intergroup orientation exists and the lower-status group has high subjective vitality coupled with a belief in social change (i.e. that one cannot pass into the higher-status group), bilateral divergence occurs: both speakers pursue psycholinguistic distinctiveness.

The social psychology of gossip

According to the Machiavellian intelligence or social brain hypothesis of how our minds evolved, the intelligence of primates evolved in order to solve social, rather than non-social, technological problems (such as finding food). The hypothesis is partly supported by research showing that when people are allowed to converse freely, two-thirds of their conversation comprises social topics – gossip (rather than work, leisure, arts, politics). Researchers from the

Cutting edge – I don't mean to be rude, but . . .

People often think that if they preface saying something socially difficult or unpleasant with a self-effacing disclaimer, the difficult or unpleasant thing will be more positively received. A recent study has tested whether such disclaimers work (El-Alayli *et al.*, 2008). In the first study, participants rated the arrogance of people who began what they were saying with 'I don't mean to sound arrogant, but . . .' These people were only rated as arrogant when the disclaimer was actually followed by an arrogant statement. Similar findings were found when the disclaimer involved selfishness or laziness.

The researchers found that a tendency to believe that a person is what they claim to be (selfish, arrogant, lazy etc.) is

enhanced not because we categorise them using the information we have available but because we make assumptions about their personality, based on the same information. Making the arrogance salient, then following it up with an arrogant statement means that the disclaimer has backfired because the initial information has already shaped our view of the speaker.

Of course, there are different sorts of disclaimers, as the researchers point out: 'I'm not prejudiced but . . .', 'I could be wrong, but . . .' and 'This may sound mad, but . . .' Would these also undermine the meaning of what a person is trying to convey?

universities of St Andrews and Liverpool investigated the type of social information that was better transmitted from person to person (Mesoudi *et al.*, 2006).

In one study, they found that when participants read about social interactions, their recall of these interactions was no different for gossip or non-gossip content. The interactions they read about involved very 'social' topics such as infidelity, deception and pregnancy. However, transmission was more accurate when there were a

number of third party people interacting, i.e. the more people there were to gossip with, the more accurate the recall of that gossip. The authors suggest that this supports the Machiavellian hypothesis although perhaps the type of material described as gossip might have some other feature that might explain why it was more salient. If the protagonist had violated a social norm, for example, this would be more salient than if somebody had given a man, who was not her boyfriend, a lift into work early that morning.

Chapter review

Social influence

- Compliance with a request can be strengthened by ingratiation, reciprocity, or making multiple requests to prepare the target for the focal request – foot-in-the-door, door-in-the-face, low-balling.
- People have a tendency to blindly obey orders from people in authority, even when the consequence of obedience is terrible suffering for others. Obedience drops dramatically when there is social support for disobedience.
- Social interaction, particularly when people are uncertain or are in need of social approval, produces group norms that subsequently regulate behaviour.
- People conform because they are unsure, in need of approval, or define themselves – their identity – in terms of a group that is defined by the norms.
- Although people usually conform to majorities, minorities can change attitudes and behaviour through a conversion process. To do this, minorities need to be internally consensual in repeatedly, but not dogmatically, promulgating the same message.

People in groups

- The presence of other people enhances the performance of a well-learned behaviour but interferes with the performance of complex or poorly learned behaviour.
- When a group of people must collectively perform a task, the effort of any one individual is usually less than we would predict had the individual attempted the task alone – a behaviour known as social loafing.
- Loafing is reduced among people who value their group and feel they must compensate for others' performances. It is also reduced when people feel more identifiable and when they feel the task is important.
- Groups often exist to make decisions. Effective group decision-making can be hampered by elements of the discussion leading to the decision. This can cause groups to make very extreme decisions (polarisation) or very bad decisions (groupthink).
- Groups often need to remember a great deal of information. One way to do this effectively is to have a transactive memory structure in which different individuals or different sub-groups

are responsible for remembering different information, but all members of the group know who is responsible for what.

- Groups usually have leaders. Leadership effectiveness ultimately rests on whether the group perceives the leader as being legitimate, as having the requisite skills, as being a loyal and focal group member, and as having the appropriate relationships with followers.
- People in crowds can sometimes behave antisocially because they feel anonymous and not responsible for the consequences of their actions – they are deindividuated.
- Collective events can also change people's identities so that they identify with the identity of the crowd and conform strongly to group norms.

Intergroup relations and prejudice

- Intergroup relations exist whenever people belonging to one group interact collectively or individually with another group or its members in terms of their group identifications.
- Where groups have the same goal, but only one group can achieve the goal at the expense of the others, then intergroup relations become highly conflictual. Where groups have the same goal, but the goal can only be achieved by the groups working cooperatively together, intergroup relations are more harmonious.
- Where groups feel their goals are being frustrated by another group, or that they are deprived relative to another group, conflict and negative attitudes arise – the target is often a weaker scapegoat group.
- The framework of intergroup competition or hostility is also contained in the mere fact of the existence of different categories – in-groups and out-groups.
- People derive a sense of who they are – a social identity – from the groups they belong to, and thus they are prepared to protect these groups against other groups. Because groups define and evaluate one's identity, and thus self-concept, people strive to evaluate their groups more positively than other groups.
- Prejudice is an attitude, usually negative, towards a particular group. Its cognitive component is stereotypes, and its behavioural manifestation is discrimination.

- Stereotypes and prejudices may be strengthened because people inflate the co-occurrence of negative behaviours and distinctive groups, and also exaggerate the perceived homogeneity of out-groups.
- Some people may be more prejudiced than others, but generally we can all be prejudiced if the social conditions favour prejudice. Prejudice stigmatises and disadvantages other people, but prejudice can be difficult to detect where social norms and legislation outlaw blatant prejudice.
- Teaching people to think about members of other groups as individuals and to consider them in terms of their personal situations and characteristics can reduce prejudices and tendencies towards stereotyping.
- Although initially appealing, simply bringing different groups into contact with one another, so that they become familiar with one another, is not reliably effective in reducing prejudice.

Aggression and helping behaviour

- Arousal, frustration, disinhibition and elevated testosterone levels are all factors that can lead to human aggression.
- People can also learn to be aggressive by witnessing other people being reinforced for aggressive behaviour.
- Alcohol and media violence may also contribute to aggression.
- People often find it difficult to sacrifice their own personal short-term gains for long-term collective gains. This is the social dilemma that underpins many of the world's greatest environmental problems. Social dilemmas can be reduced when people feel themselves part of a community or group that accesses a resource. Leadership, resource management and limited access to a resource, can also help.
- People often fail to help in an emergency (called bystander apathy) if there are many other potential helpers available or if they feel they do not have the resources to help. Misperception of norms can sometimes inhibit people from offering assistance in an emergency.

- Bystander intervention is facilitated if there are only few bystanders present and if they feel they have the resources (time, ability and so forth) to help.

Attraction and relationships

- We tend to be attracted to others who think positively of us, who are similar to us, who are physically attractive, and who live, work or play near us.
- Sternberg's theory of love describes how the elements of intimacy, passion and commitment are involved in the different kinds of love.
- The course of a relationship is strongly influenced by the degree of commitment the partners have to the relationship.

Communication and language

- Speech conveys information not only through the words we use but also through how we say things. The speech style we adopt (language, accent) is a reliable cue to group membership (age, sex, ethnicity and so on).
- Language and accent are often defining features of groups, particularly ethnic groups. Whether an ethnic language thrives or perishes is influenced by the vitality of the language and the group it defines – a high-vitality language is one that has substantial material and social support in society, and contributes positively to one's sense of self.
- Because speech style cues group membership, people can consciously or unconsciously accentuate or de-emphasise their speech style to conceal or to publicise their group membership.
- Speech is accompanied by non-verbal cues that are particularly important for communicating feelings and relationships, and for regulating conversation. Some of the most important non-verbal channels are gaze, facial expression, postures, gestures, touch and interpersonal distance.

Which? Calls for 'fat tax' on unhealthy food

Rebecca Smithers

The government is being urged to consider a 'fat tax' on foods high in fat, salt and sugar, in a report which says existing policies aimed at ending the obesity crisis through healthier eating are confusing. In the report, called *Hungry for Change*, the consumer group *Which?* calls on the government to explore a range of radical financial incentives to encourage families to eat more healthily, including imposing an extra tax on foods deemed unhealthy.

Source: from 'Which? Calls for 'fat tax' on unhealthy food', *The Guardian*, 11 March 2009 (Smithers, R.), Copyright Guardian News & Media Ltd 2008.

Explore the accompanying videos, simulations and animations on MyPsychLab. This chapter includes activities on: Factors that contribute to health • Selye's general adaptation syndrome • Why do you drink? • What personality type are you? • Check your understanding and prepare for your exams using multiple choice, short answer and essay practice tests also available.

WHAT YOU SHOULD BE ABLE TO DO AFTER READING CHAPTER 17

- Define health psychology.
- Describe some of the factors that can lead to (or prevent) overeating, cigarette smoking, sexually transmitted disease, alcohol use and physical inactivity.
- Evaluate the psychological strategies that have been employed to reduce ill health.
- Describe and understand the process of stress and its effects on the immune system.
- Define psychoneuroimmunology and understand its significance to health.
- Evaluate the role of personality and specific styles of behaving in the maintenance of health and ill health.

QUESTIONS TO THINK ABOUT

- What is health psychology and how does it differ from abnormal psychology?
- What illnesses can psychology help to prevent? How can it do this?
- How can people stop eating fatty food, smoking or be encouraged to take up physical exercise?
- What is the role of personality in the development or prevention of illness?
- What effect do stressors have on health and the immune system?
- Can public health education campaigns change behaviour? How would you design an effective one?

Health psychology: a definition

The particular behaviours that make up an individual's way of life have important consequences for that individual's quality of life. Whether a person smokes, drinks alcohol, eats specific foods, exercises, has regular health checks and is susceptible to stress can all have an impact on a person's health and beliefs about their health. Such beliefs and behaviour are at the core of what health psychology seeks to understand. **Health psychology** is the branch of psychology that applies psychological principles to the understanding of health and illness. Factors influencing health can be external (in the form of stressors, health promotion, advertising of health-impairing products) or internal (in the form of thoughts, beliefs, decision-making and coping responses).

According to Matarazzo (1982), the aims of health psychology are to promote and maintain health, to prevent and treat illness, to identify the causes and symptoms of illness and the causes of health, and to analyse and improve healthcare systems/policy. It is a relatively new branch of psychology and, as its subject matter suggests, has a slight overlap with clinical psychology. Both health psychology and clinical psychology study stress and how people cope with it, but health psychology tends to concern itself with bodily illness whereas clinical psychology is primarily concerned with mental illness. (Clinical psychology is the subject of the next chapter.) Many of the theories and explanations for health-related behaviour and experience derive from work in cognitive and social psychology. Because of this fusion of psychologies and because of the subject matter of health psychology, the sub-area was not regarded as a distinct branch of the discipline until relatively recently.

Health and ill health

The starting point for all health psychologists is the definition of health and the determinants of health. Health has been defined as 'a positive state of physical, mental and social well-being – not simply the absence of injury or disease – that varies over time along a continuum. At the wellness end of the continuum, health is the dominant state. At the other end of the continuum, the dominant state is illness or injury' (Sarafino, 2002). A healthy lifestyle is one that can enhance an individual's physical and mental well-being; an unhealthy lifestyle is one that diminishes physical and psychological well-being. According to Whitehead (1995), the determinants of good health can be conceived of in the way suggested in Figure 17.1.

Figure 17.1 The types of factor which Whitehead suggests are contributors to health.

Source: Whitehead, M., *Tackling health inequalities: An agenda for action*. In M. Benzenal, K. Judge and M. Whitehead (eds) *Tackling Inequalities in Health: An agenda for action*, p. 23. London: King's Fund, 1995. © 1995 King's Fund. Reprinted by permission

In this model, the individual is at the centre and possesses immutable characteristics which can influence health (such as age, sex, race, genetic make-up). Surrounding the individual are four interacting layers which represent external determinants of health. These include the individual's lifestyle, their social and community influences, living and working conditions, and the general cultural and environmental conditions in which the individual lives.

Some specific examples of factors within each of these layers include nutrition, alcohol consumption, smoking, sexual behaviour and exercise. Health psychologists attempt to understand the factors which influence health and, if these factors are detrimental to health, apply psychological techniques in order to promote good health and discourage unhealthy behaviour. They are also involved in psychological aspects of healthcare and in determining the effects of government health policy on behaviour. The following sections evaluate the role of specific behaviours – eating, exercising, smoking, drinking alcohol and having unprotected sex – in health and illness.

Nutrition

Over the past 150 years or so, our diet has changed considerably: it is higher in fat and lower in fibre, largely because processed foods, fast food and sweets are high in fat and low in fibre. Diets too high in saturated fats (those fats found in animal products and a few vegetable oils) and too

low in fibre have been associated with specific health disorders, such as **coronary heart disease (CHD)**, the narrowing of blood vessels that supply nutrients to the heart, and cancer, a malignant and intrusive tumour that destroys body organs and tissue (Cohen, 1987). CHD and cancer are two of the leading causes of death in Western nations (World Health Organization, 2007).

The chief culprit in CHD is **serum cholesterol**, a chemical that occurs naturally in the bloodstream where it serves as a detoxifier. Cholesterol is also the source of lipid membranes of cells and steroid hormones. It is a vital substance and we would die without it. Cholesterol has two important forms: HDL (high-density lipoprotein) and LDL (low-density lipoprotein). HDL is sometimes called 'good' cholesterol because high levels of it are inversely associated with CHD; it seems to play a protective role in the bloodstream. LDL is often called 'bad' cholesterol because high levels of it are associated with the formation of atherosclerotic plaques, which clog arteries. Fibre is an important dietary component because it helps to reduce LDL cholesterol levels (and aids digestion). People with pre-existing heart complaints are prescribed the cholesterol-reducing drugs, statins.

Cohen (1987) has shown that cultures having the highest death rates due to breast cancer are those in which large amounts of fats are consumed. People in countries such as the UK, the Netherlands, Canada and the USA have a relatively high fat intake and relatively high death rates due to breast cancer. In contrast, people in countries such as Japan and Thailand have both relatively low fat intake and relatively low death rates due to breast cancer. There is

evidence that specific lifestyles within these cultures can help to reduce the risk of cancer and other illnesses, and this is discussed below.

Of course, bad nutrition is different from malnutrition and the latter is more serious. According to the World Health Organization's (2007) estimates, 55 million children under 5 years of age show signs of wasting/malnutrition, and the global pattern of stunting in children can be seen in Figure 17.2. The highest number of these children live in south central Asia.

Heart disease and eating – explaining the French paradox

A paradox familiar to health researchers and gourmands alike is this: the French diet is laden with highly palatable saturated fat, and the nation's blood cholesterol level is high yet the incidence of death caused by heart disease is lower in France than it is in the United States. Of course, a highly fatty diet may not necessarily lead to heart disease and there could be other explanations for the French paradox including genetic differences, metabolism, a less stressful life, differences in attitudes towards illness, different eating patterns, greater exercise and so on (Rozin, 1999).

The body mass index of French people tends to be significantly lower than that of Americans: they are leaner. One reason for the leanness, despite the content of the diet, may be that they actually eat less. Although the diet may appear superficially frightening in terms of its nutritional content, it is a diet of moderation, rather than excess.

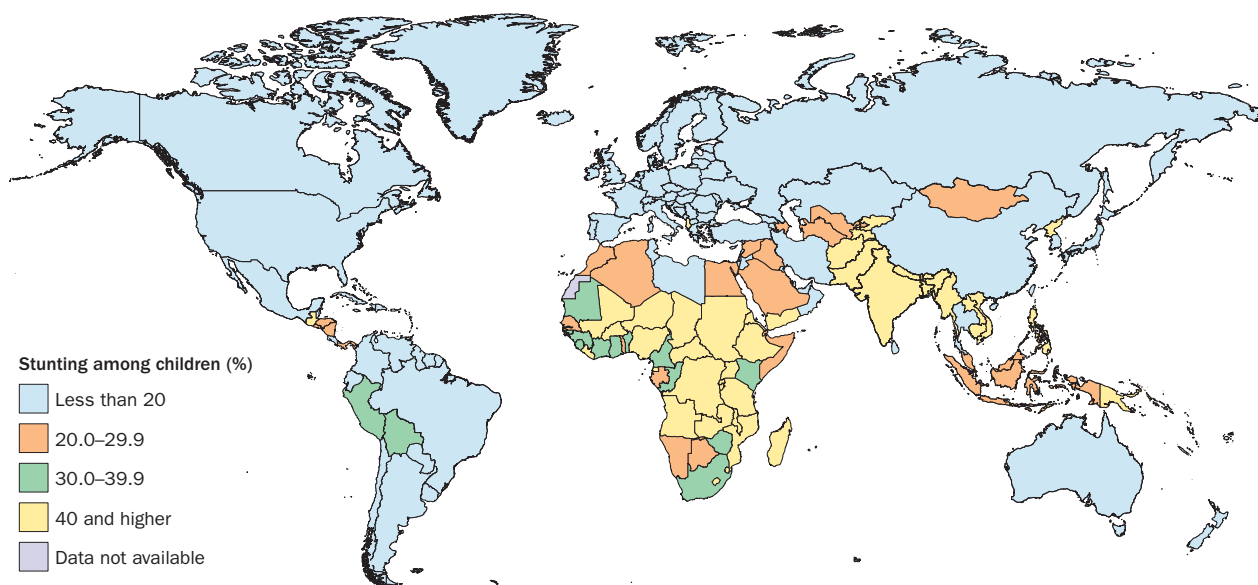

Figure 17.2 Geographical pattern of stunting in children under 5 years of age.

Source: World Health Statistics, 2007.

To examine whether this could explain the French paradox, Paul Rozin and a group of researchers at the University of Pennsylvania, USA, and CNRS in Paris, examined portion sizes in French and American fast-food restaurants (e.g. Pizza Hut, McDonald's, Hard Rock Café, Quick, Burger King, etc.), more upmarket restaurants (e.g. bistros) and supermarkets (Rozin *et al.*, 2003). The study took place in Pennsylvania and Paris. The portion sizes described in the cities' respective *Zagat* guide (a restaurant guide) were also compared.

When supermarket and restaurant foods were analysed, the French portions were indeed smaller. Of course, even small portions can be calorifically intense but the eating of many small, highly-calorific portions does not appear to occur in the French diet. The French also spent more time eating than did the Americans suggesting that the eating experience for the French amounts to more than the ingestion of food: it is a social, cultural – possibly, emotional – experience.

Physical fitness

People in developed countries lead increasingly sedentary lives; our work has changed (it is less physical) as have our leisure opportunities (we can watch more television, surf the internet and play computer games). Like high-fat, low-fibre diets, lack of exercise is correlated with increased risk of CHD (Peters *et al.*, 1983; Powell *et al.*, 1987). People who exercise regularly appear to accumulate less body fat and to be less vulnerable to the negative effects of stress than are people who do not exercise regularly (J.D. Brown, 1991).

There is some evidence that regular exercisers are likely to live longer (Paffenbarger *et al.*, 1986). This evidence comes from a longitudinal study of the lifestyles of 17,000 Harvard University alumni. Between 1962 and 1978, 1,413 of the original 17,000 participants died, 45 per cent from CHD and 32 per cent from cancer. Significantly more of these deaths occurred in participants who had led sedentary lives. Those alumni who reported that they exercised the equivalent of 30–35 miles of running or walking per week faced half the risk of dying prematurely compared with those who reported exercising the equivalent of five or fewer miles per week. On average, those who exercised moderately (an equivalent of 20 miles running or walking per week) lived about two years longer than those who exercised less than the equivalent of five miles.

These results have been replicated in a sample of elderly individuals. The relationship between the time that elderly (61–81 years old) non-smoking participants spent walking and the death rate was monitored over a period of 12 years (Hakim *et al.*, 1998). Men who walked more than two miles a day lived significantly longer than those who

exercised less. Only 21.5 per cent of the two-mile walkers had died after 12 years, whereas 43 per cent had died in the group that undertook less exercise. Cancer and CHD was also lower in the walkers: this effect occurred even when other factors (such as blood pressure, alcohol consumption, medical condition, cholesterol level) had been taken into account. However, diet was not considered and there is the possibility that healthy eating may have been responsible for the reduced death rate. If a factor (such as walking or diet) can benefit health or make an individual less susceptible to illness or ill health, this factor is called a protective factor. In other words, this factor protects the individual from ill health. (Of course, it cannot prevent an illness, only protect a person from developing it.)

Although a brisk walk is often recommended to those who are not as agile as they once were, many elderly individuals continue to lead a sedentary lifestyle. Our immune system, the part of the body that fights infection (as you'll see later on), deteriorates with age, and this may expose the elderly to an increased risk for illnesses, such as upper respiratory tract infection.

To see if regular exercise could protect against infection, a group of researchers at the University of Tokyo measured immune system response on three occasions over 12 months in a group of normally sedentary elderly individuals who engaged in two bouts of 60-minute exercise a week for the duration of the study (Akimoto *et al.*, 2003). Participants, who were aged 65 years and older, engaged in resistance training (back, chest and inner thigh exercises) and endurance training (aerobic exercise such as 'step' and ball games).

MRI scans of a clinically obese and a healthy individual.

Source: Marty Chobot/National Geographic Image Collection.

The secretion and concentration of an important antibody (a chemical produced by the body to fight infection) increased significantly over the period of study – before training, 4 months in and 12 months in – suggesting the benefits of this simple exercise regime to immune system functioning. Although the study did not use a control group, or examine the possible different effects of resistance and endurance training, the findings suggest a relatively easy way of protecting immune system functioning in a group that is susceptible to immune system decline.

Types of exercise

According to Cooper (1985), aerobic exercises such as running, walking, cycling and swimming are superior to other forms of exercise for improving cardiovascular health. **Aerobic exercises** are those which expend consid-

erable energy, increase blood flow and respiration and thereby stimulate and strengthen the heart and lungs and increase the body's efficiency in using oxygen. Running at least two miles in less than 20 minutes four times a week (or any equivalent aerobic exercise), significantly increases cardiovascular health (Cooper, 1985). One study showed that aerobic exercise had an additional benefit: reduced heart response to mental stress (Kubitz and Landers, 1993). Two groups of students who had not exercised for at least three months prior to the study were divided into two groups. One group rode an exercise bike three times a week for 40 minutes for eight weeks; the other group did not perform any aerobic exercises. At the end of the eight-week period, both groups were given timed colour perception and maths tests. Participants in the aerobic exercise programme showed lower absolute heart rates in response to the tests than did the participants who did not exercise.

Controversies in Psychological Science – Can exercise improve mood?

The issue

Exercisers frequently report that they feel better after a bout of vigorous exercise (the so-called feel-good effect). They feel an increase in positive mood and self-confidence that can sometimes translate into better work performance or cognitive ability. But is there scientific evidence demonstrating the positive effects of exercise on mood?

The evidence

Although exercise can have significant immediate effects on mood, these effects are dependent on the types of exercise taken (Biddle, 1995; Scully *et al.*, 1998). Petruzello *et al.* (1997), for example, found that exercise reduced state anxiety (the anxiety felt at the time) only after aerobic exercise. When trait anxiety was examined (the anxiety that individuals consistently feel, independently of their environment), a training programme lasting ten weeks reduced anxiety.

An analysis of a large number of studies investigating the effect of exercise on depression has found a moderate effect of acute and chronic exercise on depression, with those requiring clinical treatment showing the greatest reduction in depression (North *et al.*, 1990). In fact, exercise seems to be better than psychotherapy in alleviating negative mood, and exercise and psychotherapy seem to be better than exercise alone (Martinsen, 1995).

Other studies suggest similar effects of exercise on mood but in more specific contexts. Mondin *et al.* (1996), for example, examined the effects of exercise deprivation on the mood

of ten volunteers who regularly exercised for 45 minutes a day, 6–7 days a week. The participants exercised for a day, took three days off and resumed exercise on the fifth day. Depriving participants of exercise was associated with an increase in self-reported mood disturbance, state anxiety, tension, depression, confusion and a decrease in vigour. These changes were reversed when exercise resumed. Of course, one could attribute these results to factors other than exercise. Perhaps the disturbance in these individuals' routine affected their performance.

In a comparison of participants' mood before and after aerobic dance exercise, soccer, tennis or bowling, Rudolph and Kim (1996) found that mood improved only after the aerobic exercise and soccer. Biddle's review (Biddle, 1995) suggests that intensity of exercise may be a factor in enhanced mood, and perhaps this explains the result of this study. Running at intense levels over short durations increased stress but running over long distances increased arousal (Kerr and van den Wollenberg, 1997).

If exercise does improve mood, how much is needed and at what intensity? Hansen *et al.* (2001) measured mood before and after resting (sitting quietly) and before and after three bouts of exercise, lasting 10, 20 and 30 minutes, respectively, in a group of 20–25-year-olds. During the exercise conditions, participants worked on a bicycle ergometer (in essence, an exercise bike) which allowed participants to exercise with moderate intensity. After 10 minutes of cool-down – the post-exercise period – mood was measured again.

Controversies in Psychological Science – *Continued*

They found that vigour, fatigue and total mood improved after 10 minutes of exercise but no improvement in mood was seen after 20 minutes of exercise, suggesting that up to 20 minutes' worth of exercise may be the maximum required to attain a positive mood state.

Many people abandon exercise regimes because the intensity is too great and may feel negatively because of this level of strain and difficulty. In one experiment, 24-year-old undergraduates rested for two minutes as their respiration was monitored, then walked for three minutes on a treadmill at 4.8 kph (Hall *et al.*, 2002). Speed was subsequently increased to 8 kph and workload was increased every two minutes by 1.6 kph. The study continued until the participant reported being too physically exhausted to participate.

During the increments, there was an increase in arousal but little improvement in mood. When exercise reached a moderate intensity, however, there was still an increase in arousal but also a shift towards negative mood. When the exercise session was over and participants had cooled down, there was a recovery in mood. Within a minute, participants reported increased levels of positive mood.

Conclusion

The studies reviewed here suggest that exercise can have a beneficial effect on mood by decreasing state anxiety and depression if the exercise is relatively acute and is of a specific type. Deprivation of exercise in those who habitually exercise may be detrimental to mood.

Cigarette smoking – An international perspective

It has been estimated that between 1950 and 2000, 25 million deaths in the European Union were caused by smoking (Cancer Research UK, 2006; Peto 1994), and in 2005 5.4 million deaths were attributable to smoking (World Health Organization, 2007). The pattern varies by country, but approximately 35 per cent of men and 25 per cent of women in the EU smoke – rates of women smoking have fallen in Denmark, the Netherlands, Sweden and the UK but have risen in Greece, Portugal and Spain. Figure 17.3 shows the degree of cigarette consumption across the world.

Smoking is thought to cause a third of cancers (Doll and Peto, 1981). According to the Imperial Cancer Research Fund, the death rate is the equivalent of a jumbo jet crashing every day of the year and killing all the passengers. Worldwide, smoking is thought to cause 4 million deaths a year, and this is estimated to increase to 7 million by 2030 (Peto, 1994; World Health Organization, 2002b). Concerned by this fatal relationship, more and more governments have begun to ban smoking in public places – California in 1996 and 1998; Ireland in March 2004, Scotland in 2006 and the rest of the UK in 2007. Almost all industrialised societies now have some sort of ban in place, as you can see in Figure 17.4.

The largest reduction in smoking is found in the most well-off (Marsh and McKay, 1994); the failure to quit has been associated with low income (Nevid *et al.*, 1996), as Figure 17.5 shows.

Prompted by international data suggesting that smoking and its health-related problems were more prevalent in lower socio-economic groups than in higher ones, Droomers *et al.*

(2002) obtained data on smoking and socio-economic status from the Dutch GLOBE study of 27,000 individuals recruited from south-eastern Netherlands in 1991. GLOBE is the Dutch acronym for Health and Living Conditions of the Population of Eindhoven and its Surroundings.

Droomers *et al.* examined the relationship between educational level and the intention to smoke in 1,354 beginning Dutch smokers. Smoking information was obtained in 1991 and then 6.5 years later. The researchers found that participants at the lower end of the education spectrum were significantly more likely to continue smoking than were their better-educated counterparts.

Smoking is also associated with many problem behaviours such as a higher intake of fatty food (Shah *et al.*, 1993), lower fruit and vegetable intake, higher alcohol intake (Morabia and Wynder, 1990), and less physical activity. Current smokers have been found to consume more alcohol, meat, eggs and chips more frequently than former or non-smokers, although sweet consumption in those who have stopped smoking is higher (French *et al.*, 1996).

In addition to these health risks, people who use tobacco also face increased risks of cancer, bronchitis, emphysema, strokes and ulcers. Non-smokers who are exposed to air contaminated with cigarette smoke (second-hand smoke) also face increased risks of CHD and cancer. As a result of the negative effects of smoking, this behaviour is banned in many public places such as public transport, restaurants, cinemas, offices, hospitals, schools and so on.

A 'stigmatised habit'

People hold justifiably negative views of smoking and because of this it has been labelled a 'stigmatised habit' (Furnham *et al.*, 2002). Their research showed that when people are asked to prioritise who should receive health-care, for example, smokers are normally given the lowest priority. A study at University College London confirmed this view. The researchers asked 100 adults to rank 16 hypothetical patients in terms of priority for treatment for three medical conditions: heart transplantation, *in vitro* fertilisation (IVF) and cosmetic surgery. Participants were told that these patients would be treated by a UK National Health Service hospital, that is, a hospital directly funded by public taxation and which offers treatment free at the point of delivery. Information about patients varied according to age, annual income, smoking behaviour and whether the patient had children. The researchers found that young people, non-smokers and those on a low annual income were given highest priority and smokers the lowest priority. The existence of children only influenced decisions about IVF and heart transplant.

The results are consistent with other studies of people's attitudes to smokers, with young people preferentially prioritised for kidney dialysis treatment (Furnham and Briggs, 1993) and smokers given lower priority (Furnham *et al.*, 2000). As dialysis is unrelated to smoking, this result coupled with the findings from Furnham *et al.*'s study indicates little sympathy towards those who smoke. Smoking appears to be a 'stigmatised habit' which can

cloud perceptions of smokers and their treatment for illnesses unrelated to their habit. Of course, these studies asked for the general public's attitudes, and not doctors'.

Factors which promote the initiation and maintenance of smoking

What causes people, especially adolescents, to begin smoking? Psychologists know that both imitation and peer pressure contribute to the acquisition of the smoking habit (Lynskey *et al.*, 1998). Adolescents who have favourable impressions of a smoker are likely to imitate that person's actions. Cigarette manufacturers use this knowledge to advertise their products: they often portray smoking as a glamorous, mature, independent, and sometimes rebellious behaviour. In a longitudinal study of 643 14–17-year-olds and their smoking behaviour, the best predictor of smoking was peers' smoking six months earlier; parental smoking also predicted smoking (Biglan *et al.*, 1995).

The news and entertainment media are powerful shapers of our opinions, beliefs and behaviours. Magazine advertisements generally portray cigarette smokers as young, healthy, attractive and exciting individuals, despite the reality. A survey of European women's magazines reported that only four of the highest selling weekly and monthly magazines refused tobacco advertising (Amos *et al.*, 1998).

Some of the strategies which may prevent the recruitment of smokers include price increases, limiting access to young people, developing non-smoking policies for

schools, banning advertising and tobacco sponsorship of sporting (and any other public) events, and spending more on health education. A survey of 80 Australian smoking experts (from government, universities and professional and volunteer organisations) who had been asked to rate the smoking reduction strategies they considered to be most effective, reported that increased tobacco taxes would be the most effective strategy, followed by TV campaigning, having smoke-free areas and banning tobacco advertising (Paul and Sanson-Fisher, 1996). As we will see from the evidence below and in the Psychology in Action section, some of these strategies may be more effective than others.

Two American studies of adolescents' smoking habits show an interesting pattern of recruitment and cessation. Chassin *et al.* (1996) examined the history of smoking from adolescence to adulthood in a longitudinal study of 4,035 participants (with roughly equal numbers of men and women, with an average age of 29 at the end of the study). The authors reported an increase in the initiation of smoking from adolescence to adulthood, with a slight decrease in the participants' initiation in their mid-twenties and no initiation in adulthood. This finding suggests that smoking begins in adolescence and that the discouragement of smoking should target this age group. Those who did not quit were likely to have smoking parents and be less well educated than those who successfully quit. Rose *et al.*'s (1996) study of 700 adolescents found that attempting to quit was associated with being female, attaining some college education, perceiving smoking as dangerous (both generally and personally), being married and occupying several social roles. Health beliefs about the dangers of smoking did not predict cessation.

In two separate studies, Lucas and Lloyd (1999) and Crisp *et al.* (1999) investigated why girls start smoking and why they persist in smoking, respectively. Lucas and

Lloyd (1999) conducted a questionnaire survey of 11–16-year-old schoolchildren's experiences of their first cigarette. This included asking them about their age at first cigarette, the source of the supply, the location of the first smoke, the people present at the first smoke and the perceived degree of coercion involved in smoking for the first time. The average age of the first smoke was significantly lower for boys than for girls (the only measure to show a sex difference; in fact, men also seem to be able to give up more successfully [Wetter *et al.*, 1999]). Smoking for the first time tended to involve two friends and did not lead to regular smoking. This trend (the lack of a tendency to smoke regularly) is also reported in a study by Bell *et al.* (1999). They looked at the incidence of smoking in adolescents from their last year at secondary school to 22 months after leaving school. There was no straightforward progress from 15-year-old smoker to 17-year-old smoker. Peer pressure appeared to play little role in maintaining smoking, but smokers did indicate that they were likely to start smoking with friends and when drinking alcohol, suggesting that adolescents socialise with individuals with similar interests rather than with those they necessarily call role-models or peers whose behaviour needs to be emulated.

One of the reasons why girls are thought to take up smoking is a belief that it protects them from eating disorders. Crisp *et al.* (1999) looked at the relationship between smoking and eating disorder concerns in adolescents and middle-aged women with eating disorders. Smokers were prone to be slightly overweight in the teenage years but below normal weight in middle age. In the teenage smoking group, weight dropped from puberty onwards. The relationship between smoking and vomiting was especially strong in both eating-disordered and normal teenage girls.

Psychology in action – How to stop smoking

A number of measures have been put in place to help people give up smoking – they range from the economic – bans on tobacco advertising, restricting sales, increasing prices, to the psychological – providing education and behavioural strategies for quitting. Figures 17.6 and 17.7 show the countries that now have in place advertising bans and health-warnings on tobacco products.

When Willemsen and De Zwart (1999) reviewed studies examining the effect of these measures on adolescent smoking, they found that, in isolation, few of them were effective; the

measures were most effective in combination. Of the isolated measures, price increases were the single most prohibitive factor. Setting an age limit had no effect on smoking.

Non-psychological intervention programmes for cigarette smokers have explained nicotine replacement. This replacement is normally undertaken via a nicotine gum or a transdermal patch, a plaster-like patch that allows nicotine to be absorbed through the skin. The patch was developed by a behavioural psychologist, Frank Etscorn. Over several months, the nicotine levels of the patches are reduced, and the individual is weaned

Psychology in action – Continued

from nicotine altogether. The success rate is mixed. A review of the effectiveness of nicotine gum and patches suggests success rates of 11 per cent and 13 per cent for each therapy respectively (Law and Tang, 1995). These figures are comparable to the success of other treatment approaches.

Quitting smoking has both immediate and long-term positive effects, as Table 17.1 shows, although quitting (and maintaining that quitting) is not easy for smokers.

Prevention programmes designed by health psychologists and health professionals are generally aimed at combating social factors such as imitation, peer pressure and influence from advertisements that can initially induce people to light up (Evans *et al.*, 1984). Situations in which quitters may lapse are those in which smoking cues and alcohol consumption are present (Schiffman, 1982). When smokers and quitters are tempted to smoke, they are usually feeling quite negative and restless, are exposed to smoking cues and are likely to be eating or drinking in company (Schiffman *et al.*, 1996).

Exposing smokers to positive images of smoking has been shown to predict their willingness or intention to smoke (Dinh *et al.*, 1995) whereas exposing them to negative images predicts successful abstinence from smoking (Gibbons and Eggleston, 1996). These findings suggest that altering the way in which a person thinks about smoking can help stop the

behaviour. One Canadian anti-smoking programme, the Waterloo Smoking Prevention Project (Flay *et al.*, 1985), has been especially effective in reducing the number of young adolescents who experiment with smoking, by asking students to seek out information about smoking, to think about their beliefs regarding smoking, to learn about the social pressures involved in smoking and to give them explicit training in how to resist those pressures – for example, politely turning down a cigarette when one is offered.

By the end of the two-year period, fewer than 8 per cent of the students who had been involved in the prevention programme were experimenting with smoking. In contrast, almost 19 per cent of the students who had not gone through the programme had experimented with smoking. While these results are encouraging, the students were only monitored for two years.

Studies over longer time periods suggest that a large proportion of patients with heart disease who were smokers quit smoking following a specially constructed smoking cessation programme. One compared the rates of quitting over five years in 160 patients with coronary heart disease (Rosal *et al.*, 1998). The patients were randomly assigned to two groups: one received basic advice about stopping smoking; the other received a more intensive intervention programme which involved a 30-minute in-patient counselling session, an out-

Table 17.1 The body's response to stopping cigarette smoking

Timescale	Response
<i>Within 20 minutes of last puff</i>	Blood pressure and pulse return to normal levels
<i>Within 8 hours</i>	Nicotine and carbon monoxide levels in the blood are halved, oxygen levels in the blood return to normal
<i>Within 1 day</i>	Carbon monoxide is eliminated from the body and lungs start to clear out the accumulated tar
<i>Within 2 days</i>	There is no tar left in the body Taste and smell start to return to normal
<i>Within 3 days</i>	Breathing becomes easier due to relaxing of bronchial tubes Energy levels increase
<i>From 2 weeks to 3 months</i>	Circulation of the blood improves Walking and running become easier
<i>From 3 months to 9 months</i>	Coughs, wheezing and breathing problems improve as lung function is increased by up to 10 per cent
<i>After 5 years</i>	Risk of heart attack falls to about half that of a smoker
<i>After 10 years</i>	Risk of lung cancer falls to half that of a continuing smoker

Source: No Smoking Day website, <http://www.nosmokingday.org.uk>

Psychology in action – Continued

patient counselling visit and counselling by telephone. The group which received the intensive counselling maintained significantly higher quit rates over five years. Factors, apart from the intervention programme, which were associated with successful quitting included having 12 years of education, having the intention to quit and having high self-belief.

Between 2000 and 2001, the American Cancer Society trialled a telephone counselling programme for smokers who wanted to quit (Rabius *et al.*, 2004). Over 3,000 callers notified the Society of their intent to quit; of these, 420 were aged between 18 and 25 years. When intention to give up smoking was measured, quit rates were significantly higher among older and younger smokers who received telephone coun-

selling (compared with those who received a self-help booklet). Although cessation was reported by the participant – and there was no attempt to verify this – the results suggest that telephone counselling may be a useful way of helping smoking cessation.

The psychological evidence suggests that a number of specific factors can trigger smoking: these include visual, social and physiological cues. Evidence from studies in which an attempt is made to stop smoking by engaging smokers in an intervention programme shows that the studies' success rate is variable but that specially designed intervention programmes are more effective than doing nothing at all to stop smoking.

The physiology of smoking

Cigarette smoking, like other forms of drug use, is addictive: the nervous system may develop a tolerance to the drug or become physically dependent on the drug. Tolerance simply means that the neurons in the central nervous system (CNS) respond progressively less to the presence of the drug; larger doses of the drug are required to produce the same CNS effects that smaller doses produced earlier. Physical dependence means that CNS neurons now require the presence of the drug to function normally. Without the drug in the CNS, the individual will experience withdrawal symptoms, or uncomfortable physical conditions, such as sweating, tremors and anxiety. In addition to tolerance and physical dependence, many drugs, including the nicotine in cigarette smoke, produce psychological dependence, a craving to use the drug for its pleasurable effects. Consequently, obtaining and using the drug become focal points of an individual's life. An objective way of describing psychological dependence is to say that it involves behaviour that is acquired and maintained through positive reinforcement. A reinforcing drug is one that strengthens or maintains the behaviour that constitutes seeking, acquiring and using the drug.

The nicotine contained in cigarette smoke exerts powerful effects on the CNS and heart by stimulating postsynaptic receptors sensitive to the neurotransmitter acetylcholine (these are called nicotinic acetylcholine receptors). This stimulation produces temporary increases in heart rate and blood pressure, decreases in body temperature, changes in hormones released by the pituitary gland, and the release of adrenalin from the adrenal glands, as well as changes in motor and cognitive behaviour.

In common with all reinforcers, natural and artificial, it also causes secretion of dopamine in the brain; the release of dopamine in the brain is reinforcing, so this effect contributes to the maintenance of cigarette smoking. An

injection of nicotine increases firing in dopamine neurons in one part of the brain (ventral tegmental area) and enhances its release in another (Besson *et al.*, 2007). When the ventral tegmental area is injected with nicotine, this increases self-administration of nicotine (David *et al.*, 2006). Cigarette smoking may also be maintained by negative reinforcement. People who try to quit smoking usually suffer withdrawal symptoms, including headaches, insomnia, anxiety and irritability, and at a neurophysiological level, the acetylcholine receptors might be desensitised. These symptoms are relieved by smoking another cigarette. Such negative reinforcement appears to be extremely powerful. Over 60 per cent of all smokers have tried to quit smoking at least once, but have started again in order to escape the unpleasant withdrawal symptoms.

Nicotine alone cannot be blamed for the health risks posed by cigarette smoking. These risks are caused by the combination of nicotine with other toxic substances, such as the carbon monoxide and tars found in cigarette smoke. For example, while nicotine causes an increase in heart rate, the carbon monoxide in smoke deprives the heart of the oxygen needed to perform its work properly. The smoker's heart undergoes stress because it is working harder with fewer nutrients than normal. Over a period of years, this continued stress weakens the heart, making it more susceptible to disease than is the heart of a non-smoker.

Alcohol use

Alcohol is probably the most widely used and abused substance that requires the consumer to be of a given age before it is sold or used. When psychologists refer to substance abuse, they mean that the substance is used in a way that poses a threat to the safety and well-being of the user, to another, or to both. Most people who use alcohol do not abuse it, and not all people

who abuse alcohol are alcoholics. People who drive under the influence of alcohol pose a serious threat to both themselves and others, but they may not be alcoholics.

Data suggest that people in the age range typically representing students (18–24 years) drink more alcohol than their non-student counterparts (O'Malley and Johnston, 2002); over 40 per cent of students say that they are heavy or binge drinkers (Wechsler *et al.*, 2002). According to a study of 300 first-year students at the University of South Florida, however, this heavy drinking may be dependent on the year in which the students are studying; it may not, for example,

appear in the first year (Del Boca *et al.*, 2004). Students were asked to self-report their monthly alcohol consumption during their first year at university. About a fifth of the students were abstinent during the 32-week period of the study. Binge drinking varied from week to week but did not exceed 30 per cent. Drinking was heaviest during the holiday period.

Figures 17.8 (a) and (b) show the pattern of drinking consumption in the EU, recorded in 2002. Figures 17.9 (a) and (b) show the pattern of mortality from alcohol-related illness in men and women (such as cirrhosis and head/neck cancers) in the EU.

Source: From IAS Fact Sheet: Alcohol Consumption and Harm in the UK and EU. London: IAS, 2003.

Alcoholism is an addiction to ethanol, the psychoactive agent in alcoholic drinks. A psychoactive substance is any substance that affects central nervous system functioning. Male alcoholics outnumber female alcoholics by a ratio of about four or five to one (Lauer, 1989). Table 17.2 describes some of the physical, psychological and cultural consequences of alcohol abuse. Abusing other drugs, such as cocaine or heroin, can produce similar effects.

Because neuronal activity of the brain becomes suppressed and reduces inhibitory controls on behaviour

when moderate to heavy amounts of alcohol are consumed, individuals become more relaxed and more outgoing, show impaired motor coordination, and have difficulty thinking clearly. As more alcohol is consumed, neuronal activity in the brain is depressed further, producing distortions in perception, slurred speech, memory loss, impaired judgement and poor control of movement (Stritzke *et al.*, 1996). Unconsciousness and death may result from ingesting large amounts of alcohol over a short period of time.

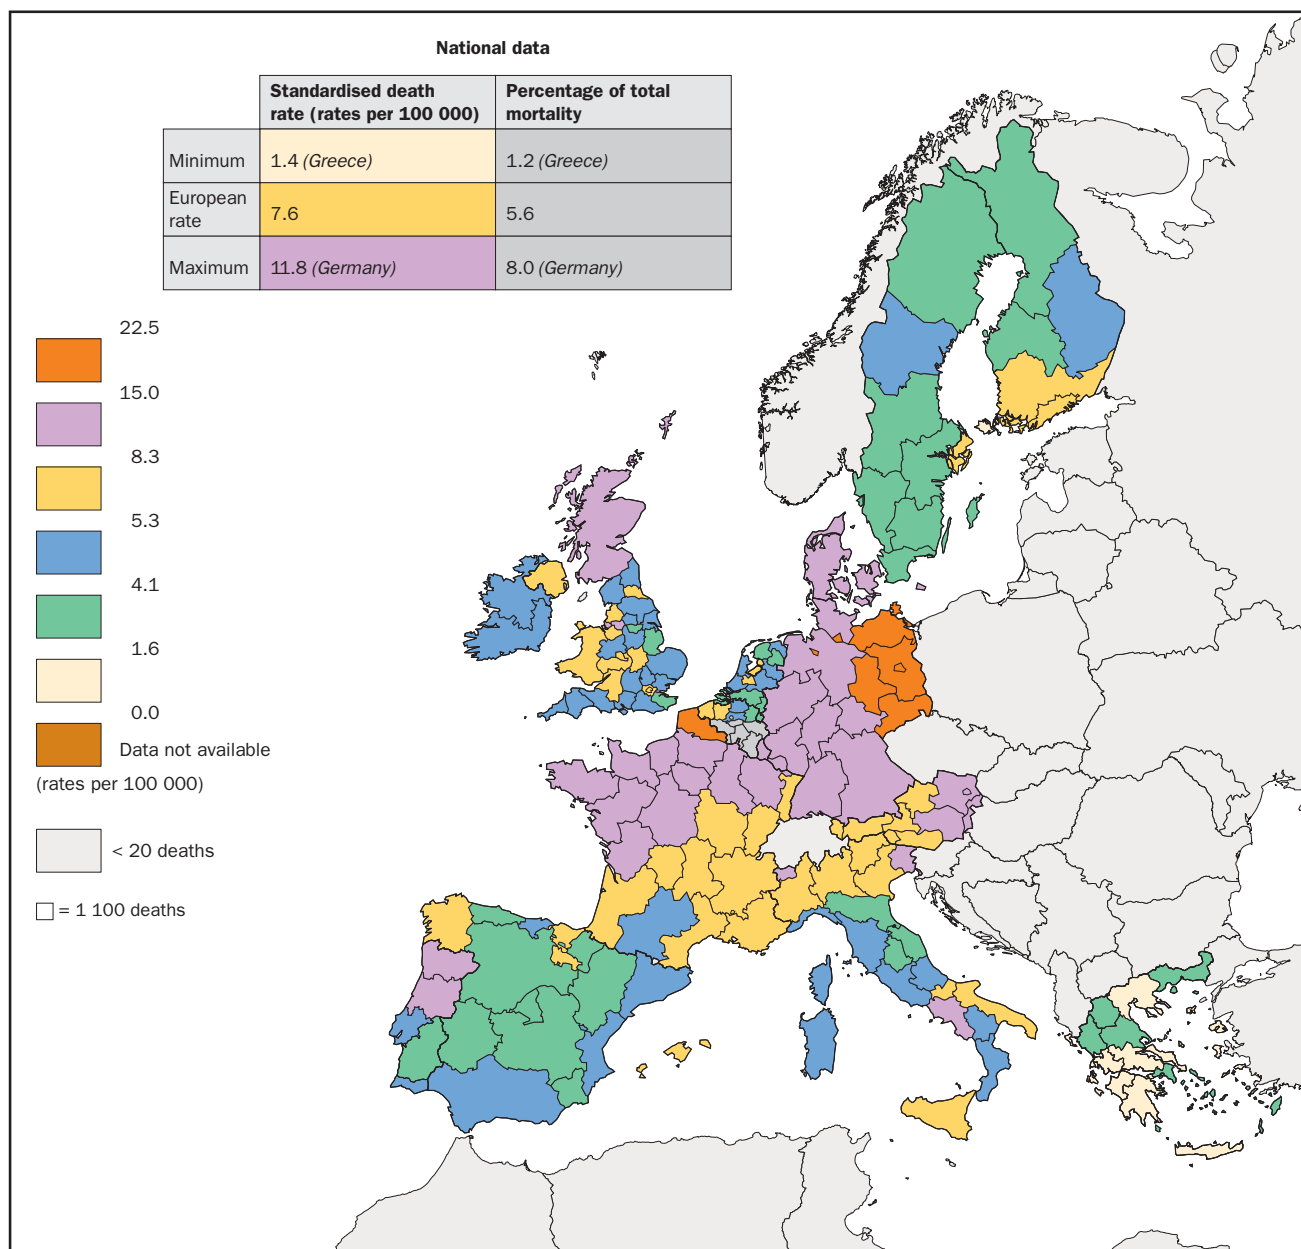

Figure 17.9 (b) Mortality arising from alcohol-related illness in women aged between 0–64 from the EU (data taken from 1994–1996).

Source: From IAS Fact Sheet: Alcohol Consumption and Harm in the UK and EU. London: IAS, 2003.

Once ingested, alcohol is rapidly absorbed from the stomach and intestinal tract. Because alcohol is a small fat- and water-soluble molecule, it is quickly and evenly distributed throughout the body via the circulatory system. Blood alcohol levels are affected by body weight and muscularity. Generally speaking, an obese or muscular individual would have to consume more alcohol than a slender person to attain the same level of intoxication. In addition, regardless of body characteristics, blood levels of alcohol increase more slowly in people who drink on a full stomach than in

those having little or no food in their stomach. Food in the stomach impairs absorption of substances through the gastrointestinal tract. Men appear to be heavier drinkers than women. Even when total body weight, coping style and sensation-seeking are taken into account, men remain the heaviest consumers (Watten, 1997).

Inebriation is related to the manner in which alcohol is metabolised by the body. Unlike most other drugs, alcohol is metabolised by the liver at a constant rate, regardless of how much alcohol has been consumed. For

Table 17.2 The negative physical, psychological and cultural consequences of alcohol abuse

Physical

Cirrhosis of the liver, which results in death
Poor nutrition
Impaired sexual functioning

Psychological

Gradual deterioration of cognitive functioning
Increased feelings of anxiety and irritability
Aggressive behaviour

Cultural

Impaired social skills and interpersonal functioning
Divorce
Employee absenteeism and decreased productivity

example, in one hour, the body will metabolise the alcohol in 400 g of beer or 35 g of 80–100 per cent proof spirits. Hence, if a person consumes more than 400 g of beer or 35 g of spirits per hour, their blood alcohol level rises beyond that level caused by the first drink, and they may begin to become intoxicated. When blood alcohol levels reach 0.3–0.4 per cent, people lose consciousness, and at 0.5 per cent neurons in the brain that control the respiratory and circulatory systems stop functioning, causing death. Driving under the influence of alcohol is defined in most countries as a blood alcohol level greater than 0.1 per cent.

Some recent evidence suggests that drinking moderate amounts of alcohol can serve as a protective factor against coronary heart disease (CHD). For example, drinking moderate to light amounts daily has been associated with a reduced risk of CHD (Rehm *et al.*, 1997; Thun *et al.*, 1997). Men suffering from myocardial infarction (a severe heart disease) but who consumed light to moderate amounts of alcohol (two to six drinks a week) showed a lower mortality rate than did those patients who abstained from alcohol (Muntwyler *et al.*, 1998).

However, these studies are correlational or epidemiological, that is, alcohol consumption is noted in retrospect and the mortality rates of those who drink a little or not at all are compared: scientists do not directly manipulate the independent variable, alcohol consumption, by prescribing alcohol to one group and no alcohol to another.

Alcohol-related illness

Although moderate drinkers develop little or no tolerance to alcohol, people who regularly consume large quantities of alcohol usually develop a tolerance. Heavy drinkers often suffer delirium tremens – the DTs – a pattern of withdrawal symptoms that includes trembling, irritability, hallucinations, sleeplessness and confusion when they attempt to quit drinking. In many cases, alcoholics become so physically dependent on the drug that abrupt cessation of drinking produces convulsions and sometimes death. Consumption of alcohol and other drugs is also dangerous. Table 17.3 illustrates the consequences of mixing alcohol with various drugs.

Table 17.3 The effects of mixing alcohol with other drugs

Drug	Example	Possible consequences of using simultaneously with alcohol
Narcotics	Codeine or Percodan	Increased suppression of CNS functions and possible death due to respiratory failure
Minor pain relievers	Aspirin or Tylenol	Stomach irritation and bleeding; increased likelihood of liver damage from acetaminophen
Antidepressants	Tofranil, Triavil	Increased suppression of CNS functions; drinking some red wines while using some kinds of antidepressants may produce extremely high blood pressure. May also lead to death due to respiratory failure
Antihistamines	Actifed	Increased drowsiness, making operation of motor vehicles and power equipment more dangerous
CNS stimulants	Caffeine, Dexedrine	Reverses some of the depressive effects of alcohol; however, they do not produce increases in sobriety if consumed while one is inebriated
Antipsychotics	Thorazine	Impaired control of motor movements and possible death due to respiratory failure
Anti-anxiety drugs	Valium	Decreased arousal; impaired judgement, which can lead to accidents in the home or on the road

Source: Based on Palfai and Jankiewicz, 1991, and data from the National Institute for Alcohol Abuse and Alcoholism Clearinghouse for Alcohol Information, 1982.

The use of alcohol is prompted by the same factors that contribute to the initiation of smoking: imitation and peer pressure. Many young people see drinking as the thing to do because it seemingly represents maturity, independence and rebelliousness and because it is associated with having fun. In one experiment, 100 participants monitored their drink consumption on a hand-held Psion computer over 30 days and recorded how they felt (Mohr *et al.*, 2001). They also noted where they were when they drank. Their aim was to determine whether there was a significant relationship between a person's mood and their tendency to drink alcohol.

On days where participants encountered negative experiences, drinking was more likely to be solitary; the individual was home and alone. When interpersonal experiences were positive, drinking was more likely to occur in social contexts. Experiences also interacted with personality type. Those who were more neurotic were more likely than stable individuals to drink alone when they had experienced negative interpersonal experiences. When the researchers looked at the participants' normal drink levels, they found that people who drank more at home were more likely to do so in response to negative experiences.

Treatment programmes for drug abuse, including smoking and drinking, may take several forms. In some cases, aversion therapy is used; in others, less intrusive forms of therapy involving extensive counselling are used. In the latter case, the psychologist's or therapist's general aim is to teach the individual the following:

- 1 To identify environmental cues or circumstances that may cause the addictive behaviour to occur or recur.
- 2 To learn to behave in ways that are incompatible with the undesired behaviour.
- 3 To have confidence that they can overcome the addiction.
- 4 To view setbacks in overcoming the addiction as temporary and to treat them as learning experiences in which new coping skills can be acquired.

Prevention programmes for people with addictive behaviours are only moderately successful. Many alcohol management programmes have only a 30–50 per cent success rate (Marlatt *et al.*, 1986).

Sexually transmitted diseases and AIDS

Sexual activity represents the most emotionally intense form of intimacy. Through casual sexual relationships, however, sexual activity may have severely negative consequences: it may result in contracting a sexually transmitted disease (STD). Individuals who contract an STD experience a loss of self-esteem and often they lose their ability to initiate or maintain sexual relationships. Table 17.4 lists the major types of STD, their symptoms and their treatment.

The most life-threatening illness that is transmitted sexually is acquired immune deficiency syndrome, or AIDS, which can also be transmitted through blood transfusions

Table 17.4 Four STDs, their causes, symptomology and treatment

STD	Cause	Symptoms	Treatment
Gonorrhoea	Gonococcus bacterium	Appear 3–5 days after sexual contact with afflicted person. In both sexes, discharges of pus. Urination accompanied by a burning sensation. In female, pelvic inflammatory disease. If untreated, fevers, headaches, backaches and abdominal pain develop	Penicillin or other antibiotics
Genital herpes	Herpes simplex type I and II virus	Small blisters around point of sexual contact. Blisters burst, causing pain. Symptoms recur every 1 to 2 weeks	No cure, but acyclovir ointment speeds the healing process if applied early in the first episode of the disease
Syphilis	Treponema pallidum bacterium	Chancre or lesion where bacteria first entered body. If untreated, the bacteria penetrate body tissue, including the brain. May result in death	Penicillin or other antibiotics
AIDS	Human immune deficiency virus (HIV)	Destruction of body's immune system allowing diseases like cancer and pneumonia to infect the body	Still in experimental stages. Several drugs are currently being tested. So far, results are mixed – none is successful in curing AIDS, but some appear promising in lessening the symptoms

and the sharing of hypodermic needles among intravenous drug users. It can be easily diagnosed by using an antibody test. Men are most affected and it is the third most important cause of death in those aged between 25 and 44 (Atlas on Mortality in the EU, 2002). AIDS is the last stage of the illness triggered by the human immunodeficiency virus (HIV). AIDS has been reported in 163 countries and the incidence of AIDS (HIV)-related deaths in men and women can be seen in Figures 17.10 (a) and (b). Mortality from AIDS in the EU is high in the Spanish

provinces, southern France, northern Italy, the Algarve, the Balearics, Corsica and Sardinia but comparatively low in the Netherlands, Austria and Greece.

Between 50 and 70 per cent of people infected with HIV will develop AIDS within 8–10 years (Moss and Bacchetti, 1989). Changes in lifestyle, such as practising safe sex, can reduce one’s risk of contracting an STD or AIDS. These practices include limiting the number of one’s sexual partners, finding out the sexual history of partners before engaging in sexual relations, using a

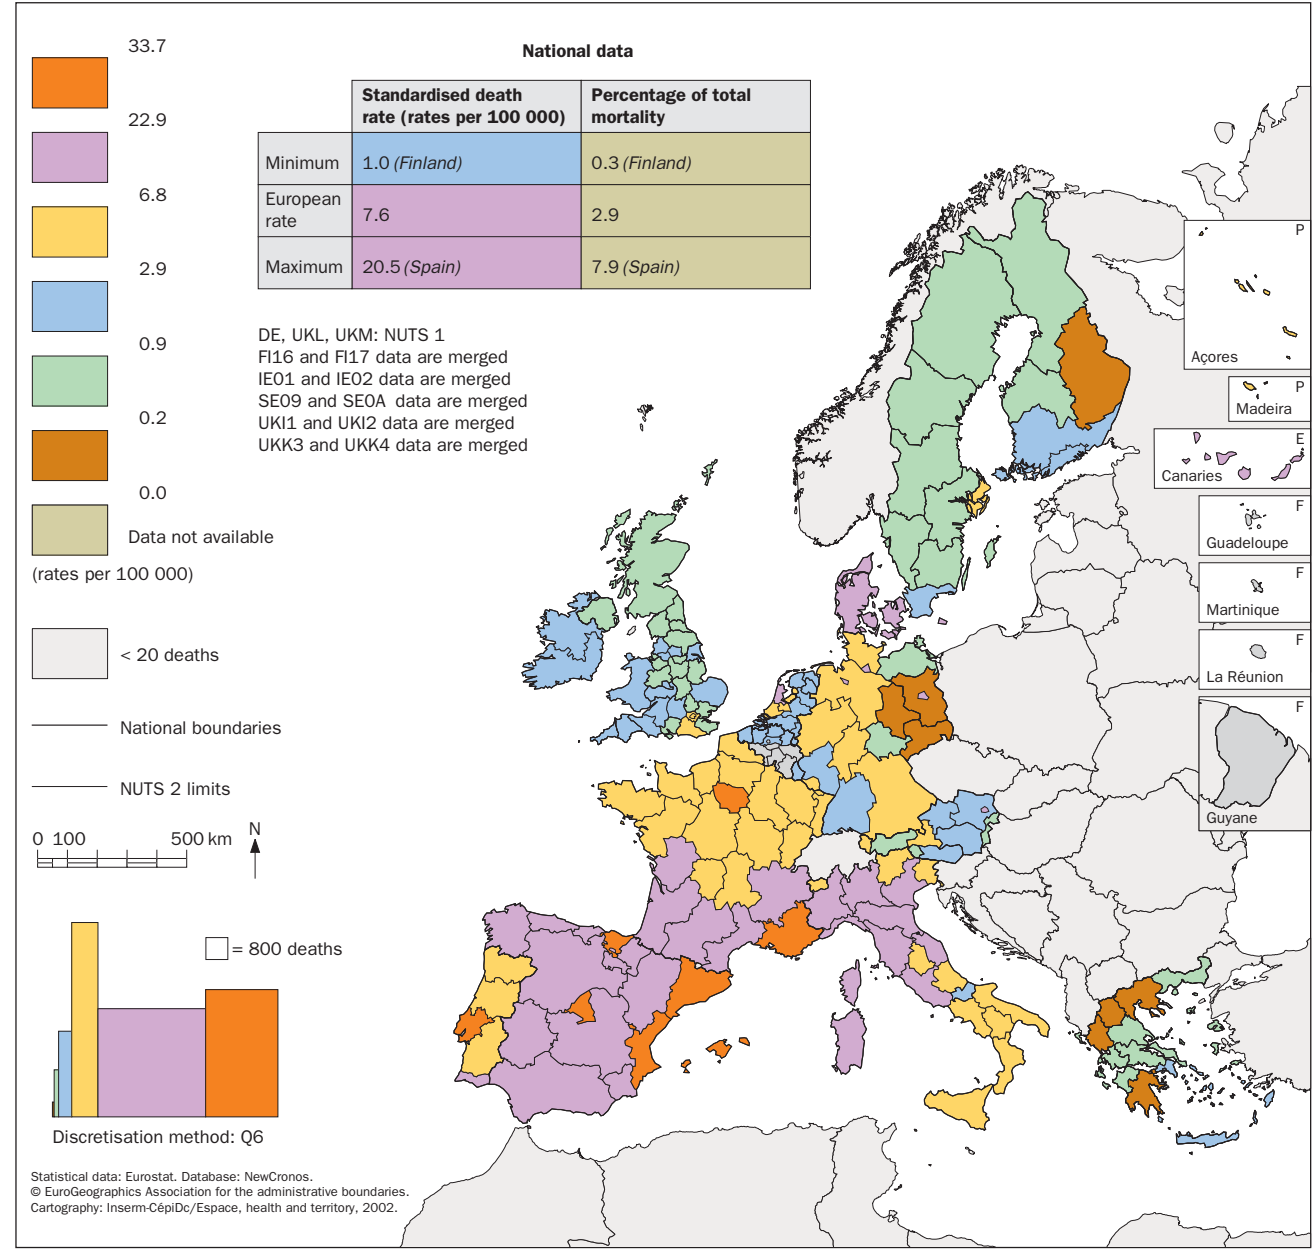

Figure 17.10 (a) Deaths due to HIV/AIDS in European men.

Source: *Health Statistics: Atlas on Mortality in the European Union*. Publications Office for the European Union, © European Communities (2002).

condom during sex, and abstinence from sexual intercourse. In the case of AIDS, these lifestyle changes must involve not only safe sex practices but also behaviours that will prevent non-sexual transmission of the AIDS virus, such as refusal to share hypodermic needles.

Prevention programmes have been based on changing knowledge, attitudes, beliefs and practices (Janz and Becker, 1984; Ajzen, 1985, 1991; Sheeran and Abraham, 1996). One model, the theory of reasoned action, is based on principles from social and cognitive psychology

(Ajzen, 1985, 1991; Conner and Sparks, 1996). According to the model, behaviour follows from an intention to act. These intentions are based on the individual's beliefs, attitudes and feelings. Attitudes, in turn, are based on beliefs about the evaluation of the consequences of behaviour. The model takes into account the possibility that an individual's attitude can be influenced by social factors and that others' perception of them can determine their intention to act. Thus, if we apply the model to AIDS: an individual will intend to act in a particular way

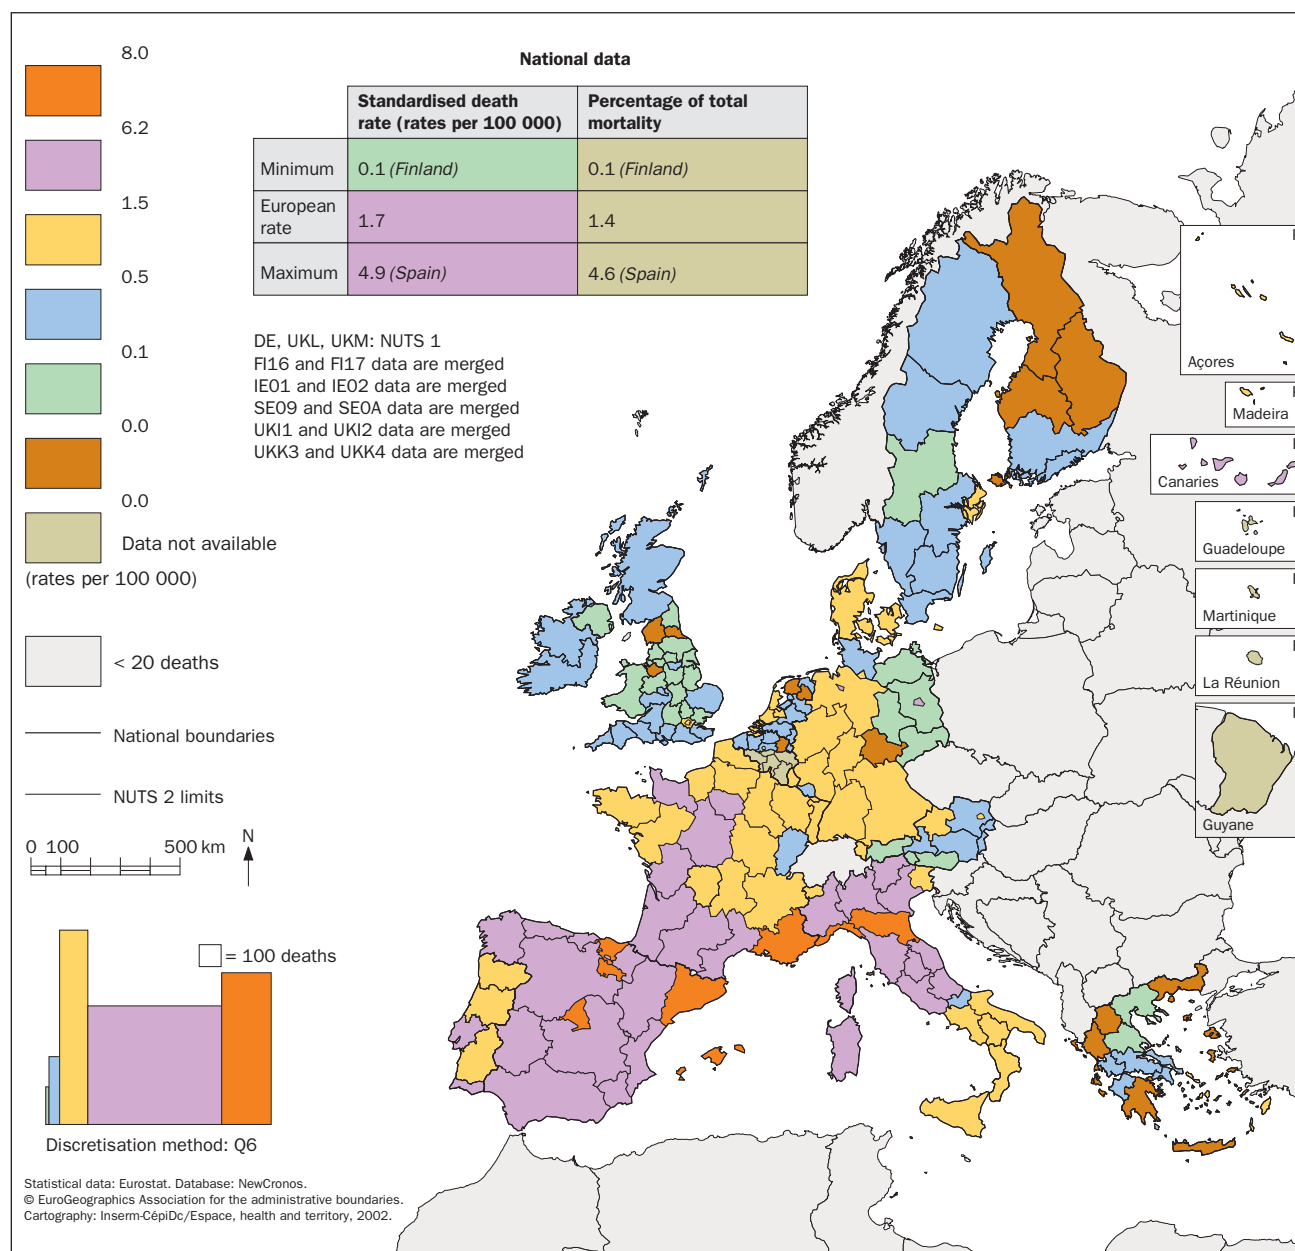

Figure 17.10 (b) Deaths due to HIV/AIDS in European women.

Source: *Health Statistics: Atlas on Mortality in the European Union*. Publications Office for the European Union, © European Communities (2002).

(for example, using a condom) if they have a positive view of condoms and think that others would approve (Abraham *et al.*, 1998).

Critics of the social cognitive models argue that the models do little to explain AIDS-related behaviour change and that intention to act does not explain behaviour change (Joffe, 1996, 1997; Fife-Shaw, 1997). Others, however, suggest that there is considerable evidence for the efficacy of the models (Abraham *et al.*, 1998). Sheeran *et al.* (1997) (cited in Abraham *et al.*, 1998), for example, reported a positive correlation between behavioural intention and condom use. Abraham *et al.* (1998) also note that interventions based on theory are more effective than those based on information-giving (Kalichman *et al.*, 1996).

The most successful interventions are those which combine information-giving and the teaching of behavioural skills (Fisher and Fisher, 1992). A school curriculum intervention programme based on social cognitive models was significantly more effective in changing feelings and cognitions about HIV and safe sex than was standard Dutch sex education (Schaalma *et al.*, 1996). At the beginning, 45 per cent reported inconsistent condom use; this had been reduced to 36 per cent by the end of the intervention.

Although prevention programmes have been partially successful in reducing high-risk sexual behaviours, they are least successful in situations in which a person's personal or cultural values prevent them from engaging in safe sex practices (Herdt and Lindenbaum, 1992). These values generally involve misperceptions of what practising safe sex means. Some men refuse to wear condoms because doing so would detract from their conception of what it means to be a man. Many people, especially young people, have the mistaken belief that they are invulnerable to any type of misfortune, including contracting an STD or AIDS.

Attitudes towards HIV and AIDS

Despite widespread media coverage of the AIDS epidemic throughout the world and instructional programmes designed to educate the general public about AIDS, the disease remains the most feared, stigmatised and publicly misunderstood contagious disease of our time (Rushing, 1995). When negative behaviour of this sort occurs, especially on a collective, widespread social basis, it is referred to as fear of contagion. Historical analyses of previous epidemics, such as the Black Death (bubonic plague) that struck Europe during the fourteenth century and the outbreak of cholera in Europe and the USA in the seventeenth century, have shown that fear of contagion is likely to occur only when four conditions are met: the disease must

be deadly, it must appear suddenly, it must have no apparent explanation, and people must believe that many people are at risk of contracting it (Rushing, 1995).

The AIDS epidemic meets these four conditions. It is deadly and it appeared suddenly: the first cases of AIDS were reported in 1981, a year in which 295 diagnoses of AIDS were made worldwide and 126 people died from it. Only ten years later, in 1991, 41,871 new cases were reported and 31,381 people had died from AIDS. According to the World Health Organization (2007), an estimated 40 million had been infected by AIDS by 2006.

It is relatively easy to explain fear of contagion during the periods of the bubonic plague and cholera. At that time, medical science was unsophisticated and lacked the technology needed to understand basic physiology. Fear of contagion in the time of AIDS is not so easily explained.

Bishop (1994) offers three possible explanations. First, some people may reason that just because no evidence currently exists that AIDS is spread through casual contact, it does not mean that such evidence may not be discovered. Medical experts tend to describe the transmission of AIDS through casual contact as being 'near impossible' or 'very unlikely', which leaves room for doubt in many people's minds.

Secondly, some people may mistake AIDS as having the same general characteristics of more typical contagious diseases such as chicken pox or influenza. People often use prototypes to represent concepts. Recall that a prototype represents the typical member of a class of things and that people organise information about other members in that class around the prototype. For example, if you think of influenza as a prototypical contagious disease, you may then apply the characteristics of this disease to other members of the same category, such as AIDS. Thus, because you know that influenza is a contagious disease spread by casual contact, you extend this same characteristic to AIDS and believe that it, too, is spread by casual contact.

Finally, the availability heuristic may also play a role in people's thinking about the transmission of AIDS. Recall from the discussion of the availability heuristic in Chapter 15 that when people attempt to assess the importance or the frequency of an event, they tend to be guided by the ease with which examples of that event come to mind. In the case of contagious diseases, AIDS has captured the world's attention.

Managing HIV and AIDS

Although psychologists and other health professionals have helped to develop programmes for the prevention of AIDS by devising interventions based on safe sex practices, these programmes are clearly too late for those with

the HIV virus who may later develop AIDS. Psychology's contribution to the management of the virus has focused on the degree of support given to carriers, the reduction of risky sex following a positive diagnosis, and in helping to maintain a regular drug regime for those infected.

For example, the standard drugs for treating the HIV virus are currently nucleoside analogue reverse transcriptase inhibitors (NARTIs), which interfere with the ability of the virus to produce DNA needed for cell replication (Perelson *et al.*, 1996; Kelly *et al.*, 1998). However, this drug is currently taken in combination with other drugs called protease inhibitors. Protease inhibitors reduce the viral load in patients, that is, they reduce the viral quantity in blood. The NARTIs attack the virus in its early stages, the protease inhibitors attempt to halt the maturation of cells that have already developed. The difficulty with such combination therapy, however, is that these drugs are taken at various dosages at various times of the day; some need refrigeration, some cannot be taken on a full stomach (whereas others must be).

Even brief lapses in the drug regime can cause an increase in viral load and replication of the HIV virus (it is also an expensive lapse). Some of the factors which can influence a successful adherence to the drug regime include a belief that the drugs are effective and beneficial (Geletko *et al.*, 1995) – this is sometimes difficult when the effects of the drugs are not seen for a considerable time – and personal involvement in decision-making (Becker and Maiman, 1980), that is, the patient believes that the regime is constructed for their condition and that they have responsibility for this regime. The absence of negative affect and the availability of social support also enhance successful adherence (Freeman *et al.*, 1996).

Another problem associated with HIV infection is continued risky sexual and drug-use behaviour (Kelly and Kalichman, 1998). Between 30 and 35 per cent of HIV-infected individuals engage in unprotected sex and in unsafe needle-sharing drug practices, and a recent longitudinal study of women who were tested for HIV and given HIV counselling, showed no disengagement from high-risk sexual behaviour (Ickovics *et al.*, 1998). A more recent study, however, showed that if the support given is HIV-specific and not general, risky HIV behaviour is reduced (Darbes and Lewis, 2005).

Two models have been formulated for the prediction of HIV-relevant risk behaviour. The information-motivation-behaviour model (Fisher and Fisher, 1992) argues that the factors which influence risk reduction are knowledge about AIDS risk reduction, a change in motivation and the presence of behavioural skills that can reduce risky practice. An alternative model, the Aids risk reduction model (Catania *et al.*, 1990), suggests that a change in risky behaviour depends on the perception of the prob-

lem, a change in commitment and taking action. These factors can significantly influence the decision to use condoms (Kelly *et al.*, 1990).

With the seriousness of the illness being the most obvious and most pressing source of concern for carriers of the disease, the psychological effects of the disease have not been widely studied. There is insidious, cognitive impairment as the disease progresses (it is called a dementia) and this is well documented (Grant *et al.*, 1999). The social, personal consequences of the disease and its effects on mental health are less well understood. Studies reviewed by Emmelkamp (1996) suggest that individuals who have not accepted their homosexuality, who have received little or no social support and who have denied the effects of illness to themselves, are those most likely to develop severe psychological disturbances. In general, however, the degree of psychological distress is comparable to those of psychiatric outpatients or seronegative (those low in antibodies) homosexuals: that is, after the initial shock of discovering their positive status, patients are not more depressed or anxious than are those who were diagnosed negative.

Stress and health

Stress is a term that causes psychologists headaches. There is a great deal of controversy over what the term means and whether the term reflects a genuine psychological variable. This controversy is not helped by the suggestion that the man who popularised it probably meant another word that was similar, as you will see later. In general terms, stress is a pattern of physiological, behavioural, emotional and cognitive responses to real or imagined stimuli that are perceived as preventing a goal or endangering or otherwise threatening well-being. These stimuli are generally aversive and are called stressors. Stress is not a direct product of cultural evolution but is a product of natural selection. It is a behavioural adaptation that helped our ancestors to fight or flee from wild animals and enemies. Stress often helps us to confront or escape threatening situations (Linsky *et al.*, 1995).

Stressors come in many forms. They may be catastrophic, such as floods and rape, or they may be relatively trivial, such as being stuck in traffic when you are late for an appointment. Stressors are not always bad. Some stressors, such as athletic competition, having to perform in front of an audience or sitting an exam, can affect behaviour in positive ways. However, when stress is extended over long periods, it can have negative effects on both a person's psychological health and a person's physical health (Selye, 1991).

Selye's general adaptation syndrome

Much of what we know about the effects of dealing with prolonged and severe stressors on the body stems from the work of the Austrian-born Canadian endocrinologist Hans Selye. There is some suggestion that Selye was unclear about the difference between the terms 'stress' and 'strain' (when he talked about stress this was seen as something new whereas people had been more than used to speaking of people being under strain). As Youngston (1998) neatly summarises:

The other thing Selye did was to use what was actually the correct term. The terms 'stress' and 'strain' come from engineering . . . Stress is the force exerted on a body that tends to cause it to deform, while strain is a measure of the extent to which a body is deformed when it is subjected to stress. A strain gauge is a simple device that measures the amount of the deformity.

The terms can, of course, be applied to human bodies in exactly this mechanical way. A bone can be stressed and can bend a little, thus exhibiting strain. But when we talk, these days, about a human being experiencing stress, we are not thinking of the application of a physical force that causes a bit of body squashing (strain). Our usage is purely metaphorical.

Through his work with laboratory animals, Selye found that chronic exposure to severe stressors produces a sequence of three physiological stages: alarm, resistance and exhaustion, as illustrated by Figure 17.11. Selye (1956) referred to these stages collectively as the **general adaptation syndrome (GAS)**.

The responses in the alarm stage involve arousal of the autonomic nervous system and occur when the organism is first confronted with a stressor. During this stage, the organism's resistance to the stressor temporarily drops below normal, and the organism may experience shock – impairment of normal physiological functioning. With continued exposure to the stressor, the organism enters the stage of resistance, during which its autonomic nervous system returns to normal functioning. Resistance to the stressor increases and eventually levels out at above normal levels. The stage of resistance, then, reflects the organism's adaptation to environmental stressors. However, with continued exposure to the stressor, the organism enters the stage of exhaustion. During this stage, the organism loses its ability to adapt, and resistance plummets to below normal levels, leaving the organism susceptible to illness and even death.

Most of Selye's work was focused on physical stressors, such as cold or heat or pain, but psychological stressors

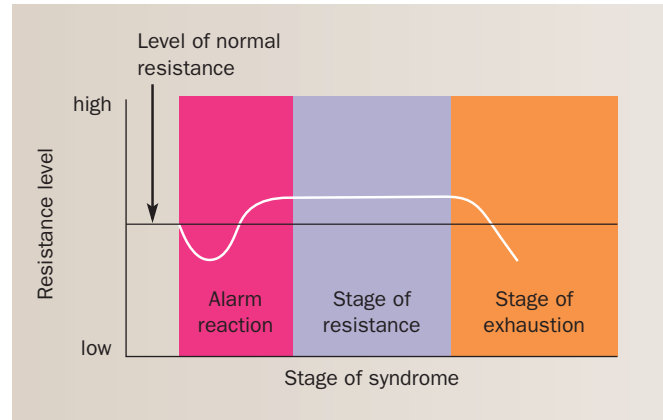

Figure 17.11 The general adaptation syndrome as proposed by Hans Selye.

Source: From Selye, H., *Stress without Distress*, © Lippincott Williams & Wilkins 1974.

might exert considerably worse effects on health and behaviour. The extent to which people can adapt varies across individuals and depends on how the stressor is perceived. Some stressors are absolute (being tortured or being in an earthquake/tsunami, for example); others are relative and depend on how we respond to them. Our emotional responses seem designed primarily to cope with short-term events. The physiological responses that accompany the negative emotions are described below and prepare us to threaten or fight rivals or to run away from dangerous situations. The absolute stressors provoke an adaptive stress response (relative stressors provoke this variably). Walter Cannon coined the phrase **fight or flight response** to refer to the physiological reactions that prepare us for the strenuous efforts required by fighting or running away. Normally, once we have bluffed or fought with an adversary or run away from a dangerous situation, the threat is over and our physiological condition can return to normal. The fact that the physiological responses may have adverse long-term effects on our health is unimportant as long as the responses are brief. But when the threatening situations are continuous rather than episodic, they produce a more or less continuous stress response. This continued state of arousal can lead to coronary heart disease (CHD) and other physical problems.

The biological basis of stress

Physical response to stressors is governed by the autonomic nervous system, which is controlled by the hypothalamus. Stress is a biological response that is experienced as an emotion, although the form it takes varies depending on the nature of the stressor. In some situations we may feel frightened, and in others we may feel inspired or exhilarated.

When an individual senses a stressor, the hypothalamus sends signals to the autonomic nervous system and to the pituitary gland, both of which respond by stimulating body organs to change their normal activities:

- Heart rate increases.
- Blood pressure rises.
- Blood vessels constrict.
- Blood sugar levels rise.
- Blood flow is directed away from extremities and towards major organs.
- Breathing becomes deeper and faster.
- Air passages dilate, which permits more air to enter the lungs.
- Digestion stops.
- Perspiration increases.
- Adrenal glands secrete adrenalin (epinephrine), which stimulates the heart and other organs.

It is easy to see why these changes are adaptive. They each prepare the body to deal with the stressor – collectively, these physiological responses produce a heightened psychological and physical state of alertness and readiness for action. Regardless of the nature of the stressor and whether we confront the stressor or run from it, the biological response is generally the same. Whether you find yourself in a dark alley confronted by a man with a knife or are facing your next psychology exam, the autonomic nervous system and the pituitary gland stimulate the body to respond to the stressor.

There are two cases in which such responses can be maladaptive. First, stress can produce anxiety, which may impair one's ability to perform a task. As you may have experienced yourself, anxiety can hinder a variety of behaviours from performing in examinations, to speaking in public, competing during sporting events, or remembering lines in a play.

The second case involves the effects of prolonged and severe stress. Many people's lifestyles place them in situations in which they are daily confronted with stressors. These lifestyles place these people at increased risk of illness.

Physiological mechanisms involved in stress

Emotions consist of behavioural, autonomic and hormonal responses. The latter two components – autonomic and hormonal responses – are the ones that can have adverse effects on health. Because threatening situations generally call for vigorous activity, the autonomic and hormonal responses that accompany them help to make the body's energy resources available. The sympathetic branch of the autonomic nervous system is active, and the

adrenal glands secrete epinephrine, norepinephrine and steroid stress hormones. This is known by the name hypothalamic-pituitary-adrenal (HPA) axis.

Epinephrine (adrenalin) releases the stored form of glucose that is present in the muscles, thus providing energy for strenuous exercise. Along with norepinephrine (nore-drenalin), it also increases blood flow to the muscles by increasing the output of the heart, which also increases blood pressure. Over the long term, these changes contribute to CHD.

The hypothalamus releases a substance called corticotropin-releasing hormone which triggers the production of adrenocorticotropin in the pituitary gland (Lupien *et al.*, 2007). This travels in the blood and arrives at the adrenal glands where it triggers the release of two types of stress hormone: the glucocorticoids and catecholamines (adrenaline and noradrenaline). These are responsible for the fight or flight response. In humans, the glucocorticoid released is called cortisol. Cortisol is called a **glucocorticoid** because it has profound effects on glucose metabolism, effects similar to those of epinephrine. In addition, glucocorticoids help break down protein and convert it to glucose, help make fats available for energy, increase blood flow, and stimulate behavioural responsiveness, presumably by affecting the brain. They also have other physiological effects, some of which are only poorly understood. Almost every cell in the body contains glucocorticoid receptors, which means that few parts of the body are unaffected by these hormones. Figure 17.12 illustrates the effects of hormones on various body organs and their functions.

Glucocorticoids tend to be at their highest levels in the morning and decline throughout the afternoon. There is evidence that they bind to two brain receptor sub-types, and during responses to highly stressful events the T1 receptor type is awash with glucocorticoids and the T2 type is 70 per cent occupied (Lupien *et al.*, 2007).

Selye (1976) suggested that most of the harmful effects of stress were produced by the prolonged secretion of glucocorticoids. Although the short-term effects of glucocorticoids are essential, the long-term effects are damaging. These effects include increased blood pressure, damage to muscle tissue, a particular form of diabetes, infertility, stunted growth, inhibition of the inflammatory responses and suppression of the immune system. High blood pressure can lead to heart attack or stroke.

Selye's research involved exposing laboratory animals to chronic and intense stressors under controlled laboratory conditions. In addition to showing that resistance to stressors appears to involve three stages, his results also showed that animals became seriously ill during the stage of exhaustion. Can prolonged exposure to severe stressors produce similar risks for humans? Many studies investigating the relationship of lifestyle to health have

Figure 17.12 Control and the effects of secretion of epinephrine, norepinephrine and cortisol by the adrenal gland.

shown that the answer to this question is ‘yes’. Specifically, stressful lifestyles have been shown to be related to increased risk of impaired immune system functioning, ulcers, high blood pressure, cancer and CHD.

One of the commonest ulcers in the human body is peptic ulcer which is found in the stomach (the world’s best-selling drug helps to combat ulcers). The cause of peptic ulcer is *Helicobacter pylori*, although, until this discovery, psychological stress was thought to be a principal precipitating factor. Since the discovery of this cause, interest in the psychological causes of ulcers has receded (Levenstein, 1998), although psychological stressors can influence the degree and course of ulcers. These stressors have been found to impair ulcer healing and to lead to an increase in the secretion of gastric acid. Patients with ulcers also seem to have experienced a greater number of life stressors compared with matched controls.

Several lines of research suggest that stress is also related to ageing. First, older people, even when they are perfectly healthy, do not tolerate stress as well as younger people do (Shock, 1977). Secondly, stress may accelerate the ageing process (Selye and Tuchweber, 1976). Sapolsky and his colleagues have investigated one rather serious long-term effect of stress: brain damage. As you saw in Chapter 8, the hippocampal formation plays a crucial role in learning and memory. Evidence suggests that one of the causes of memory loss that occurs with ageing is degeneration of this brain structure. Research conducted on animals has shown that long-term exposure to gluco-

corticoids destroys neurons located in a particular zone of the hippocampal formation. The hormone appears to destroy the neurons by making them more susceptible to the normal wear and tear that accompanies the ageing process (Sapolsky, 1986; Sapolsky *et al.*, 1986).

A review of the effects of sex and hormonal status on people’s response to stress has found that men and women differ. Men, for example, are more susceptible to diseases such as infection and heart attack but women are more susceptible to autoimmune disorders. Kajantie and Phillips (2006) from the Public Health Institute in Finland and the University of Southampton found that pubertal and menopausal girls/women (respectively) display lower autonomic responses and lower levels of physiological stress than boys/men of the same age. The physiological stress response (the hypothalamic-pituitary-adrenal axis response) was higher in the luteal phase of women’s menstrual cycle. The response is lower during pregnancy.

A study from the universities of Glasgow and Birmingham, UK, has found that women who perform a stressful task in the presence of a spouse or partner show lower blood pressure and heart rate activity when they engaged in stressful tasks. The effect of a partner was not found for men, an unusual finding given that men are more likely to benefit from social support than are women. The presence of a non-partner reduced physiological activity in both sexes but when this was controlled for, the sex difference remained.

In a neuroimaging study in which healthy volunteers underwent moderate stress (they participated in a mental arithmetic task), increased activation was seen in the ventral right prefrontal cortex and left insula (Wang *et al.*, 2005). This response continued after the task in those participants who found the arithmetic particularly stressful. The increase was unrelated to the cognitive demands of the task, suggesting that changes in blood flow to these brain regions may mediate the response to moderately stressful events.

Cognitive appraisal and stress

Many of the harmful effects of long-term stress are caused by our own reactions – primarily the secretion of stress hormones. Some events that cause stress, such as prolonged exertion or extreme cold, cause damage directly. These stressors will affect everyone; their severity will depend on each person’s physical capacity. Selye’s model has been useful for understanding the biological components involved in stress, but it does not explain the role of psychological components in stress. The effects of other stressors, such as situations that cause fear or anxiety, depend on people’s perceptions and emotional reactivity. That is, because of individual differences in

Cutting edge – Going off the rails?

If you have to use the train to get to work or college every morning, you probably don't find it the most pleasurable experience of the day – delays, long journeys, crowded carriages . . . it amounts to a stressful experience. An American study has examined the relationship between stress and rail commuting in 208 men and women who lived in the suburbs (New Jersey) and commuted to Manhattan, New York (Evans and Wener, 2006). Over 100 million Americans, according to the authors, commute to work and the percentage using trains has increased by a fifth since 1980.

They found that the longer the length of the journey, the greater the amount of salivary cortisol produced by participants (an index of stress). At the end of the journey, the researchers gave participants a proof reading exercise to complete. Those who had taken longer journeys, persisted less at this task. They also reported experiencing more stress.

The study's conclusion seems to be: avoid long journeys on trains when going to work.

temperament or experience with a particular situation, some people may find a situation stressful and others may not. In these cases, it is the perception that matters.

One of the most important variables that determines whether an aversive stimulus will cause a stress reaction is the degree to which the situation can be controlled. When an animal can learn a coping response that allows it to avoid contact with an aversive stimulus, its emotional response will disappear. Weiss (1968) found that rats that learned to minimise (but not completely avoid) shocks by making a response whenever they heard a warning tone developed fewer stomach ulcers than did rats that had no control over the shocks. The effect was not caused by the pain itself, because both groups of animals received exactly the same number of shocks. Thus, being able to exert some control over an aversive situation reduces an animal's stress. Humans react similarly. Situations that permit some control are less likely to produce signs of stress than are those in which other people (or machines) control the situation (Gatchel *et al.*, 1989). Perhaps this phenomenon explains why some people like to have a magic charm or other 'security blanket' with them in stressful situations. Perhaps even the illusion of control can be reassuring.

Some psychologists argue that the psychological components in stress may influence the degree to which stressors arouse the autonomic nervous system. One such psychologist is Richard Lazarus, who argues that our perception of the stressor does, to a large extent, determine the stress we experience (Lazarus and Folkman, 1984). According to Lazarus, an individual's stress levels are affected by their cognitive appraisal, or perception, of the stressful situation.

Cognitive appraisal is a two-stage process. In the first stage, we evaluate the threat: we attempt to judge the seriousness of the threat posed by the stressor. If we decide that the threat is real, we pass to the second stage, during which we assess whether we have the resources necessary to cope adequately with the threat. The extent

to which we believe both that the stressor is a serious one and that we do not have the resources necessary to deal with it determines the level of stress we will experience. The belief that we cannot deal effectively with a stressor perceived as being extremely dangerous leads to the highest levels of stress. Because different people may evaluate differently both the stressor and their ability to cope with it, they are likely to show different levels of stress when faced with the same stressor. We know from experience that this is true. For example, people vary tremendously in their reactions to snakes: a harmless grass snake will arouse intense fear in some people and none in others.

Selye's findings, then, do not apply to all people; there are individual differences in how people react to prolonged exposure to stress. Some people show little, if any, risk of becoming ill during or after chronic stress. Kobasa (1979) refers to these people as hardy individuals. In a study of how business executives coped with long-term stress, she found that some of her subjects became ill and some did not. She wanted to find out what caused this difference. Through detailed analyses of her subjects' responses to different psychological inventories, she found that the hardy subjects viewed the stressors in their lives as challenges and that they met these challenges head on; they did not avoid them or become anxious about them. They also felt that they had control over the challenges (stressors).

In other words, Kobasa's findings support Lazarus's idea of the importance of cognitive appraisal in dealing with stress: how we initially assess the stressor, how we tackle it, and the extent to which we believe that we can control the stressor seem to influence whether we become at risk of illnesses related to being chronically stressed.

Psychoneuroimmunology

In addition to causing elevated levels of glucocorticoids, epinephrine and norepinephrine, stressors can also impair the function of the immune system, which protects us

from assault by viruses, microbes, fungi and other types of parasite. Study of the interactions between the immune system and behaviour is called **psychoneuroimmunology**. Before discussing the effect of stressors on immune system functioning, it is useful to have an understanding of how the immune system works.

The immune system

The function of the **immune system** is to protect the body from infection. It is a network of organs and cells that protects the body from invading bacteria, viruses and other foreign substances, and is one of the most complex systems of the body. Because infectious organisms have developed devious tricks through the process of evolution, our immune system has evolved devious tricks of its own.

The immune system derives from white blood cells that develop in the bone marrow and in the thymus gland. Some of the cells roam through the blood or lymph glands and sinuses; others reside permanently in one place. The immune reaction occurs when the body is invaded by foreign organisms.

There are two types of specific immune reaction: chemically mediated and cell mediated. Chemically-mediated immune reactions involve antibodies. All bacteria have unique proteins on their surfaces, called **antigens**.

These proteins serve as the invaders' calling cards, identifying them to the immune system. Through exposure to the bacteria, the immune system learns to recognise these proteins. The result of this learning is the development of special lines of cells that produce specific **antibodies** – proteins that recognise antigens and help to kill the invading micro-organism. One type of antibody is released into the circulation by **B lymphocytes**, which receive their name from the fact that they develop in bone marrow. These antibodies, called **immunoglobulins**, are chains of protein. Each of five different types of immunoglobulin is identical except for one end, which contains a unique receptor. A particular receptor binds with a particular antigen, just as a molecule of a hormone or a transmitter substance binds with its receptor. When the appropriate line of B lymphocytes detects the presence of an invading bacterium, the cells release their antibodies, which bind with the bacterial antigens. The antibodies either kill the invaders directly or attract other white blood cells which then destroy the invaders. This process is illustrated by Figure 17.13.

One class of antibody, **secretory immunoglobulin A (sIgA)** is secreted by and covers the mucosal surfaces such as those found in the respiratory and gastrointestinal tracts. Its role appears to be to provide protection against infection by creating a barrier to invading organisms (Kraehenbuhl and Neutra, 1992). Because this antibody

Figure 17.13 Immune reactions. **(a)** Chemically mediated reaction. The B lymphocyte detects an antigen on a bacterium and releases a specific immunoglobulin. **(b)** Cell-mediated reaction. The T lymphocyte detects an antigen on a bacterium and kills it directly or releases a chemical that attracts other white blood cells.

can be measured from saliva, it has been one of the most widely researched of the antibodies (Evans *et al.*, 1997).

The other type of defence mounted by the immune system, cell-mediated immune reactions, is produced by T lymphocytes, which develop in the thymus gland. An example of T lymphocyte appears in Figure 17.14.

T lymphocytes also produce antibodies, but the antibodies remain attached to the outside of the cell's membrane. T lymphocytes primarily defend the body against fungi, viruses and multicellular parasites. When antigens bind with their surface antibodies, the cells either kill the invaders directly or signal other white blood cells to come and kill them.

In addition to the immune reactions produced by lymphocytes, natural killer cells continuously prowl through tissue. When they encounter a cell that has been infected by a virus or that has become transformed into a cancer cell, they engulf and destroy it. Thus, natural killer cells constitute an important defence against viral infections and the development of malignant tumours. Although the immune system normally protects us, it can cause us harm, too. Allergic reactions occur when an antigen causes cells of the immune system to overreact, releasing a particular immunoglobulin that produces a localised inflammatory response. The chemicals released during this reaction can enter the general circulation and cause life-threatening complications. Allergic responses are harmful, and why they occur is unknown.

The immune system can do something else that harms the body – it can attack its own cells. Autoimmune diseases occur when the immune system becomes sensitised to a protein present in the body and attacks the tissue that contains this protein. Exactly what causes the protein to be targeted is not known. What is known is that autoimmune diseases often follow viral or bacterial infections. Presumably, in learning to recognise antigens that belong to the infectious agent, the immune system develops a line of cells that treat one of the body's own proteins as for-

Figure 17.14 A T lymphocyte at work destroying tumour cells.

eign. Some common autoimmune diseases include rheumatoid arthritis, diabetes, lupus and multiple sclerosis.

Neural control of the immune system

Stress can suppress the immune system, resulting in a greater likelihood of infectious diseases, and it can also aggravate autoimmune diseases. It may even affect the growth of cancers. What is the physiological explanation for these effects? One answer, and probably the most important one, is that stress increases the secretion of glucocorticoids, and these hormones directly suppress the activity of the immune system. All types of white blood cell have glucocorticoid receptors, and suppression of the immune system is presumably mediated by these receptors (Solomon, 1987).

Cutting edge – Telomeres – what are they and can they predict stress?

Telomeres are sequences of DNA that cap the tops of chromosomes and help maintain the stability of cells (Epel, 2009). However, there are enzymes that cannot replicate chromosomes fully or completely at the tips which means that, in essence, they are missing. As cells replicate, these telomeres become shorter. The relevance of this to health psychologists is that shorter telomeres in white blood cells are associated with the development of chronic disease such as stroke (Fuster and Andres, 2006). There is also some evidence to suggest

that stressors are associated with shorter telomeres. For example, parents who cared for a child with a chronic illness had lower levels of the enzyme that prevents shortening and had shorter telomeres (Epel *et al.*, 2004). Similar telomere shortening is seen in people who care for people with dementia, in the depressed (Damjanovic *et al.*, 2007; Simon *et al.*, 2006), and in women with low occupational status (Cherkas *et al.*, 2006). Current evidence points to a role for these genetic anomalies in stress-reactions, but research is at an early stage.

Stress and the immune system

The immune system does not appear to react to different types of stressor in the same way. Chronic stressors such as bereavement of a close friend or relative, caring for a relative with Alzheimer's disease and marital disharmony, tend to result in reduced immune system functioning (Kiecolt-Glaser *et al.*, 1993; Zisook *et al.*, 1994). Kiecolt-Glaser *et al.* (1995), for example, reported that wounds took nine days longer to heal in carers for individuals with Alzheimer's disease than in age- and income-matched 'stress-free' controls. Figures 17.15 (a) and (b) show the relationship between caregiving and wound healing and wound size over the recovery period. Acute stress, however, does not appear to have the same effect. Acute stress appears actually to increase the number of natural killer cells (Delahanty *et al.*, 1996) and the levels of sIgA (Zeier *et al.*, 1996). Caregivers in these studies tend to be 'informal' caregivers – they are not paid to look after ill people but are relatives or friends who willingly look after a seriously ill family member or friend. A meta-analysis of 23 published studies examining the health of caregivers and non-caregivers and its relationship to caregiving found that caregivers' levels of stress hormones were 23 per cent higher and their antibody responses 15 per cent lower than those of non-caregivers (Vitaliano *et al.*, 2003). While the authors stress that it is impossible to tell from these studies whether the stress of caregiving causes changes in physical condition, they point out that caregiving is a potentially risky behaviour.

Evans *et al.* (1993) have reported that lower quality of life (such as experiencing more undesirable or fewer desirable experiences) is associated with lower levels of sIgA. However, undergraduates asked to present a piece of work orally in front of their colleagues, showed an increase in the levels of this antibody (Evans *et al.*, 1994). Levels of sIgA tend to decrease during examination periods (Jemmott and Magloire, 1988) which suggests that short- and long-term stressors have different effects on the immune system. Exam stress seems to cause more than just nerves, panic and sleepless nights. It also seems to affect brain activation. Lewis *et al.* (2007) measured EEG during periods of low exam stress and high stress in 49 students. While cortisol levels did not change between testing periods, surprisingly, frontal EEG did: leftward asymmetry in the frontal area during low exam stress shifted to rightward asymmetry during high exam stress. This increase in the right frontal area also correlated with self-reports of poorer health. The results are consistent with the model of EEG frontal asymmetry which you read about in Chapter 13.

The immune system has recently been studied in experiments designed to examine the effects of laughter and humour on stress and coping with stress. The evidence

for the role of humour and laughter in mediating the effects of the immune system is discussed in the Controversies in Psychological Science section.

Controversies in Psychological Science – Can humour reduce stress?

The issue

In 1979, Norman Cousins published a rather unusual book called *The Anatomy of Illness*. In it, he described the way in which he used laughter to help him recover from a degenerative spinal condition. Since 1979, a number of popular and scientific accounts have suggested that using humour can help to combat stress and ill health. One contributor to the field has suggested that ‘happy breathing, simulated smiles and transcendental breathing’ can uplift spirits (Holden, 1993). ‘Don your Super-Humour-Person cape,’ he exhorts, ‘and save the world from the arch-villain over-seriousness.’ While we can dismiss accounts like this as minor eccentricities of little psychological importance, more thoughtful researchers have examined whether humour does help us to cope with ill health and stress and provide immunity from these problems. These researchers have focused upon the effects of humour from several perspectives. Perhaps the most important of these are: producing humour, appreciating humour and using humour as a coping mechanism.

The evidence

Laughter is an intriguing behaviour: it can induce laughter in a passive listener, can enhance the enjoyment of comedy, despite people’s claimed dislike of audience laughter (Martin and Gray, 1996), and provides vigorous muscle exercise. According to Hans Selye, laughter is a form of eustress: a positive, life-enhancing type of stress or pressure. In one experiment, 20 men and women endured pressure-induced discomfort after either having listened to a 20-minute laughter tape, a relaxation tape or a dull narrative (Cogan *et al.*, 1987). For both the laughter and relaxation conditions, discomfort thresholds were higher, that is, participants could endure greater stress.

Does this suggest that comedy is good for you? The picture is not altogether clear-cut. In a well-controlled experiment where the effect of the appreciation of humour on stress reduction was examined, the experimenters found no relationship between appreciation and stress reduction (Martin and Lefcourt, 1983). They did, however, find a slight moderation of the stress when humour was produced by participants. Another study found that this moderating effect was significant for depression but not anxiety symptoms (Nezu *et al.*, 1988). This finding suggests that it may not necessarily be the blanket appreciation (watching, listening) of humour that is important but the way in which humour is used.

Martin and Lefcourt and their colleagues have conducted a number of experiments in which they examined the relationship between a person’s sense of humour, their use of humour as a coping mechanism and their response to stress.

In a small number of detailed studies, the experimenters took measures of individuals’ physical stress by sampling their salivary immunoglobulin A concentrations (sIgA). In one study, 40 participants provided saliva samples, completed a Daily Hassles Scale (a measure of the degree of stress experienced daily), and a sense of humour questionnaire. The experimenters found a negative correlation between low scores on the sense of humour questionnaire and sIgA levels. A different experiment measured sIgA concentrations before and after the presentation of humorous stimuli and examined whether the presentation would interact with the participants’ sense of humour (Lefcourt *et al.*, 1990). The researchers found that not only did saliva concentrations increase after presentation of humour but also those participants with the greatest sense of humour had larger concentrations of sIgA after exposure to an audio comedy tape.

More recently, Lefcourt *et al.* (1997) examined the relationship between pain endurance, coping and blood pressure in men and women. There is evidence to suggest that men and women do use humour in different ways. Men are reported to make more frequent attempts at humour, for example, and use it for more negative reasons than do women (Myers *et al.*, 1997). In Lefcourt *et al.*’s experiment, women who used coping humour a great deal exhibited lower systolic blood pressure than did low-scoring women. Men, on the other hand, showed the reverse pattern. On the basis of the participants’ responses to the stressful tasks, the experimenters concluded that humour may moderate the effect of uncontrollable and passively experienced stress but that stressful problem-solving tasks involving active participation are less susceptible to these moderating effects.

In a recent review of studies examining the relationship between humour and good health, Rod Martin (R.A. Martin, 2001) concludes that evidence is mixed at best. Some studies show beneficial effects of exposure to humour on health, others no effect. Furthermore, stimuli that are perceived as generally pleasant stimulate similar responses to those elicited by humour. Conversely, a stimulus need not be pleasant to reduce a painful experience. Studies have shown that both positive and negative emotional stimuli can reduce the perception of pain, for example. Martin suggests that experiments need to distinguish more clearly between effects that are specific to humour and effects that are general to positive emotional stimuli.

Conclusion

From what you have read so far, are you convinced that humour can help reduce the effect of stress? What influences your decision? Can you think of better ways of measuring the

Controversies in Psychological Science – *Continued*

effects of sense of humour, or perceiving humour or generating humour, on stress reduction? Would you expect the effects of sense of humour on stress reduction to be long term? If so, why? If not, why not?

Finally, in an ingenious test of the hypothesis that laughter and humour help us combat the effects of stressful events,

Rotton (1992) examined the death rates of comedians, literary humorists and non-humorous individuals by examining published biographical details. He found no significant difference between the lifespan of humorous entertainers and that of others.

Infectious diseases

A wide variety of stress-producing events in a person's life can increase the susceptibility to infectious diseases. For example, Glaser *et al.* (1987) found that medical students were more likely to contract acute infections – and to show evidence of suppression of the immune system – during final examinations than before. In addition, autoimmune diseases often get worse when a person is subjected to stress, as Feigenbaum *et al.* (1979) found for rheumatoid arthritis.

Stone *et al.* (1987) attempted to see whether stressful events in people's daily lives might predispose them to upper respiratory infection. If a person is exposed to a micro-organism that might cause such a disease, the symptoms do not occur for several days, that is, there is an incubation period between exposure and signs of the actual illness. The authors therefore reasoned that if stressful events suppressed the immune system, one might expect to see a higher likelihood of respiratory infections several days after such stress. To test their hypothesis, they asked volunteers to keep a daily record of desirable and undesirable events in their lives over a 12-week period. The volunteers also kept a daily record of any discomfort or symptoms of illness.

The results were as predicted: in the 3–5 days just before showing symptoms of an upper respiratory infection, people experienced an increased number of undesirable events and a decreased number of desirable events in their lives. Stone *et al.* (1987) suggest that the effect is caused by decreased production of a particular immunoglobulin (IgA) that is present in the secretions of mucous membranes, including those in the nose, mouth, throat and lungs. This immunoglobulin serves as the first defence against infectious micro-organisms that enter the nose or mouth. When a person is unhappy or depressed, IgA levels are lower than normal. The results suggest that the stress caused by undesirable events may, by suppressing the production of IgA, lead to a rise in the likelihood of upper respiratory infections.

However, this study did not manipulate exposure to the illness directly. In an extraordinary and well-con-

trolled experiment, Cohen *et al.* (1998) exposed individuals to one of two common cold viruses, measured various personality and behavioural variables (such as sex, alcohol consumption, sleep pattern), and monitored which individuals developed a respiratory infection that led to the cold. Eighty-four per cent became infected but only 40 per cent developed a cold. Those who did were reported to have endured chronic life stressors for at least a month; those who had endured little stress or experienced the effect of stressors for less than a month did not, on average, develop the cold. Other factors which were positively related to developing a cold were smoking, fewer than three exercise sessions a week, poor sleep, drinking fewer than two alcoholic drinks a day, ingesting less than 85 mg of vitamin C and being introverted.

Bereavement

Bereavement, another source of stress, also suppresses the immune system. Cancer and other illnesses have been observed to occur at higher than average rates among people who are widowed. To investigate the possibility that bereavement suppresses the immune system, Schleifer *et al.* (1983) drew blood samples from 15 men whose wives were dying of terminal breast cancer. Two blood samples were drawn, the first before the spouse's death and the second within two months afterwards. Each time, an agent that normally stimulates blood lymphocyte activity was mixed with the lymphocytes, and the resultant level of activity was measured. On average, the activity level of blood lymphocytes after the spouse's death was less than before her death, which meant that the bereaved spouses were more susceptible to illness. Taken together, the results of these studies (and many other similar studies) suggest a strong link between stress and weakening of the immune system.

Loneliness

Loneliness, the feeling or perception of being alone, is stressful and is associated with poor health. Loneliness does not depend on having a small social network: even

people with lots of friends and acquaintances can feel lonely. A factor that can facilitate good relations with others, and therefore predict good/ill health, is sociability, defined as ‘the quality of seeking others and being agreeable’ (Cohen *et al.*, 2003). Two of the dimensions of the Big Five personality scale you read about in Chapter 14 seem to measure this behaviour: extraversion and agreeableness. Cohen *et al.* used these measures and another which measures how well people develop good relations with others (and how often they interact with others) to examine whether high scorers were less prone to illness.

The researchers took baseline measures of sociability in over 300 adults aged between 18 and 54, then exposed participants to one of two rhinoviruses which caused the common cold. Five days after exposure, physical symptoms were noted and any infection development measured. Four weeks later, blood samples were taken to verify whether an illness had developed.

Sociability predicted susceptibility to the common cold: the greater the degree of sociability, the less likely the person was to develop a cold. The highly sociable individuals had more social relationships and relationships of greater quality than less sociable ones but the link between sociability and the development of illness remained even when these factors were taken into account. This suggests that it is not simply being sociable which could be a protective factor against illness but that it is the trait of sociability which acts as the protector. Interestingly, high extraversion scores, high agreeableness scores and positive relations individually predicted the decreased likelihood of a cold developing. However, when the measures were combined, the effect was greater.

In a direct examination of whether loneliness (and the size of a person’s social network) influenced health, a group of North American researchers investigated the antibody response to influenza immunisation in first-year students whose social networks and degrees of loneliness throughout their first semester were assessed (Pressman *et al.*, 2005). These measures were then used to predict the degree of health or ill health experienced by the students.

Students experiencing either the greatest degree of loneliness or the smallest social networks showed poorer antibody response to one viral component of the vaccine (there were four in total). Those who were most lonely and who also had the smallest social networks showed the lowest antibody response of all. People who were lonely also had more circulating cortisol, slept less well, experienced greater stress and experienced more negative (and less positive) emotion. These outcomes were not significantly affected by social network size. The antibody responses at 1 and 4 months can be seen in Figures 17.16 (a) and (b).

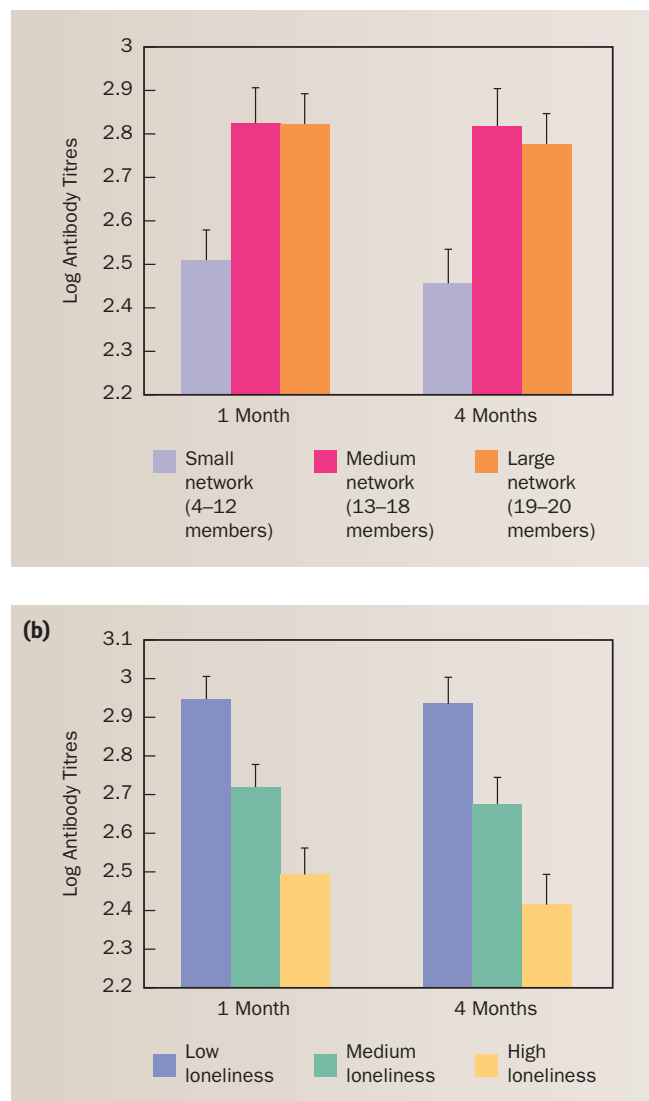

Figure 17.16 (a) Antibody levels at 1 month and 4 months, according to size of social network. (b) Antibody level at 1 month and 4 months, according to degree of loneliness.

Procrastination

Procrastination refers to the tendency to put off tasks and chores that could be done immediately. You might think that in the short term, this produces less stress because the individual is under less pressure to perform. In a study of procrastination among health psychology students, Tice and Baumeister (1997) noted the date on which students submitted coursework and took measures of procrastination from each. Not surprisingly, procrastinators submitted their coursework significantly later. They also received lower grades. However, and oddly, they also seemed to experience less stress than did non-

procrastinators. In a term-long study, the researchers found that this was true, but only at the beginning of the term; at the end of the term their symptoms of stress were significantly greater than those of non-procrastinators, as seen in Figure 17.17. Readers should, perhaps, consider the implications of this study very, very carefully.

Personality

Friedman and Rosenman (1959) identified a behaviour pattern that appeared to be related to a person's susceptibility to CHD. Heart attacks occur when the blood vessels that serve the heart become blocked, whereas strokes involve the blood vessels in the brain. The two most important risk factors in CHD are high blood pressure and a high level of cholesterol in the blood. Friedman and Rosenman characterised the disease-prone **type A pattern** as one of excessive competitive drive, an intense disposition, impatience, hostility, fast movements and rapid speech. People with the **type B pattern** were less competitive, less hostile, more patient, easy-going and tolerant, and they moved and talked more slowly; they were also less likely to suffer from CHD. Friedman and Rosenman developed a questionnaire that distinguished between these two types of people. The test is rather interesting, because the person who administers it is not a passive participant. The interviewer asks questions in an abrupt, impatient manner, interrupting the subject if they take too much time to answer a question. The point

of such behaviour is to try to elicit type A behaviour from the subject.

Researchers have devoted much attention to the relation between the type A personality and CHD. The Western Collaborative Group study (Rosenman *et al.*, 1975), which studied 3,154 healthy men for eight years, found that the type A behaviour pattern was associated with twice the rate of CHD relative to non-type-A behaviour patterns.

Research since has not been so conclusive, however. For example, one large study found that although people classified as type A were more likely to have heart attacks, the long-term survival rate after having a heart attack was higher for type A patients than for type B patients (Ragland and Brand, 1988). In this case, it would seem better to be type A, at least after having a non-fatal heart attack. Other studies have failed to find a difference in the likelihood of CHD in people with type A and type B personalities (Dimsdale, 1988).

The personality characteristic of submissiveness has been associated with lower rates of CHD in a group of Scottish individuals (Whiteman *et al.*, 1997). Submissiveness refers to a preference for staying in the background, letting others lead/dominate, and lacking self-assurance and self-confidence. Submissiveness, however, is not type B behaviour because submissive people do not have the type B personality's sense of security.

Other characteristics which seem to be part of the type A personality are a greater need for control (Furnham, 1990), placing less value on avoiding problems and responsibilities (Smith and Brehm, 1981), and greater alertness and focus (Matthews and Brunson, 1979). Williams *et al.* (1980) suggested that one aspect of the type A personality – hostility – is of particular importance in CHD. Several studies carried out in the early to mid 1980s confirmed that hostility was an important risk factor for CHD, but more recent studies have not.

Personality type may also be hazardous in another way. While a study of 108 drivers found that type A behaviour was associated with faster driving but not increased accidents (West *et al.*, 1993), a study of bus drivers in India and the USA (Evans *et al.*, 1987), however, found that type A behaviour was associated with high traffic accident rates per month, a finding that was replicated in Italian traffic policemen (Magnavita *et al.*, 1997).

There also seems to be a relationship between the competitive aspect of type A personalities and blood pressure and heart rate. In one study, blood pressure and cardiovascular activity was measured in 36 male and female undergraduates who took part in a motorised racing game experiment (Harrison *et al.*, 2001) where they played alone, or in competition with the experimenter, or in collaboration with the experimenter.

Figure 17.17 The number of symptoms reported by student procrastinators and non-procrastinators across a term on a health psychology course.

Source: Tice, D.M. and Baumeister, R.F., Longitudinal study of procrastination, performance, stress and health: The costs and benefits of dawdling. *Psychological Science*, 1997, 8(6), 454–8. Reprinted by permission of Blackwell Publishers Ltd.

The competitive condition was associated with significant increases in blood pressure and heart rate whereas the cooperative condition produced barely discernible changes in activity, a finding that echoes reports in the literature of reduced or stable cardiovascular activity in response to stress in the presence of a supportive person. As expected, the competitive condition was rated the most competitive condition and the cooperative condition was rated the most cooperative while the solo condition was rated the least difficult and engaging of the three.

Competitiveness and need to win were associated with increased blood pressure and heart rate, suggesting that the heart rate increases seen in the type A personality may be due to competitiveness. It is possible, however, that more physical activity may be exerted in tasks requiring competition. Perhaps it is the excess effort which produces the changes.

Occupational stress

Occupational stress refers to the degree of stress experienced by members of different professions. This area of research is a popular one in organisational psychology and the Whitehall study of CHD in British civil servants is a good example of the type of work carried out in this area. This study has shown that the lower the grade of employment in the civil service, the higher the mortality rate from CHD. The Whitehall II Study followed a different cohort and investigated whether two factors might be associated with CHD-related mortality: high psychosocial pressure and low control over their environment (Marmot *et al.*, 1997).

Swedish studies suggest that sickness-related absenteeism from work is more common in blue-collar than white-collar workers (Steers and Rhodes, 1984). Several factors can influence the rate of sickness, including the physical work environment, psychosocial factors, risk of unemployment, education level and absentee culture (Drago and Wooden, 1992). In an extensive study of absenteeism in 84,319 individuals in two counties in Sweden, Knutsson and Goine (1998) found that the professions showing highest degrees of absenteeism for men were shop assistants, repairmen and welders, whereas loggers and mechanics were absent for the fewest days. The professions with the highest absenteeism rates for women were shop assistants, assistant nurses and secretaries (the lowest rates were for primary school teachers). Of course, these findings do not necessarily suggest that these professions are marked by acute stress (and, therefore, by high rates of absenteeism) although they might, but they suggest that some professions may be more susceptible to stressors.

As the books of the chefs Anthony Bourdain and Marco Pierre White, and television shows such as Gordon Ramsay's *Hell's Kitchen* and *Kitchen Nightmares* illustrate, working in a professional kitchen is a hard, time-consuming and stressful occupation.

Source: OnEdition/Rex Features.

Much of the applied work in occupational or organisational psychology has been directed towards helping people to cope with the stress generated by heavy workloads or excessive working hours (Warr, 1990; Buunk *et al.*, 1998). This work can lead to 'burn-out'. Burn-out has been defined as 'a unique affective response to stress [and] a multidimensional construct consisting of emotional exhaustion, physical fatigue, and cognitive weariness' (Melamed *et al.*, 2006). In the workplace, it can result from constant and persistent exposure to stressors. Melamed *et al.* (2006) investigated the relationship between burn-out and risk of cardiovascular disease and reported an association with ill health, sleep disturbance and impaired immune system functioning. 'The evidence', the authors suggest, indicates that 'burn-out and vital exhaustion pose an increased risk of incident myocardial infarction, stroke and sudden cardiac death' (p. 339).

There appears to be a significant relationship between the number of hours worked and the degree of physical and mental illness an employee experiences, but the extent of this relationship is unclear: most conclude that the two are related but the relationship is not particularly strong (Sparks *et al.*, 1997). Studies from Japan, however, suggest that individuals who work in excess of 11 hours a day are more at risk of myocardial infarction than are those who work a moderate number (Sokejima and Kagamimori, 1998). In Japan, it is thought that long working hours can cause sudden fatal heart attacks, called 'karoshi' (Uehata, 1991, cited in Kageyama *et al.*, 1997). Kageyama *et al.*'s study of working commuters suggests that those with the longest commuting times and who work the most overtime show greater variability in heart rate than do those who commute and work less.

The ferocious work ethic of the Japanese is famed: they work longer hours than the British, Germans or North Americans. This devotion has been blamed for the estimated drop in birth rate from 1.28 to 1.26 per couple in 2006: people are too busy working to procreate and bring up a family.

A study of 968 Canadian employees has found that those in higher-status occupations suffer greater conflicts between home and work than do those in lower-status occupations (Schieman *et al.*, 2006). This conflict was most pronounced in the self-employed, those with greater job authority and those who worked longer hours.

Psychology in action – The health benefits of saintliness – when it is better to give (and forgive) . . .

Psychologists know that forgiving is better for mental health than is harbouring a grudge. Hostility, anger and blame – the behavioural litany of the aggrieved – have been associated with increased risk of coronary heart disease and even premature death, although no study has directly examined the relationship between forgiveness and physical health.

Research on the effects of hostility on people's respiratory function has found that increased hostility is associated with reduced lung function such as lung capacity and the ability to expire air (Jackson *et al.*, 2007). The group collected data from over 5,000 18–30-year-old US dwellers from metropolitan cities. Our pulmonary (lung) function peaks in young adulthood and plateaus thereafter: the poorer this function, the more likely we are to develop illness; it is also a risk factor for increased mortality. Researchers have found that some illnesses, such as myocardial infarction, increase in middle- to old-aged men who are hostile (remember that some personality characteristics, such as Type A behaviour, are associated with increased risk of cardiovascular disease). Jackson *et al.* sought to discover whether high levels of hostility predicted pulmonary function.

This is what they found, regardless of the participant's sex, age, height, socio-economic status, smoking, asthma or ethnicity. However, the group cautions against drawing cause-and-effect conclusions. They argue that low pulmonary function might cause high hostility, rather than vice versa, although this is unlikely.

One study has found that unforgiving thoughts produce greater aversive emotion and higher heart rate, blood pressure and brow muscle activity than do forgiving thoughts (Witvliet *et al.*, 2001). Over 70 men and women were asked either to rehearse hurtful memories and to bear grudges against real-life offenders, or to respond in a more forgiving way (such as imagining granting forgiveness). Participants felt more negative, aroused, angry, sad and less in control when they imagined being unforgiving. These cognitive and emotional responses were partnered by increased muscle tension at the brow, an index of anxiety.

The researchers suggest that although people cannot undo the wrong done to them in the past, they can change their

response to the wrongdoing in such a way as to protect their physical and mental health.

A Finnish study has reported that women who gave, rather than received, support in intimate relationships took fewer days off sick from work (Vaananen *et al.*, 2005). A different pattern, however, was seen in men. They took fewer days off if they received more support from their partner than they gave.

Researchers at the University of Michigan looked at the relationship between mortality and the giving and receiving of social and emotional support in a group of 423 elderly married couples (Brown *et al.*, 2003). In the late 1980s, participants were interviewed about how much social support they gave to relatives, neighbours and spouses, such as running errands, shopping, helping with housework, providing transport or childcare, and so on. They were also asked whether they made their spouse feel loved and whether they were willing to listen to their spouse in times of need. In addition, respondents were asked how often they were the recipients of such support. Five years after the interviews took place, the mortality rate in the sample was assessed and correlated with the survey responses.

Surprisingly, those who reported giving support to others showed least risk for mortality, whether the support was social or emotional. This relationship held even when demographic, personality and health variables were controlled for.

Conscientiousness – the ability to delay gratification, to plan appropriately, to follow rules and norms and so on – may be another saintly trait that protects against ill health. Studies since the 1990s have suggested that this trait correlated with longevity (Friedman *et al.*, 1993). In a meta-analysis of 194 studies in which conscientiousness-related traits were associated with risk factors for mortality such as smoking, drinking alcohol, using drugs, being sexually promiscuous and so on, Bogg and Roberts (2004) found that the relationship between conscientiousness and risky health-related behaviours was weak but the relationship between this trait and beneficial health-related behaviours was significant. The more conscientious the participants were, the fewer symptoms of ill health they reported.

Unemployment

Almost all of us have to earn a living; money allows us to do many of the things we want to do and employment gives structure and meaning to our lives. Unemployment, however, has been associated with an increase in ill health and psychological disturbance – see Figure 17.18.

One consequence of unemployment is increased isolation and loss of social context (Donovan and Oddy, 1982). A Danish study of employed and unemployed single mothers found that isolation can lead to depression (Beck-Jorgensen, 1991) and that lower self-esteem is characteristic of people who become unemployed (Winefield and Tiggemann, 1994). A longitudinal study of 1,060 young people who were monitored over five years since their last term at school in northern Sweden found that unemployment was correlated significantly with increases in depressive symptoms, even when their initial health status was accounted for (Hammarstrom and Janlert, 1997).

However, it is possible that being in a job that you loathe may be just as detrimental to your physical and psychological well-being. Broom *et al.* (2006) investigated this possibility in a group of 2,500 40–44-year-old Australians. They found, as perhaps expected, that unemployed people reported generally worse health than those who were employed. However, people who had job insecurity, low marketability and experienced great strain at work expressed poorer health than did those who were in jobs with few or no stressors. If all three negative outcomes were reported, those people reporting them indicated that it was no better than being unemployed.

Figure 17.18 Average depression score for adults ages 63–73, by workstatus.

Source: from The impact of work on the psychological health and well-being of older Americans, *Annual Review of Gerontology and Geriatrics*, 26, pp. 153–174 (James, J.B. and Spiro, A. 2007) (c) Springer Publishing Company, Reproduced with the permission of the Springer Publishing Company, LLC, New York, NY 10036

‘These findings challenge the assumption that any job is better for health than is no job at all,’ say the authors, ‘suggesting that the quality of work tempers the health benefits of employment’ (p. 583).

Optimism

Optimism refers to a disposition to believe in positive outcomes. Evidence suggests that dispositional optimists (those who are characteristically optimistic) are more successful at coping with ill health (Stanton and Snider, 1993), are not as emotionally perturbed by stressors (Aspinwall and Taylor, 1992), can cope better with breast cancer surgery (Stanton and Snider, 1993), report better physical health (Scheier and Carver, 1992), have a better quality of life (Fitzgerald *et al.*, 1993), and show an increase in helper T cells and natural killer cells (Segerstrom *et al.*, 1998). Optimism is also associated with better adjustment in university (Segerstrom *et al.*, 1998) and to the stress generated by missile attack (Zeidner and Hammer, 1992). A study of 163 early-stage breast cancer patients found that 5–13 years after surgery the degree of initial optimism expressed before treatment was positively related to people’s feelings of well-being later on (medical variables predicted very little of reported well-being at follow-up) (Carver *et al.*, 2005). Similar findings are found in gerontology. A study of 128 men and women aged between 65 and 80 years found that optimism was associated with not smoking, moderate alcohol consumption, vigorous physical exercise and brisk walking (Steptoe *et al.*, 2006).

A study of middle-aged men and women supports the hoary idea that looking on the bright side leads to a healthier life (Steptoe *et al.*, 2005). The 216 participants came from the longitudinal British Whitehall II study in which 10,308 London-based civil servants have been followed since 1985–8 to monitor correlates of risk for heart disease. Those who showed more positive affect – as measured by noting the moments of happiness the participants experienced over the course of the working day – were more likely to show reduced neuroendocrine, inflammatory and cardiovascular activity. This effect was found regardless of sex, age, socio-economic position, body mass and smoking status and was also found on leisure days. Happiness was also associated with lower heart rate across the day.

Social support

Although all of us experience stress, the experience is a subjective and private matter. Nobody else can truly know what we feel. However, being confronted by a stressor and coping with stress are often social matters.

We learn as children to seek others – parents, siblings and friends – when we need help. This is a pattern of coping that continues over the lifespan. Social support – the help that we receive from others in times of stress – is an important coping strategy for many people for two reasons. First, we can benefit from the experience of others in dealing with the same or similar stressors. Other people can show us how to cope, perhaps by teaching us how to reappraise the situation. Secondly, other people can provide encouragement and incentives to overcome the stressor when we may otherwise fail to cope with the stressful situation.

Eighty-nine first-year undergraduates completed a battery of depression, stress, social support and friendship measures at the beginning and end of their first term (Brissette *et al.*, 2002). When greater optimism was expressed at the beginning of the term, smaller increases in stress and depression and greater perception of social support were reported later in the term. The number of friends in the social network, however, did not seem to affect response to stress. Social support was found to contribute significantly to the better adjustment experienced by the optimistic, suggesting that this could be a mediating factor.

Coping with everyday stress

The degree to which we experience stress and the degree to which stress impairs our health depends to a large extent on our perception of the threat posed by the stressor. The number of potential stressors is very large. Depending on the individual, almost any aspect of the environment can be perceived as a stressor.

Sources of stress

Stress can be induced by changes that threaten or otherwise complicate life. The death of a spouse, being promoted at work, changes in social activities, getting married, and sustaining a personal injury or illness are significant life changes that cause stress and disrupt everyday life (Holmes and Rahe, 1967). Some evidence has accumulated that suggests that if an individual experiences enough changes in lifestyle over a short time period, they are likely to develop a physical illness within the next two years (Rahe and Arthur, 1978). Other research suggests that not all people who encounter a series of significant stressors over a short period are at risk of illness (DePue and Monroe, 1986). Why? Once again, the answer lies in the way that people perceive stressors. Recall Lazarus's idea of cognitive appraisal: the

amount of stress induced by a stimulus perceived to be a stressor is determined by how significant we believe its threat to be and whether we feel competent to cope with that threat.

Stressors do not have to be catastrophic or cause significant changes in lifestyle to induce stress. Often, the everyday hassles we experience are enough to leave us feeling stressed out. Locking our keys in the car, being late for an appointment, or having a disagreement with a friend are examples of stressful everyday events.

A common source of daily stress comes simply from making routine choices about what to do, how to do it or when to do it. Consider, for example, a choice between studying tonight for a test you have tomorrow or going to a party with some friends. You want to do both, but you can only do one (you are back into the classic self-control situation again – the choice between a small, short-term reward and a larger, long-term reward). Psychologists refer to this as an approach–approach conflict because the choice involves two desirable outcomes. Other choices involve approach–avoidance conflicts – one outcome is desirable and the other is not. For example, you live in Kent, want to visit Oslo and decide to travel by sea because you are afraid of flying. Still other choices involve avoidance–avoidance conflicts in which both outcomes are undesirable. For instance, choosing between having a root canal procedure or having a tooth extracted creates stress because you do not want to have either one of them, yet one needs to be done.

Several different tests have been developed to measure the severity of various stressors on people. Among the first measures to be developed was Holmes and Rahe's (1967) Social Readjustment Rating Scale (SRRS), which was devised on the assumption that any change in a person's life is a stressor. The test asks people to rate the amount of change or adjustment caused by recent events in their life, such as getting married or divorced, getting a new job or being sacked, moving to a new location, and losing a loved one. Responses are given in terms of life-change units (LCUs) – how much change or adjustment is caused by specific events. Once a person completes the SRRS, the LCUs are summed, resulting in a single score. High scores indicate high levels of stress and low scores low levels of stress. People who get high scores have been shown to have more illness and adjustment problems than have people who get lower scores (Holmes and Rahe, 1967; Monroe *et al.*, 1992).

Another commonly used scale, the Daily Hassles and Uplifts Scale, measures daily events that are either troublesome (hassles) or pleasant (uplifts) (DeLongis *et al.*, 1988). This scale requires people to rate, at the end of each day, the extent to which an event, such as the weather, deadlines, family, or physical appearance, served as a hassle or uplift for them on that day. This scale may

be completed daily over extended periods to provide a picture of how the routine events of everyday life create stress for people. Daily hassles yield a more accurate prediction of physical illness and adjustment problems than do daily uplifts (DeLongis *et al.*, 1988) and major life events (Garrett *et al.*, 1991).

Coping styles and strategies

So far, we have considered the negative effects of stress: its damaging effects on the body and mind. However, each of us can learn to control stress. We may not always be able to predict when and where we will encounter stressors or to control their intensity, but we can mitigate their damaging effects by adopting coping strategies that are consistent with our lifestyles. A **coping strategy** is simply a plan of action that we follow, either in anticipation of encountering a stressor or as a direct response to stress as it occurs, which is effective in reducing the level of stress we experience.

According to Lazarus and Folkman (1984; Folkman and Lazarus, 1991), there are two types of coping response: problem-focused and emotion-focused. **Problem-focused coping** is directed towards the source of the stress. For example, if the stress is job related, a person might try to change conditions at work or take courses to acquire skills that will enable them to obtain a different job. **Emotion-focused coping** is directed towards a person's own personal reaction to the stressor. For example, a person might try to relax and forget about the problem or find solace in the company of friends. Obviously, if the source of a stress-producing problem has a potential solution, problem-focused coping is the best strategy. If it does not, then emotion-focused coping is the only option.

We each have our own idiosyncratic ways of dealing with stress that can be categorised as being emotion-focused. In fact, health psychologists have shown several of these methods to be effective in controlling stress, including aerobic exercise, cognitive reappraisal, progressive relaxation training and social support. Some people engage in other activities such as smoking, although evidence suggests that smoking results in no significant self-reported decrease in anxiety.

Resilience

You have already seen how various personality factors can act as protective agents against stress and ill health. Optimism is one – an optimistic disposition is associated with significantly fewer symptoms of ill health and stress.

Another factor is resilience. People are sometimes said to have 'bounced back' from some misfortune or some

adversity, suggesting that they are resilient. Some psychologists have likened resilience to the property of metals: cast iron is hard and brittle (not resilient) whereas wrought iron is soft and malleable (resilient). Resilient individuals, in a psychological rather than metallurgical sense, are said to be able to bounce back from negative experiences and adapt to changing, adverse environmental conditions: they are optimistic, energetic, curious and express high degrees of positive emotion. Some psychological research has explored whether these positive emotions are a by-product of resilience or whether they are essential to resilient people's ability to cope.

Tugade and Fredrickson (2004) induced stress by asking participants to prepare a speech and deliver it to a video camera. The participants were told that their performance would be evaluated by their peers. In fact, this was an experimental ruse and there was no evaluating group. Cardiovascular and psychological responses were measured during and after the delivery of the speech.

Individuals who characteristically expressed positive emotion were more likely to show cardiovascular recovery after the stressful task (giving a speech). They were also more likely to find positive meaning in negative events. Given that increased cardiovascular reactivity produced by negative events predicts ill health, this degree of resilience suggests that the factor may protect against such ill health by reducing one of its predictors.

The study based their characterisation of resilience on participants' self-report. It would be useful to see whether a group of individuals rated by peers as resilient would show a similar pattern of behaviour. Furthermore, it would be useful to see whether this resilience is constant or whether it fluctuates and is affected by different types of negative experiences.

Some people use retrieval of positive memories to offset the unpleasant emotion created by negative experiences. Joormann and Siemer (2004) examined whether undergraduates' ability to cope with negative mood involved evoking positive memories. People who were slightly depressed were unlikely to evoke positive memories to cope with the unhappy memories; those who did not experience depression but were unhappy did use positive emotion. Even when the depressed participants were asked to recall only pleasant memories, they still reported being unhappy.

Cognitive reappraisal

Aerobic exercise is not the coping strategy of choice for everyone. Some people find that simply altering their perception of the threat posed by stressors reduces stress. This coping strategy is called **cognitive reappraisal** (or cognitive restructuring) and is an extension of Lazarus and Folkman's idea of cognitive appraisal. The rationale under-

lying this strategy is easy to grasp: if our cognitive appraisal of a stressor is a determining factor in producing stress, then by reappraising that stressor as being less threatening, stress should be reduced. Sometimes, simply learning to substitute an incompatible response, such as replacing a negative statement with a positive one, is sufficient to reduce stress (Lazarus, 1971; Meichenbaum, 1977). For example, students who suffer from test anxiety perceive tests as extremely threatening. They may say to themselves, 'I am going to fail the exam tomorrow', or, 'That test is going to be far too hard'. To reappraise the stressor in this case would involve replacing these statements with ones such as 'I'm going to pass that test tomorrow' or 'Yes, the test will be difficult, but I'm ready for it'.

Cognitive reappraisal is an effective coping strategy because it is often a more realistic approach to interpreting the threat posed by stressors than is the original appraisal. We have good reason to appraise a charging bear as a real threat, but not a university examination. After all, we may not be able to deal with the bear, but we can always learn how to take tests and improve our study habits. An additional benefit of cognitive reappraisal is that it teaches the individual that they can take control of stressful situations.

Relaxation training

Another coping strategy is simply learning to relax when confronted with a stressor. Relaxing is based on the same principle as cognitive reappraisal: substitute an incompatible response for the stress reaction. One procedure for producing relaxation is the **progressive relaxation technique**. It involves three steps: (1) recognising your body's signals informing you that you are experiencing stress; (2) using those signals as a cue to begin relaxing; and (3) relaxing by focusing your attention on different groups of muscles, beginning with those in the head and neck and then those in the arms and legs. Imagine that when confronted by a stressor, for example an exam, you respond by tensing certain muscles: those in your hand and fingers that you use to hold your pen or pencil and those around your mouth that you use to clench your teeth. Once you become aware of these responses, you can use them as cues to relax the muscle groups involved.

Some have also suggested that the use of aromas can alleviate stress and anxiety; this is sometimes called aromatherapy. Aromatherapy is, in fact, a misnomer because there is usually more to aromatherapy than just the presentation of odour; clients normally receive massage as well. The evidence for a long-term, or even short-term, effect of odour on mental health is sparse; few studies have investigated this relationship scientifically and those

that have done so have serious methodological or statistical flaws (see G.N. Martin, 1996, for a review).

Stress inoculation training

According to psychologist Donald Meichenbaum, the best way to cope with stress is to take the offensive – to have a plan in mind for dealing with stressors before you are actually confronted by them. In other words, people should not wait until they are faced with a stressor to cope with it; instead, they should anticipate the kinds of stressor most likely to affect them and develop the most effective coping plan for dealing with specific stressors. Meichenbaum (1985), in fact, has devised a problem-focused coping method, called **stress inoculation training**, which focuses on helping people to develop coping skills that will decrease their susceptibility to the negative effects of stress. Stress inoculation training has been found to be effective in reducing stress levels among people working in a variety of settings, including nurses, teachers, police trainees (Bishop, 1994) and professional athletes (Cox, 1991).

In Meichenbaum's words (1985, p. 21), stress inoculation training

is analogous to the concept of medical inoculation against biological diseases . . . Analogous to medical inoculation, [stress inoculation training] is designed to build 'psychological antibodies', or coping skills, and to enhance resistance through exposure to stimuli that are strong enough to arouse defenses without being so powerful as to overcome them.

Stress inoculation training usually occurs in a clinical setting involving a therapist and a client and takes place over three phases aimed at achieving seven goals, summarised in Table 17.5.

The first phase is called the conceptualisation phase and involves two basic goals. Goal 1 involves learning about the transactional nature of stress and coping. Stress and coping are strongly influenced by the interaction of cognitive and environmental variables. A person experiences stress to the extent that they appraise the stressor – an environmental variable – as taxing or overwhelming their ability to cope with it – a cognitive variable. In Meichenbaum's view, coping is any behavioural/cognitive attempt to overcome, eliminate or otherwise control the negative effects caused by the stressor (see also Lazarus and Folkman, 1984).

Goal 2 involves becoming better at realistically appraising stressful situations by taking stock of, or self-

Table 17.5 Summary of the phases and goals of Meichenbaum's stress inoculation training programme**Conceptualisation phase**

Goal 1: Learning the transactional nature of stress and coping

Goal 2: Learning to become better at realistically appraising stressful situations by learning self-monitoring skills with respect to negative or maladaptive thoughts, emotions and behaviours

Skills acquisition and rehearsal phase

Goal 3: Learning problem-solving skills specific to the stressor

Goal 4: Learning and rehearsing emotion-regulation and self-control skills

Goal 5: Learning how to use maladaptive responses as cues to implement the new coping strategy

Application and follow-through phase

Goal 6: Learning to practise imagery rehearsal using progressively more difficult or stressful situations

Goal 7: Learning to apply new coping skills to other, perhaps unexpected, stressors

Source: Adapted from Meichenbaum, D., *Stress Inoculation Training*. New York: Pergamon Press, 1985.

monitoring, patterns in maladaptive thinking, feeling and behaving. A person may keep a diary, or a 'stress log', to record stressful events, the conditions under which these events occur, and their reactions to these events.

The second phase is called the skills acquisition and rehearsal phase and involves goals 3–5. Goal 3 involves learning specific problem-solving skills aimed at reducing stress. For example, a person may learn to identify and define a specific stressor and outline a plan for dealing with it in behavioural terms. The plan should include developing alternative ideas for dealing with the stressor and considering the possible consequences that correspond to each alternative. At this point, a person may find relaxation training and self-instructional training, in which they learn to make positive self-statements when confronted by a stressor, helpful.

Goal 4 involves learning and rehearsing emotion-regulation and self-control skills. These skills help people to remain calm and rational when confronted with a stressor. Goal 5 involves learning how to use maladaptive responses as a cue to invoke the new coping strategy. For example, when faced with a stressor, you may feel yourself getting tense. This feeling of tension is your cue to implement specific aspects of your inoculation training, which presumably would reduce your level of stress.

The third and final phase of Meichenbaum's programme is called the application and follow-through phase and comprises goals 6 and 7. Goal 6 involves imagery rehearsal, in which a person practises coping with the stressor by imagining being confronted by that stressor in progressively more difficult situations. The purpose of rehearsing the coping skills is to build confidence in one's ability to use the new coping strategy. Goal 7 involves learning to apply new coping abilities to both expected and unexpected stressors. This might be accom-

plished by imagining several situations in which you feel anxious, imagining implementing the coping strategy in response to the anxiety, and, finally, imagining feeling relieved as a result of coping with the stressor.

Stress is an inevitable consequence of environmental change. Both large changes, such as a natural disaster or changing jobs, and small changes, such as remembering that we have an exam tomorrow, contribute to the overall level of stress that we experience at any one time. Whether stress impairs our health depends on three variables: the extent to which we appraise the stressor as threatening, whether we engage in good health practices, and the extent to which we use coping strategies effectively. The combined effects of these variables on the relationship between stress and health are summarised in Figure 17.19.

Do psychological interventions reduce stress?

Psychologists know that psychological stress is linked to immune system responses: one causes disruption of the other. If psychological factors can affect the immune system, it seems reasonable to hypothesise that psychological factors that play a large part in intervention treatment can also affect immune system response. Over 85 intervention studies of the effect of psychological variables on stress have now appeared in journals, most of them appearing since the 1980s (Miller and Cohen, 2001).

Miller and Cohen's review suggests that the success of interventions are modest. The authors reviewed studies which examined the effects of different types of intervention on immune system functioning. These included (1) stress management interventions which are normally undertaken with patients with medical illness; these interventions involve educating the person about the illness, and providing coping skills training and psychological sup-

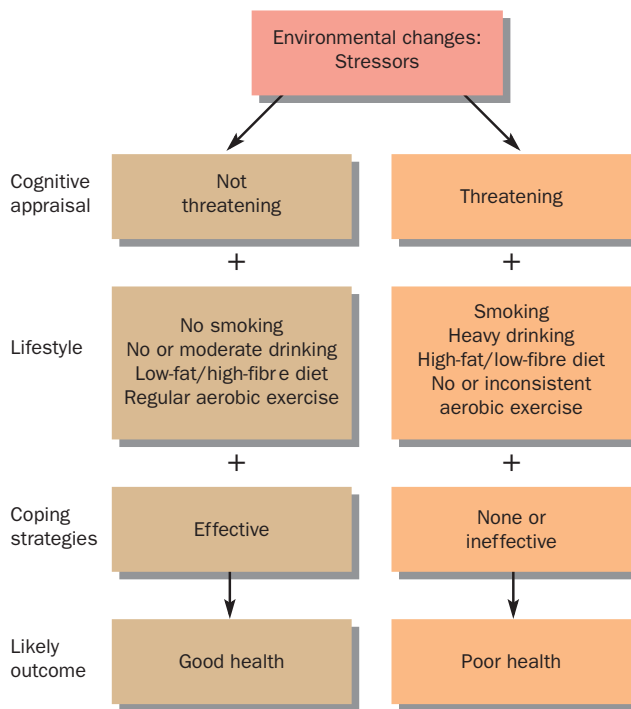

Figure 17.19 The effects of stress on health are mediated by cognitive appraisal, lifestyle and coping abilities.

port; (2) relaxation interventions which involve muscle relaxation; (3) disclosure interventions which usually ask participants to write about their stressful experiences; (4) hypnosis; and (5) conditioning interventions in which a neutral stimulus is paired with an immune system facilitator so that the presentation of the neutral stimulus alone will produce the immune system response.

The researchers found that stress management interventions altered immune responses very little; relaxation interventions also showed little evidence of producing immune response changes; disclosure interventions were modestly successful in enhancing immune system response; hypnosis showed that participants could use hypnotic suggestion to alter immune responses; and conditioning interventions were also modestly successful in changing immune system response.

Although two of these interventions met with some success, none of the interventions were found to be beneficial to people suffering stress caused by illness. Perhaps such interventions are inappropriate for counteracting the stress experienced by medically ill individuals (those suffering from cancer, for example). The authors suggest that people most likely to benefit from stress management and relaxation are those suffering ongoing, chronic stress such as the bereaved and those who have been involved in natural disasters.

Chapter review

Health psychology and unhealthy behaviour

- Health psychology applies psychological principles to the study of health and illness. It examines the effects of various psychological and physical factors on health and can also evaluate the effect of health policy and health education on behaviour.
- Behaviours which have implications for health psychology include smoking, eating, sexual behaviour, exercise and alcohol use.
- Protective factors are those which make the individual less susceptible to ill health.
- Evidence suggests that people who have high-fat, low-fibre diets tend to be more susceptible to coronary heart disease (CHD) and cancer than are people who have low-fat, high-fibre diets.
- Weight gain and increased low-density lipoprotein (LDL) cholesterol levels are both risk factors for CHD and cancer.
- The decision to begin smoking is influenced by peer pressure, low income and poor education; smoking normally begins in adolescence and is rarely initiated in adulthood.
- Smoking cessation programmes have met with limited success; a combination of nicotine replacement and psychological treatments appears to show the best outcome.
- Exercise appears to be effective in increasing positive mood and alleviating mild depression.
- The best precautionary measure against contracting any sexually transmitted disease (STD) is the practice of safe sex.
- Acquired immune deficiency syndrome (AIDS) refers to a disease resulting from infection by virus (HIV). There are 21 million people living in the world with AIDS; HIV can be contracted through unprotected homosexual and heterosexual sex, intravenous injection and transfusion of contaminated blood.
- Programmes aimed at preventing the spread of STDs and AIDS focus on teaching people the relationship between their behaviour and the likelihood of contracting one or more of these diseases and how to use safe sex strategies.

Stress and health

- Stress is defined in terms of our physiological and psychological response to stimuli that either prevent us from obtaining a goal or endanger our well-being.
- Selye's model describes how prolonged exposure to stress leads to illness and sometimes death.
- The stress response, which Cannon called the fight or flight response, is useful as a short-term response to threatening stimuli but is harmful in the long term. This response includes increased activity of the sympathetic branch of the autonomic nervous system and increased secretion of epinephrine, norepinephrine and glucocorticoids by the adrenal gland.
- Although increased levels of epinephrine and norepinephrine can raise blood pressure, most of the stressor-related harm to health comes from glucocorticoids.
- Prolonged exposure to high levels of these hormones can increase blood pressure, damage muscle tissue, lead to infertility, inhibit growth, inhibit the inflammatory response and suppress the immune system.
- The most important predictor of ill health produced by stressors is the nature of a person's coping response.
- Personality characteristics which may serve as protective factors against stress include submissiveness and optimism.
- Type A behaviour pattern refers to behaviour that is competitive, hostile, rapid and intense; some of these variables, especially hostility, may predict the likelihood of CHD, but the research findings are mixed.
- Psychoneuroimmunology is the study of the effects of psychological stressors on the immune system.
- The immune system consists of several types of white blood cell that produce chemically-mediated and cell-mediated responses. The immune system can cause harm when it triggers an allergic reaction or when it attacks the body's own tissues in autoimmune diseases.
- The most important mechanism by which stress impairs immune function is by increasing blood levels of glucocorticoids. Neural input to the bone marrow, lymph nodes and thymus gland may also play a role; naturally occurring opioids appear to suppress the activity of internal killer cells.

- A wide variety of stressful situations, such as the death of a spouse or caring for a relative with Alzheimer's disease, have been shown to increase people's susceptibility to infectious diseases.

Coping with everyday stress

- Stress may stem from a wide variety of sources. Even positive events, such as the birth of a child or the marriage of a son or daughter can produce stress.
- Stress may lead to physical illness when a person undergoes several stressful events over a short period of time. The extent to which people become ill appears to depend on the extent to which they perceive a stressor as being a threat to their well-being and the extent to which they believe they can cope with that threat.
- Lazarus and Folkman have identified two types of coping. Problem-focused coping represents any attempt to reduce stress by attempting to change the event or situation producing the stress.
- Emotion-focused coping centres on changing one's personal reaction to the stressful event or situation. Emotion-focused coping may involve activities such as aerobic exercise, cognitive reappraisal, relaxation training and seeking social support.
- Meichenbaum's stress inoculation training programme is a problem-focused coping strategy that prepares people to cope with anticipated stressors. The programme involves three phases and seven goals. The first phase involves learning how to conceptualise the transactional nature of stress. The second phase entails learning coping skills specific to the stressors in their lives and practising or rehearsing these skills in hypothetical situations. The third phase involves preparing people to implement these coping skills in real-life situations. The seven goals of stress inoculation training focus on specific kinds of knowledge, behaviour and coping strategies central to preparing people to anticipate, confront and reduce the threat posed by stressful situations.
- Reviews of the benefits of psychological interventions in stress have produced mixed results; some interventions are modestly successful; others show no benefit.

JK Rowling reveals her thoughts of suicide as a young single mother

Linda Johnston

While the 42-year-old author has spoken before of her battle with depression, it is the first time she has admitted that she considered ending her life.

At the time, she was living on state benefits after having separated from her then husband and was living in a cramped and unheated flat in Edinburgh with her baby daughter.

Rowling, whose Potter novels have sold more than 400 million copies, said: 'We're talking suicidal thoughts here, we're not talking "I'm a little bit miserable."'

'Two weeks later I had a phone call from my regular GP who had looked back over the notes . . . She called me back in and I got counselling through her. She absolutely saved me because I don't think I would have had the guts to do it twice.'

She said, 'I have never been remotely ashamed of having been depressed – never. What's to be ashamed of? I went through a really rough time and I am quite proud that I got out of that.'

WHAT YOU SHOULD BE ABLE TO DO AFTER READING CHAPTER 18

- Define the term 'mental illness'.
- Explain the aim of classification of mental disorders and define mental abnormality.
- Describe the most important treatment approaches to mental disorders.
- Describe the symptoms and causes of major mental disorders.
- Evaluate theories of mental disorder.
- Evaluate treatment approaches to mental disorder.

QUESTIONS TO THINK ABOUT

- What makes an abnormal behaviour abnormal?
- Which term makes the best sense: mental disorder or mental illness?
- How, and in what ways, are mental illnesses different from 'physical' ones?
- Are mental illnesses categorical or do they fall along a continuum?
- Do all mental disorders have a biological basis?
- What are the best treatments for mental illness? Do you think some treatment approaches are more appropriate than others?

Explore the accompanying videos, simulations and animations on MyPsychLab. This chapter includes activities on: Perspectives on mental disorders • Hierarchy of anxiety • Genetic causes of schizophrenia • Mood disorders • Check your understanding and prepare for your exams using the multiple choice, short answer and essay practice tests also available.

Classification and diagnosis of mental disorders

Abnormal psychology is the area of psychology which studies and treats mental disorder. Mental disorders are disorders of thought, feeling or behaviour and are characterised by behaviourally deviant features. Their causes may be genetic, environmental, cognitive or neurobiological.

Some of these disorders you will be familiar with – depression and anxiety, for example. Others will not be so familiar, such as paraphilia and conversion disorder. Although the symptoms described for each disorder may apply to healthy individuals who exhibit a ‘bad mood’ or who are under stress, these disorders represent a severe impairment in functioning. Clinical depression is not the same as the ‘low’ we sometimes feel in life, and generalised anxiety disorder does not represent the stress we feel before an exam or speaking in public.

The term ‘mental disorder’ refers to a clinical impairment characterised by abnormal thought, feeling or behaviour. Some mental disorders, especially the less severe ones, appear to be caused by environmental factors or by a person’s perception of these factors, such as stress or unhealthy family interactions. In contrast, many of the more severe mental disorders appear to be caused by hereditary and other biological factors that disrupt normal thought processes or produce inappropriate emotional reactions. The descriptions of mental disorders in this chapter necessarily make distinctions that are not always easy to make in real life; the essential features of the more important mental disorders are simplified here for the sake of clarity. In addition, many of the cases that clinicians encounter are less clear-cut than the ones included here and are thus not so easily classified.

To understand, diagnose and treat psychological disorders, some sort of classification system is needed. The need for a comprehensive classification system of psychological disorders was first recognised by Emil Kraepelin (1856–1926), who provided his version in a textbook of psychiatry published in 1883. The classification most widely used today still retains a number of Kraepelin’s original categories.

What is ‘abnormal’?

Mental disorders are characterised by abnormal behaviour, thoughts and feelings. The term ‘abnormal’ literally refers to any departure from the norm. Thus, a short or tall person is ‘abnormal’, and so is someone who is especially intelligent or talented. Albert Einstein was ‘abnormal’, as were Oscar Wilde and Pablo Picasso. The term ‘abnormal’ is often used pejoratively – it is used to refer to characteristics that are disliked or feared – but

this is not the way in which it is used when describing mental illness. The most important feature of a mental disorder, however, may not be whether a person’s behaviour is abnormal – different from that of most other people – but whether it is maladaptive. Mental disorders cause distress or discomfort and often interfere with people’s ability to lead useful, productive lives. They often make it impossible for people to hold down jobs, raise families or relate to others socially.

The causes of mental disorders

What causes mental disorders? In general, they are caused by an interaction between hereditary, cognitive and environmental factors. In some cases, the genetic component is strong and the person is likely to develop a mental disorder even in a very supportive environment. In other cases, the cognitive and environmental components are strong. A complete understanding of mental disorders requires that scientists investigate genetic, cognitive and environmental factors. Once genetic factors are identified, the scientist faces the task of determining the physiological effects of the relevant genes and the consequences of these effects on a person’s susceptibility to a mental disorder. Understanding the cognitive factors involved in mental disorders requires identification of the origins of distorted perceptions and maladaptive thought patterns. And environmental factors encompass more than simply a person’s family history or present social interactions; they also include the effects of prenatal health and nutrition, childhood diseases and exposure to drugs and environmental toxins.

Different psychologists and other mental health professionals approach the study of mental disorders from different perspectives, each of which places more or less emphasis on these factors. The perspectives differ primarily in their explanation of the aetiology, or origin, of mental disorders. Some of these perspectives are described next.

The psychodynamic perspective

According to the psychodynamic perspective, based on Freud’s early work described in Chapter 14, mental disorders originate in intrapsychic conflict produced by the three warring factions of the mind: the id, ego and superego. For some people, the conflict becomes so severe that the mind’s defence mechanisms are ineffective, resulting in mental disorders that may involve, among other symptoms, extreme anxiety, obsessive thoughts and compulsive behaviour,

depression, distorted perceptions and patterns of thinking, and paralysis or blindness for which there is no physical cause. As you saw in Chapter 14, the id, ego and superego are hypothetical constructs, not physical structures of the brain. But Freud and his followers often spoke as if these structures and their functions were real. Even today, psychodynamic theorists and practitioners approach mental disorders by emphasising the role of intrapsychic conflict in creating psychological distress and maladaptive behaviour.

The medical perspective

The medical perspective has its origins in the work of the ancient Greek physician Hippocrates. Hippocrates formulated the idea that excesses in the four humours (black bile, yellow bile, blood and phlegm) led to emotional problems. Other physicians, Greek and Roman, extended Hippocrates' ideas and developed the concept of mental illness – illnesses of the mind. Eventually, specialised institutions or asylums were established where people with mental disorders were confined. Early asylums were ill-run and the patients' problems were poorly understood and often mistreated. During the eighteenth and nineteenth centuries, massive reforms in the institutional care of people with mental disorders took place. The quality of the facilities and the amount of compassion for patients improved, and physicians, including neurosurgeons and psychiatrists, who were specifically trained in the medical treatment of mental disorders, were hired to care for these patients.

Today, the medical perspective is the dominant perspective in the treatment of mental disorders. Individuals with mental disorders are no longer confined to mental institutions. Instead, they are treated on an outpatient basis with drugs that are effective in abating the symptoms of mental disorders. Usually, only those people with very severe mental problems are institutionalised. The **medical model**, as the medical perspective is properly called, is based on the idea that mental disorders are caused by specific abnormalities of the brain and nervous system and that, in principle, they should be approached the same way as physical illnesses. As we shall see, several mental disorders, including schizophrenia, depression and bipolar disorder, are known to have specific biological causes and can be treated to some extent with drugs. We shall also see that genetics play a pivotal role in some of these disorders.

However, not all mental disorders can be traced so directly to physical causes. For that reason, other perspectives, which focus on the cognitive and environmental factors involved in mental disorders, have emerged.

The cognitive behavioural perspective

In contrast to the medical perspective, the cognitive behavioural perspective holds that mental disorders are

learned maladaptive behaviour patterns that can best be understood by focusing on environmental factors and a person's perception of those factors. In this view, a mental disorder is not something that arises spontaneously within a person. Instead, it is caused by the person's interaction with their environment. For example, a person's excessive use of alcohol or other drugs may be negatively reinforced by the relief from tension or anxiety that often accompanies intoxication.

According to the cognitive behavioural perspective, it is not merely the environment that matters: what also counts is a person's ongoing subjective interpretation of the events taking place in their environment. Therapists operating from the cognitive behavioural perspective therefore encourage their clients to replace or substitute maladaptive thoughts and behaviours with more adaptive ones (Emmelkamp, 1994).

The humanistic and sociocultural perspective

As you saw in Chapter 14, proponents of the humanistic perspective argue that proper personality development occurs when people experience unconditional positive regard. According to this view, mental disorders arise when people perceive that they must earn the positive regard of others. Cultural variables influence the nature and extent to which people interpret their own behaviours as normal or abnormal. What is considered perfectly normal in one culture may be considered abnormal in another. Moreover, mental disorders exist that appear to occur only in certain cultures – a phenomenon called **culture-bound syndrome**. These are discussed in the International perspective section on pp. 780–82.

The diathesis-stress approach

None of the above perspectives is completely accurate in accounting for the origins of mental disorders. But elements of these perspectives may be combined to form a different, perhaps more comprehensive, perspective on mental disorders. The **diathesis-stress model** argues that the combination of a person's genetics and early learning experiences yields a predisposition (a diathesis) for a particular mental disorder. However, the mental disorder will develop only if that person is confronted with stressors that exceed their coping abilities. In other words, a person may be predisposed towards a mental disorder yet not develop it either because they have not encountered sufficient stressors to trigger its development or because they possess the cognitive behavioural coping skills needed to limit the negative effects of the stressor.

Classification of disorders

Mental disorders can be classified in many ways, but the two systems most commonly used in the world are those presented in the American Psychiatric Association's *Diagnostic and Statistical Manual (of Mental Disorders) IV* (DSM-IV TR)

(2000) and the World Health Organization's *International Classification of Diseases 10* (ICD-10). DSM-IV TR was originally devised by American psychologists for the classification of mental disorders, whereas ICD-10 was devised as an international classification system for all diseases. These two are more alike than different, although differences do exist (Andrews et al., 1999). Table 18.1 lists the classifications in DSM-IV TR, with several subclassifications omitted for the sake of simplicity.

Table 18.1 Summary of the DSM-IV classification scheme for axes I and II

Axis I – Major clinical syndromes

Disorders usually first appearing in infancy, childhood or adolescence	Any deviation from normal development, including mental retardation, autism, attention deficit disorder with hyperactivity, excessive fears, speech problems and highly aggressive behaviour
Delirium, dementia, amnesic and other cognitive disorders	Disorders due to deterioration of the brain because of ageing, disease (such as Alzheimer's disease, which was discussed in Chapter 11), or ingestion or exposure to drugs or toxic substances (such as lead)
Psychoactive substance abuse disorders	Psychological, social or physical problems related to abuse of alcohol or other drugs. (Psychoactive substance use and abuse was discussed in Chapters 3, 4 and 16 and is also discussed in this chapter)
Schizophrenia and other psychotic disorders	A group of disorders marked by loss of contact with reality, illogical thought, inappropriate displays of emotion, bizarre perceptions and usually some form of hallucinations or delusions
Mood disorders	Disorders involving extreme deviations from normal mood, including severe depression (major depression), excessive elation (mania), or alteration between severe depression and excessive elation (bipolar disorder)
Anxiety disorders	Excessive fear of specific objects (phobia); repetitive, persistent thoughts accompanied by ritualistic-like behaviour that reduces anxiety (obsessive–compulsive behaviour) panic attacks; generalised and intense feelings of anxiety; and feelings of dread caused by experiencing traumatic events such as natural disasters or combat
Somatoform disorders	Disorders involving pain, paralysis or blindness for which no physical cause can be found. Excessive concern for one's health, as is typical in persons with hypochondriasis
Factitious disorders	Fake mental disorders, such as Munchausen syndrome, in which the individual is frequently hospitalised because of their claims of illness
Dissociative disorders	Loss of personal identity and changes in normal consciousness, including amnesia and multiple personality disorder, in which there exists two or more independently functioning personality systems
Sexual and sex identity disorders	Disorders involving fetishes, sexual dysfunction (such as impotence or orgasmic dysfunctions), and problems of sexual identity (such as transsexualism)
Eating disorders	Disorders relating to excessive concern about one's body weight, such as anorexia nervosa (self-starvation) and bulimia (alternating periods of eating large amounts of food and vomiting). (Eating disorders were discussed in Chapter 13)
Sleep disorders	Disorders including severe insomnia, chronic sleepiness, sleepwalking, narcolepsy (suddenly falling asleep) and sleep apnoea. (Sleep disorders were discussed in Chapter 9)
Impulse control disorders	Disorders involving compulsive behaviours such as stealing, fire setting or gambling
Adjustment disorders	Disorders stemming from difficulties adjusting to significant life stressors, such as death of a loved one, loss of a job or financial difficulties, and family problems, including divorce. (Some adjustment disorders, as they pertain to difficulty in coping with life stressors, were discussed in Chapter 17)

Axis II – Personality disorders

Personality disorders are long-term, maladaptive and rigid personality traits that impair normal functioning and involve psychological stress. Two examples are antisocial personality disorder (lack of empathy or care for others, lack of guilt for misdeeds, antisocial behaviour, and persistent lying, cheating and stealing) and narcissistic personality disorder (inflated sense of self-worth and importance and persistent seeking of attention)

DSM-IV TR classification

The DSM-IV TR is the latest version of a scheme that was devised to provide a reliable, universal set of diagnostic categories having criteria specified as explicitly as possible. The DSM-IV TR describes an individual's psychological condition using five different criteria, called **axes**. Individuals undergoing evaluation are assessed on each of the axes. Axis I contains information on major psychological disorders that require clinical attention, including disorders that may develop during childhood. Personality disorders are found on Axis II. Diagnoses can be made that include both Axis I and Axis II disorders, and multiple diagnoses can occur on either axis alone. For example, major depression and alcohol dependence are both Axis I disorders, and both disorders may characterise one individual at any one period of time. A person's psychological condition may be due to several different psychological disorders described in the DSM-IV TR, just as one person may suffer simultaneously from several different physical disorders.

Axes III through V provide information about the life of the individual in addition to the basic classification provided by Axes I and II. Axis III is used to describe any physical disorders, such as skin rashes or heightened blood pressure, accompanying the psychological disorder. Axis IV specifies the severity of stress that the person has experienced (usually within the last year). This axis details the source of stress (for example, family or work) and indicates its severity and approximate duration. Axis V describes the person's overall level of psychological,

social or occupational functioning. The purpose of Axis V is to estimate the extent to which a person's quality of life has been diminished by the disorder. Ratings are made on a 100-point global assessment of functioning (GAF) scale, with 100 representing the absence or near absence of impaired functioning, 50 representing serious problems in functioning, and 10 representing impairment that may result in injury to the individual or to others.

The DSM-IV TR provides a systematic means of providing and evaluating a variety of personal and psychological information about any one specific individual. Alcohol dependence (Axis I) often leads to marital problems, which may also be partially associated with an antisocial personality disorder (Axis II). Marital problems may lead to a divorce and these problems and the divorce are themselves stressors (Axis IV) that may subsequently contribute to an episode of major depression (Axis I). Alcohol dependence may eventually lead to physical problems, such as cirrhosis of the liver (Axis III). These problems, now acting in concert, are likely to lead to an increased impairment in overall life functioning (Axis V) so that the individual has only a few friends, none of them close, and is unable to keep a job. The evaluation of this person might be summarised as follows:

- Axis I: Alcohol dependence
- Axis II: Antisocial personality disorder
- Axis III: Alcoholic cirrhosis of the liver
- Axis IV: Severe – divorce, loss of job
- Axis V: GAF evaluation = 30 (a very serious impairment of functioning)

Controversies in Psychological Science – How valid and reliable is the DSM?

The issue

Although the DSM-IV TR is the most widely used classification system for mental disorders, it is not without its problems. Reflecting the fact that the DSM-IV TR has been strongly influenced by psychiatrists, the DSM-IV TR tends to be more consistent with the medical perspective on mental disorders. This means that diagnosis and treatment based on the DSM-IV TR emphasise biological factors, which, in turn, means that potential cognitive and environmental determinants may be overlooked.

The evidence

Another potential problem with the DSM-IV TR (and perhaps with any classification scheme) is questionable reliability. Reliability in this context means what it did in the context of psychological testing discussed in Chapter 2 – consistency

across applications. If the DSM-IV TR was perfectly reliable, users would be able to diagnose each case in the same way. But evaluating psychological disorders is not so easy. Using the DSM-IV TR is not like using a recipe; it is more like navigating your way through an unfamiliar city using only a crude map. Using this map, you may or may not reach your destination. Mental disorders do not have distinct borders that allow a mental health professional to diagnose a disorder in a person with 100 per cent accuracy all of the time. Some critics argue, for example, that DSM encourages the making of false-positive judgements – claiming a disorder exists when there only exists a moderate, normal disruption in behaviour. For example, one in four cases of bereavement might be diagnosed as major depressive disorder when these people are undergoing a natural, event-specific change in mood (Wakefield *et al.*, 2007).

Personality disorder is one of the most commonly used diagnoses (Verheul and Widiger, 2004), but critics have highlighted

Controversies in Psychological Science – *Continued*

inconsistencies in how each type of personality disorder is rated – one type has five or eight criteria that have to be met but only two of the types have any published rationale for the criteria (Widiger and Trull, 2007). These authors also note that the approach to diagnosing personality disorders is now polythetic – that is, four out of five criteria need to be met, rather than all. Widiger and Trull suggest that each diagnostic category might be scored along a 5-point scale and this may be one solution.

This is why evidence suggests that actuarial (statistical) analysis of symptoms is better than clinical analysis (Meehl, 1954; Aegisdottir *et al.*, 2006). Specific indicators such as sex, age, test scores, medical history and so on (actuarial measures) are superior to expert ‘experience’ and knowledge of previous cases. You might guess that this name comes from the world of insurance (hence, *actuary*) and you’d be right: the actuarial method was used to assess how long a person would live (using statistics such as age, sex, height, weight, etc.) and to set levels of insurance.

Of course, not every individual will follow the pattern predicted by these statistics (not every overweight, short, old man will live longer than a slim, tall woman) but as a general guide they are a useful statistical predictor of groups of people’s behaviour as a whole. In the clinical realm, aegisdottir *et al.* (2006)’s meta-analysis found that actuarial method was 13 per cent more accurate. Reasons for the success include its reliability – a decision is based on the same criteria and not based on the subjective impression of the clinician who may be influenced by irrelevant variables or not pay attention to relevant ones. Most clinicians, however, adopt the clinical method, despite the advantages of the actuarial method. As Chapter 2 showed, people are always more persuaded by the importance of narrative than the importance of statistics.

There will probably always be dangers in classifying mental disorders. No classification scheme is likely to be perfect, and no two people with the same diagnosis will behave in exactly the same way. Yet once people are labelled, they are likely to be perceived as having all the characteristics assumed to accompany that label; their behaviour will probably be perceived selectively and interpreted in terms of the diagnosis.

An experiment by Langer and Abelson (1974) illustrated how labelling can affect clinical judgements. A group of psychoanalysts were shown a videotape of a young man who was being interviewed. Half of the psychoanalysts were told that the man was a job applicant, while the other half were told that he was a patient. Although both groups of clinicians watched the same man exhibiting the same behaviour, those who were told that he was a patient rated him as being more disturbed, that is, less well adjusted.

It is easy to lapse into the mistaken belief that, somehow or other, labelling disorders explains why people are like they

are. Diagnosing a psychological disorder only describes the symptoms of the disorder; it does not explain its origins. To say that someone did something ‘because he’s schizophrenic’ does not explain his behaviour. We need to be on guard against associating the names of disorders with people rather than with their symptoms. It is more appropriate to talk about ‘someone who displays the characteristics of schizophrenia’ than to say that ‘he’s a schizophrenic’.

According even to DSM-IV TR’s defenders, ‘the most ridiculed aspect of DSM classification system is its ever-expanding size’ (Wakefield, 2001), and commentators have remarked that each new edition of the manual brings with it a new classification of a behaviour as a mental illness. Some view this enlargement as enlightenment and a recognition of a behaviour as a serious mental problem, illness or psychiatric condition. Others see the expansion as over-inclusive, over-eager and as inappropriately labelling odd or eccentric behaviour as deviant or as an illness without sufficient scientific evidence for doing so (Houts and Follette, 1998). New disorders are invented, according to critics, and previously accepted behaviours are labelled as disorders, in effect creating a ‘social invention of mental disorders’ (Houts, 2001).

Houts (2001), one of DSM’s fiercest critics, refers to sleep disorders as an example of this invention and over-inclusiveness. Until DSM-III-R, sleep disorders were not considered mental disorders. ‘It is as though sleep problems became mental disorders overnight sometime in 1987’, he notes. Other behaviours which Houts argues are inappropriately classed as mental disorder include frotteurism (touching or rubbing up against another in a sexual way without consent), kleptomania (compulsive theft), dyscalculia (a disorder of mathematical thinking), pathological gambling and voyeurism. There is also the ‘wastebasket’ category of ‘sexual disorder not otherwise specified’ which represents exactly what it says: any sexual behaviour considered deviant by a psychiatrist that does not meet the criteria of the other disorders.

There are, therefore, some well-argued objections to the inclusion of these categories, and there are equally well-intentioned arguments for the inclusion of these and others.

Conclusion

DSM-V is being planned and professionals are currently being asked to comment on how it could be improved. One major theme that clinicians are being asked to explore is whether having categories of illness is now inappropriate and whether a more dimensional approach to diagnosis is better, i.e. is it better to view disorders as a dimension with major depression at one end and post-traumatic stress disorder (PTSD, described later on in the chapter) at the other, rather than as discrete disorders, independent of all others. Many clinicians are now

Controversies in Psychological Science – Continued

expressing frustration with the category approach (Widiger and Samuel, 2005). As Rounsaville *et al.* (2002: 12) argue:

In the past 20 years . . . the disease entity assumption has been increasingly questioned as evidence has accumulated that prototypical mental disorders such as major depressive disorder, anxiety disorders, schizophrenia, and bipolar disorder seem to merge imperceptibly both into one another and into normality . . . with no demonstrable natural boundaries or zones of rarity in between.

This view has consequences that are practical and scientific: it asks us to re-evaluate how we view mental illness and, therefore, its causes and treatment. A recent discussion in the *Journal of Abnormal Psychology*, suggests that an overhaul of the approach to diagnosis is overdue, as long as the dimensional approach proposed is clinically useful and backed with clear evidence (Brown and Barlow, 2005; First, 2005; Watson, 2005).

The need for classification

Because labelling can have negative effects, some people, such as Szasz (1960, 1987), have suggested that we should abandon all attempts to classify and diagnose mental disorders. In fact, Szasz has argued that the concept of mental illness has done more harm than good because of the negative effects it has on those people who are said to be mentally ill. Szasz notes that labelling people as mentally ill places the responsibility for their care with the medical establishment, thereby relieving such people of responsibility for their mental states and for taking personal steps towards improvement. As you will see in the next section, the lay view of mental illness is not positive and almost consistently ill-informed. You saw in Chapter 1 how children's television programmes referred to unlikeable or eccentric characters using terms related to mental illness. A later section in this chapter on soldier's attitudes to seeking mental health help after a tour of duty cites a study which found that over 50 per cent of soldiers who meet screening criteria for various mental health problems said that their leadership/unit would have less confidence in them and that they would be seen as weak if they sought help (Hoge *et al.*, 2004). People who feel stigmatised by being labelled with the name of a mental illness feel more rejected, devalued and are up to seven times more likely to experience low self-esteem than are those who do not regard the diagnosis as a stigma (Link *et al.*, 2001; Perlick *et al.*, 2001).

However, proper classification has advantages for a patient. One advantage is that, with few exceptions, the recognition of a specific diagnostic category precedes the development of successful treatment for that disorder. Treatments for diseases such as diabetes, syphilis, tetanus and malaria were found only after the disorders could be reliably diagnosed. A patient may have a multitude of symptoms, but before the cause of the disorder (and hence its treatment) can be discovered, the primary symptoms must be identified. For example, Graves's disease is

characterised by irritability, restlessness, confused and rapid thought processes and, occasionally, delusions and hallucinations. Little was known about the endocrine system during the nineteenth century when Robert Graves identified the disease, but we now know that this syndrome results from oversecretion of thyroxine, a hormone produced by the thyroid gland. Treatment involves prescription of antithyroid drugs or surgical removal of the thyroid gland, followed by administration of appropriate doses of thyroxine. Graves's classification scheme for the symptoms was devised many years before the

The boxer Frank Bruno's admission to a psychiatric hospital for depression was treated in two versions of the UK's best-selling daily newspaper, *The Sun*. This was the second edition, printed because of the complaints generated by the first in which the boxer was described as 'Bonkers Bruno'.

Source: The Sun/Ni Syndication. Copyright© News Group Newspapers Ltd.

physiological basis of the disease could be understood. But once enough was known about the effects of thyroxine, physicians were able to treat Graves's disease and strike it off the roll of mental disorders.

On a less dramatic scale, different kinds of mental disorder have different causes, and they respond to different types of psychological treatment and drugs. If future research is to reveal more about causes and treatments of these disorders, we must be able to classify specific mental disorders reliably and accurately.

Another important reason for properly classifying mental disorders is prognosis. Some disorders have good prognoses; the patients are likely to improve soon and are unlikely to have a recurrence of their problems. Other disorders have progressive courses; patients are less likely to recover from these disorders. In the first case, patients can obtain reassurance about their futures; in the second case, patients' families can obtain assistance in making realistic plans.

Lay knowledge of mental illness

In 2000, a protest group in the US called StigmaBusters successfully lobbied the TV channel, ABC, to pull a show, *Wonderland*, which portrayed people with mental illness as being dangerous or unpredictable (Corrigan *et al.*, 2005). Lay understanding of mental illness is not good. Many people either know little or nothing about the symptoms or treatment of mental illness or misunderstand mental illness and assume that mentally ill people behave in ways that they, in reality, do not. Landlords who believe the stereotype of the mentally ill are less likely to offer accommodation or are more likely to offer poor accommodation (Page, 1995) and employers are likely to believe the mentally ill are incapable of working effectively (Page, 1995). Fear of mental illness also appears to have increased in the past 40 years (Phelan *et al.*, 2000), and this is the subject of the Controversies in Psychological Science section below.

Jorm (2000) found that members of the public had difficulty in recognising mental disorders correctly, with schizophrenia often mistaken for depression. Patients with depression are often incorrectly described as having a physical disorder (rather than a physiological one).

Misunderstanding of the term schizophrenia is probably the commonest, as a raft of European surveys has shown. Knowledge of aetiology is similarly questionable, with most people believing that depression and schizophrenia are caused by social or environmental stressors. These are important aetiological factors, Jorm argues, but environmental stressors in schizophrenia are triggers rather than causes. The public's view of the medication used to treat mental illness is almost uniformly negative, contrary to the views of clinicians and to evidence from randomised controlled trials showing the relative success of these drugs in reducing symptoms. When the public is asked why their views of drugs are negative, side effects and dependence on the drugs are usually cited. Natural remedies (such as vitamins) are regarded more positively.

Where the public gets information about mental illness is still something of a mystery. One study reported that 33 per cent of people obtained information from a close relative or friend with mental illness. Another study found that 32 per cent of people obtained such information from the media.

Compared with public efforts to improve the public's understanding of cancer and heart disease, information campaigns about mental illness have not been a resounding success or particularly numerous. Campaigns that are run show small but significant improvements in understanding but, as Jorm notes, they are not evaluated in a scientifically sound way. Jorm suggests, however, that targeted campaigns – aimed at specific groups – are quite successful. This provocative review suggests that we have a long way to go before the public's mental health literacy is improved. Educational strategies designed to teach people more about the reality of mental illness, via books, flyers, films and DVDs, for example, lead to short-term improvements in attitude but have no long-term effect (Corrigan *et al.*, 2001; Penn *et al.*, 1999). The greater the prejudice against the mentally ill, the more resistant people are to education. Face-to-face contact is slightly better. When people are confronted with the subject of their prejudice – and realise that they are not violent, unpredictable or inhuman – their attitude becomes more positive (Corrigan *et al.*, 2001). This attitude becomes even more positive when the stigmatized person has been moderately stereotyped (Reinke *et al.*, 2004).

Mental illness – An international perspective

The two manuals used by psychiatrists to diagnose mental disorder are the *Diagnostic and Statistical Manual of Mental Disorders IV* (DSM-IV TR; American Psychiatric Association, 1994) and *International Classification of Diseases 10* (ICD-10; World Health Organization, 1992). Because these manuals are

standard reference works for the diagnosis of mental illness, there is an implication that symptoms can be grouped together to form a disorder in any culture. The DSM-IV TR, for example, lists 350 disorders which should apply across cultures. In a survey of papers submitted to six prestigious

Mental illness – Continued

psychiatry journals over a three-year period only 6 per cent of papers came from areas outside Europe and America. This 6 per cent represents 90 per cent of the world's population. Could mental disorder be culture-dependent? Are these diagnostic manuals too Western-based? Might a mental disorder in one culture be classed as normal behaviour in another?

Some clinicians have argued that we cannot apply Western diagnostic criteria such as those in DSM to other cultures (Hinton and Kleinman, 1993). This cultural relativism argues that behaviour considered abnormal in one culture may be considered normal in another. In addition, a behaviour classed as one type of mental disorder in one culture may be classed as a different one in a different culture. These two problems are generic in diagnosing mental illness across cultures. The DSM-IV TR recognises the latter problem in its appendix which contains details of 25 culture-based syndromes. The authors responsible for the DSM and ICD have also attempted to address the problem of cultural relativism by conducting extensive cross-cultural investigations on the generalisability of mental disorder diagnosis. How culture-bound, therefore, are mental disorders? Tanaka-Matsumi and Draguns (1997) have found that depression, for example, is common across most cultures. A World Health Organization (WHO) study of depression in Switzerland, Canada, Japan and Iran (World Health Organization, 1983) found that 76 per cent of individuals diagnosed as depressed exhibited symptoms of sadness, joylessness, anxiety, tension and lack of energy. Levels of guilt, however, showed large variation between cultures. Iran reported the lowest levels (22 per cent of respondents), followed by Japan (45 per cent), Canada (58 per cent) and Switzerland (68 per cent). There was also within-culture variation. For example, the two Japanese cities studied (Nagasaki and Tokyo) showed different degrees of depression, with more core symptoms reported in Nagasaki.

A study of British and Turkish outpatients found that Turkish patients reported more somatic complaints (insomnia, hypochondria) whereas the British patients reported more psychological complaints such as guilt and pessimism (Ulusahin *et al.*, 1994).

Suicidal ideation (thoughts about suicide) and suicide are also symptoms of depression which show cultural variation. In a study of the suicide rates among 15–24-year-olds in a large number of countries including Egypt, Jordan, Kuwait, Syria, the Scandinavian countries, eastern Europe, Japan, Singapore and Sri Lanka, the Arabic states (Egypt, Jordan, etc.) had the lowest suicide rates whereas Scandinavia, eastern Europe and some Asian countries had the highest (Barraclough, 1988). The highest reported rates were for Sri Lanka (47 suicides per 100,000 of the population) and Hungary (38.6 per 100,000). The exact reasons for these high rates are unknown. Some have suggested that the weakening of family structure or religious

values is responsible; others suggest that endemic group violence is responsible in Sri Lanka and a fear of failure is responsible in Hungary, but these are vague, general reasons which could apply to other countries (Jilek-Aal, 1988). Paris (1991) has also cautioned that suicide and suicide attempts fluctuate across space and time and that such fluctuation may not be detected in epidemiological surveys of suicide.

Schizophrenia has been subject to three major cross-cultural studies over 25 years in 20 research centres from 17 countries. The aim of such exhaustive research has been to collect data, standardise the instruments used for measuring schizophrenic symptoms and conduct follow-up assessments (Jablensky, 1989). If different countries have different ways of measuring schizophrenia, for example, then a higher or lower incidence of the disorder may not reflect actual incidence but differences in the ways in which schizophrenia is diagnosed. The 1979 study conducted by the World Health Organization (1979) found that the prognosis (outcome) for schizophrenia was better in developing countries (Colombia, Nigeria, India) than in developed countries (USA, UK, Denmark). Schizophrenia was diagnosed as being more chronic in the most well-educated people, but only in developing countries. Later studies indicated that the outcome for schizophrenia was worse in countries such as India.

One of the most comprehensive cross-cultural studies examined 1,379 schizophrenic patients in 12 centres from 10 countries: Denmark (Aarhus), India (Agra and Chandigarh), Columbia (Cali), Ireland (Dublin), Nigeria (Fbada), Russia (Moscow), the UK (Nottingham), Japan (Nagasaki), the Czech Republic (Prague) and the USA (Honolulu, Hawaii and Rochester, New York). In each of the countries, the incidence rates were comparable (Jablensky *et al.*, 1992).

A disorder which does present some cross-cultural problems is anxiety (Tseng *et al.*, 1990). Here, there is great cultural variability in terms of the degree of generalised anxiety reported. Tseng *et al.* (1986) asked psychiatrists in Beijing, Tokyo and Honolulu to diagnose the mental disorder of Chinese patients recorded on videotape. The Beijing psychiatrists diagnosed the patients as exhibiting neurasthenia; the others diagnosed adjustment reaction. When Japanese and American psychiatrists were asked to diagnose patients with social phobia, the Japanese psychiatrists showed greater agreement in their diagnosis of Japanese social phobics than did their American counterparts (Tseng *et al.*, 1990).

Results like these suggest that cultural variations exist in the diagnosis of some mental disorders. Perhaps because anxiety is a more vague syndrome than is depression or schizophrenia, it ought not to be surprising that great variation exists between cultures in diagnosing this disorder. When more specific anxiety disorders are examined, such as object phobia, some cross-cultural agreement occurs (Davey, 1992;

Mental illness – Continued

Davey *et al.*, 1998). In their study of the nature of object phobia in Japanese, British, American, Scandinavian, Indian, Korean and Hong Kong individuals, Davey *et al.* (1998) reported that there was broad agreement on the stimuli considered phobia-related. This consistency suggests that, at least for some anxiety disorders, there is universality.

Slightly more problematical for diagnostic manuals such as the DSM and ICD are culture-bound syndromes (Simons and Hughes, 1985). Although the DSM-IV TR lists 25 of these, it does not provide any criteria for them. Anorexia, which is not explicitly defined as culture-bound in the DSM-IV TR, seems to predominate in Western countries although there are reports of the disorder appearing in Asia (Lee, 1995). Three culture-bound syndromes are Koro, Taijin Kyofusho and anthropophobia (Tanaka-Matsumi and Draguns, 1997). Koro is found in men in

southern China or Southeast Asia and refers to a belief that genitals are withdrawn into the abdomen and a fear of death provoked by a female ghost (Tseng *et al.*, 1992). Taijin Kyofusho is a Japanese disorder similar to social phobia. However, individuals with this disorder have a specific fear of offending others by blushing, emitting offensive odours, staring inappropriately and presenting improper facial expressions (Tanaka-Matsumi, 1979). Anthropophobia seems to be the Chinese equivalent and involves the fear of being looked at.

It seems evident that although there is agreement between cultures about what constitutes a diagnosis for some mental disorders, there is clear variation for others. Anxiety, for example, seems to show the greatest variation, and depression and schizophrenia the least. Furthermore, there are some mental disorders which are culture-bound.

The treatment of mental disorders

The evolution of interventions

Mental disorder and its treatment has a long history. In the past, people suffering from mental disorder have been regarded with awe or fear; others whom we would now probably classify as paranoid schizophrenics were seen as instruments through whom gods or spirits were speaking. More often, they were considered to be occupied by devils or evil spirits and were made to suffer accordingly. The earliest known attempts to treat mental disorders involved trephining, or drilling holes in a person's skull. Presumably, the opening was made to permit evil spirits to leave the victim's head. In prehistoric times, this procedure was performed with a sharp-edged stone; later civilisations, such as the Egyptians, refined the practice. Signs of healing at the edges of the holes in prehistoric skulls indicate that some people survived these operations. An example is seen in Figure 18.1.

Many painful practices were directed at people's presumed possession by evil spirits. Individuals who were thought to be unwilling hosts for evil spirits were subjected to curses or insults designed to persuade the demons to leave. If this approach had no effect, exorcism was tried to make the person's body an unpleasant place for devils to reside. Other rituals included beatings, starving, near-drowning and the drinking of foul-tasting concoctions. The delusional schemes of psychotics often

include beliefs of personal guilt and unworthiness. In a society that accepted the notion that there were witches and devils, these people were ready to imagine themselves as evil. They confessed to unspeakable acts of sorcery and welcomed their own persecution and punishment.

Until the eighteenth century, many Europeans accepted the idea that devils and spirits were responsible for peculiar behaviours in some people. But a few people believed

Figure 18.1 Among the earliest biological approaches to the treatment of mental disorders was the ancient practice of trephining, in which a hole was made in the skull to allow evil spirits to escape from the person's head.

Source: Loren McIntyre/Woodfin Camp & Associates, Inc.

that these disorders reflected diseases and that they should be treated medically, with compassion for the victim. Johann Wier, a sixteenth-century physician, was among the first to challenge the practice of witchcraft. He argued that most people who were being tortured and burned for practising witchcraft in fact suffered from mental illness. The Church condemned his writings as heretical and banned them. However, even within the Church some people began to realise that the prevailing beliefs and practices were wrong.

As belief in witchcraft and demonology waned, the clergy, the medical authorities and the general public began to regard people with mental disorders as ill. Torture and persecution eventually ceased. However, the lives of mentally ill people did not necessarily become better. The unfortunate ones were consigned to various asylums established for the care of the mentally ill. Most of these mental institutions were inhumane. Patients were often kept in chains and sometimes wallowed in their own excrement. Those who displayed bizarre catatonic postures or who had fanciful delusions were exhibited to the public for a fee. Many of the treatments designed to cure mental patients were little better than the tortures that had previously been used to drive out evil spirits. Patients were tied up, doused in cold water, bled, made to vomit, spun violently in a rotating chair, and otherwise assaulted. See Figure 18.2.

Mistreatment of the mentally ill did not go unnoticed by humanitarians. A famous and effective early reformer was Philippe Pinel (1745–1826), a French physician. In 1793, Pinel was appointed director of La Bicêtre, a mental hospital in Paris. Pinel believed that most mental patients would respond well to kind treatment. As an experiment, he removed the chains from some of the patients, took them out of dungeons and allowed them to walk about the hospital grounds. The experiment was a

Figure 18.2 The ‘tranquillising chair’ devised by Benjamin Rush.

Source: © Bettman/Corbis.

remarkable success; an atmosphere of peace and quiet replaced the previous noise, stench and general aura of despair. Many patients were eventually discharged. Pinel’s success at La Bicêtre was repeated when he was given charge of Salpêtrière Hospital. Some mentally ill people eventually recover – or at least get much better – without any treatment at all. But if a person was put in a mental institution that existed prior to Pinel’s time, they had little chance to show improvement.

Controversies in Psychological Science – How violent are the mentally ill?

The issue

‘On Sunday afternoon, September 3, 2006, Wayne Fenton, a prominent schizophrenia expert and an associate director at the National Institute of Mental Health (NIMH) [in the US] was found dead in his office. He had just seen a 19-year-old patient with schizophrenia who later admitted to the police that he had beaten Fenton with his fists’

Source: Friedman, 2006.

On the face of it, this extract from an article by Richard Friedman in the *New England Journal of Medicine* seems to confirm lay opinion: that people with certain types of mental illness are extremely violent. Friedman quotes a National Crime Victimization Survey for 1993 to 1999 showing that, in the US, non-fatal violence was meted out to 12.6 per 1,000 workers from various occupations. In physicians, the number rose to 21.9 per 1,000. In psychiatrists and mental health professionals, the figure was 68.2. The lay view seems to be accurate. But is it?

Controversies in Psychological Science – *Continued*

The evidence

In his review, Friedman cites evidence showing that violence is committed by the mentally ill, but it is rare, and rarer than that committed by those who use drugs and alcohol, for example. Another survey by the NIMH found that patients with schizophrenia, major depression or bipolar disorder were two to three times as likely to commit acts of violence involving physical assault (Swanson, 1994). The lifetime prevalence of violence in people who are seriously mentally ill was 16 per cent compared with 7 per cent for those without mental illness.

But the prevalence is only found in certain types of disorder

– those who suffer anxiety rarely show aggression or acts of violence. One study has also found that the incidence of violence in schizophrenic patients discharged into the community and followed up over a year was no different from those with no psychiatric disorder (Steadman *et al.*, 1998).

Conclusion

What is important here is not the mental illness itself, but specific symptoms of that illness – schizophrenic individuals who are paranoid or hear voices commanding them to behave in a certain way are more likely to commit acts of violence than are those without these symptoms.

The development of modern treatment

The modern history of specific treatments for mental disorders probably began with Franz Anton Mesmer (1734–1815), an Austrian physician who practised in Paris in the late eighteenth and early nineteenth centuries. He devised a theory of ‘magnetic fluxes’, according to which he attempted to effect cures by manipulating iron rods and bottles of chemicals. In reality, he hypnotised his patients and thereby alleviated some of their symptoms. As a result, hypnosis was first known as mesmerism.

In 1815, there were approximately 2,000 individuals institutionalised in mental asylums in England. The number had increased a century later when one hundred or so asylums in England and Wales housed an average of 1,000 patients. In America, at the same time, the number housed was between 1,500 and 3,000. Dr William Black, a nineteenth-century English physician, kept a list of the causes of insanity of those individuals admitted to the Bethlem asylum, the largest madhouse in the UK at the time (it was also known as Bedlam). Figure 18.3 shows an example of one of these lists; it includes some unusual causes, such as ‘sudden loss of several cows’.

A French neurologist, Jean Martin Charcot (1825–93), began his investigations of the therapeutic uses of hypnosis when one of his students hypnotised a woman and induced her to display the symptoms of a conversion reaction (hysteria). Charcot examined her and concluded that she was a hysterical patient. The student then woke the woman, and her symptoms vanished. Charcot had

previously believed that hysteria had an organic basis, but this experience changed his opinion, and he began investigating its psychological causes.

Just before Freud began private practice, he studied with Charcot in Paris and observed the effects of hypnosis on hysteria. Freud’s association with Charcot, and later with Breuer, started him on his life’s study of the determinants of personality and the origins of mental illness. He created the practice of psychoanalysis. Some modern psychiatrists and psychologists still use some of his therapeutic methods to treat their clients.

Current treatments: the eclectic approach

Most therapists adopt a general, eclectic approach to the treatment of mental disorders. The **eclectic approach** (from the Greek *eklegein*, to ‘single out’) involves the therapist using whatever methods they feel will work best for a particular client at a particular time. Such therapists are not strongly wedded to particular theoretical orientations; instead, they seek the particular form of therapy that will best solve a particular client’s problems. This often means combining aspects of several different treatment approaches according to a particular client’s problem and personal circumstances. For example, Acierno *et al.* (1993) have shown that combinations of therapies are more effective in treating panic disorder than is any one alone.

Causes, both Moral and Physical, ascertained in 249 cases.

Types of treatment

Psychoanalysis and psychodynamic therapy

Sigmund Freud is given credit for developing **psychoanalysis** which, as you saw in Chapter 14, is a form of therapy aimed at providing the client with insight into their unconscious motivations and impulses. Freud's theory of personality suggests that unconscious conflicts based on the competing demands of the id (representing biological urges), the superego (representing the moral dictates of society), and the ego (representing reality) often lead to anxiety. The source of these conflicts, according to Freud, can usually be traced back to unacceptable, often sexually based, urges from early childhood: repressed impulses and feelings that lead to conscious anxiety. As Freud (1933, p. 26) explained:

One of the tasks of psychoanalysis . . . is to lift the veil of amnesia which hides the earliest years of childhood and to bring to conscious memory the manifestations of early infantile sexual life which are contained in them.

The purpose of therapy is to create a setting in which clues about the origins of intrapsychic conflicts are most likely to be revealed by the client. These clues are revealed in clients' dreams, physical problems, memory (or failure to remember certain things), manner of speech, and cognitive and emotional reactions to therapy. Then, by exposing the client to these clues, they will gain insight into the problem.

While the psychoanalyst's primary role is interpretation, the client's main job is to provide the psychoanalyst with something to interpret: descriptions of their fears, anxieties, thoughts or repressed memories. This is not an

easy task for the client to accomplish because the client unconsciously invokes one or more defence mechanisms, which, as you recall from Chapter 14, prevent anxiety-provoking memories and ideas from reaching conscious awareness. Together, the psychoanalyst and client work for insight into the client's problems.

Psychoanalytic techniques

Freud used **free association** to encourage the client to speak freely, without censoring possibly embarrassing or socially unacceptable thoughts. Freud achieved this goal in two ways. First, the client was encouraged to report any thoughts or images that came to mind, without worrying about their meaning. Secondly, Freud attempted to minimise any authoritative influence over the client's disclosures by eliminating eye contact. He usually sat in a chair at the head of a couch on which the client reclined.

Among the topics clients are encouraged to discuss are their dreams. Dream interpretation, the evaluation of the underlying meaning of dream content, is a hallmark of psychoanalysis (Freud, 1900). But even dream content is subject to some censoring, according to Freud, so that the analyst must be able to distinguish between the dream's manifest content (the actual images and events that occur within the dream) and latent content (the hidden meaning or significance of the dream). The manifest content masks the latent content because the latent content is anxiety-provoking and causes the person psychological discomfort.

Insight is not achieved quickly, nor do clients always find it easy to disclose private aspects of their personal lives. For example, a client may have to confront the reality of being abused as a child, or of being unloved, or of feeling peculiar, inferior or out of place. Although the client wishes to be cured, they do not look forward to the anxiety and apprehension that may result from recalling painful memories. The client often becomes defensive at some point during therapy, unconsciously attempting to halt further insight by censoring their true feelings: a process Freud called **resistance**.

Over a period of months or even years of therapy sessions taking place as often as several times a week, the client gradually becomes less inhibited, and the discussion begins to drift away from recent events to the more distant shores of early childhood. As the client relives aspects of childhood, they may begin to project powerful attitudes and emotions onto the therapist, a process called **transference**. The client may come to love or hate the therapist with the same intensity of the powerful emotions experienced in childhood towards parents or siblings.

Originally, Freud thought of transference as an impediment to therapy, a distraction from the real issues at hand. But he soon realised that the experience of transference

was essential to the success of therapy (Erdelyi, 1985). Whereas free association uncovers many of the relevant events and facts of the client's life, transference provides the means for reliving significant early experiences. The therapist contributes to this experience by becoming a substitute for the real players in the client's life and so becomes a tool for illuminating the conflicts of the unconscious. Freud reasoned that the analyst, being human too, could just as easily project his or her emotions onto the client, a process he called **counter-transference**. Unlike transference, Freud believed counter-transference to be unhealthy and undesirable. To be effective, the analyst must remain emotionally detached and objective in their appraisal of the client's disclosures. For this reason, he argued that the analyst, in order to understand their own unconscious conflicts, should undergo complete analysis with another therapist.

Modern psychodynamic therapy

Psychoanalysis is now often referred to as **psychodynamic therapy** to reflect differences between modern psychoanalytic approaches and the original form of Freudian psychoanalysis. For example, although modern forms of psychodynamic therapies still focus on achieving insight into the unconscious, they tend to place less emphasis on sexual factors during development and more upon social and interpersonal experiences. Contemporary therapists also are more likely to address concerns and issues in the client's present life than to examine childhood experiences exclusively.

Modern psychodynamic therapists also view the ego as playing a more active role in influencing a person's thoughts and actions. Instead of viewing the ego as functioning merely to seek ways to satisfy the demands of the id and superego, they believe it to be a proactive component in one's overall psychological functioning. In other words, compared with Freud, modern psychodynamic therapists see the ego as having more control over the psyche. Thus, people receiving psychodynamic therapy are seen as being less constrained by the mind's unconscious forces than Freud thought them to be.

One modern form of psychodynamic therapy, time-limited therapy, takes 25–30 sessions with the therapist to complete (Strupp, 1993). The goal of time-limited therapy is to understand and improve the client's interpersonal skills through interpretation of transference processes. This therapy is based on Freud's belief that our early experiences with others influence the dynamics of our current relationships. Time-limited therapy focuses on the schemata that a client has about interpersonal relationships and attempts to modify those that are incorrect or that otherwise prevent the client from developing fulfilling relationships with others.

Evaluation

Evaluating the effectiveness of psychoanalysis or psychodynamic therapy is difficult because only a small proportion of people with mental disorders qualify for this method of treatment. To participate in this kind of therapy, a client must be intelligent, articulate and motivated enough to spend three or more hours a week working hard to uncover unconscious conflicts. In addition, they must be able to afford the therapist's fees, which are high. These qualifications rule out most psychotics, as well as people who lack the time or money to devote to such a long-term project. Furthermore, many people who enter this kind of therapy become dissatisfied with their progress and leave. In other cases, the therapist encourages a client to leave if they decide that the client is not cooperating fully. Thus, those who actually complete a course of therapy do not constitute a random sample, and we cannot conclude that this kind of therapy works just because a high percentage of this group is happy with the results. Those who have dropped out ought also to be counted.

Another problem in evaluating psychoanalysis and psychodynamic therapy is that therapists have a way to 'explain' their failures: they can blame them on the client (Eysenck, 1985). If the client appears to accept an insight into their behaviour but the behaviour does not change, the insight is said to be merely 'intellectual'. This escape clause makes the argument for the importance of insight completely circular and, therefore, illogical: if the client gets better, the improvement is due to insight; but if the client's behaviour remains unchanged, real (as opposed to 'intellectual') insight did not occur.

Humanistic therapies

Client-centred therapy

In the 1940s, Carl Rogers (1902–87) developed the first **humanistic therapy**, creating a major alternative to psychoanalysis. The aim of humanistic therapy is to provide the client with a greater understanding of their unique potential for personal growth and self-actualisation. Humanistic therapies proceed from the assumption that people are good and have innate worth. Psychological problems reflect some type of blocking of one's potential for personal growth; humanistic therapy aims to realise this potential.

Rogers found the formalism of psychoanalysis too confining and its emphasis on intrapsychic conflict too pessimistic (Tobin, 1991). His discontent led him to develop his own theory of personality, abnormal behaviour and therapy. His **client-centred therapy** is so named because of the respect given the client during therapy: the

client decides what to talk about without direction or judgement from the therapist. The client takes ultimate responsibility for resolving the client's problems. The client, not a method or theory, is the focus of the therapy.

Rogers believed that the cause of many psychological problems can be traced to people's perceptions of themselves as they actually are (their real selves) as differing from the people they would like to be (their ideal selves). Rogers called this discrepancy between the real and the ideal perceptions of the self **incongruence**. The goal of client-centred therapy is to reduce incongruence by fostering experiences that will make attainment of the ideal self possible. Because the client's and not the therapist's thoughts direct the course of therapy, the therapist strives to make those thoughts, perceptions and feelings more noticeable to the client. This is frequently done through reflection, sensitive rephrasing or mirroring of the client's statements. For example:

Client: I get so frustrated at my parents. They just don't understand how I feel. They don't know what it's like to be me.

Therapist: You seem to be saying that the things that are important to you aren't very important to your parents. You'd like them now and then to see things from your perspective.

By reflecting the concerns of the client, the therapist demonstrates empathy, or the ability to perceive the world from another's viewpoint. The establishment of empathy is key in encouraging the client to deal with the incongruence between the real and the ideal selves.

For Rogers (1951), the 'worth and significance of the individual' is a basic ground rule of therapy. This theme is represented in therapy through **unconditional positive regard**, in which the therapist tries to convey to the client that his or her worth as a human being is not dependent on anything they think, do or feel.

In client-centred therapy, the therapist totally and unconditionally accepts the client and approves of them as a person so that the client can come to understand that their feelings are worthwhile and important. Once the client begins to pay attention to these feelings, a self-healing process begins. For example, a client usually has difficulty at first expressing feelings verbally. The therapist tries to understand the feelings underlying the client's confused state and to help them put those feelings into words. Through this process, the client learns to understand and heed their own drive towards self-actualisation. Consider the following example:

Alice: I was thinking about this business of standards. I somehow developed a sort of knack, I guess, of – well – habit – of trying to make people feel at ease around me, or to make things go along smoothly . . .

Counsellor: In other words, what you did was always in the direction of trying to keep things smooth and to make other people feel better and to smooth the situation.

A: Yes. I think that's what it was. Now the reason why I did it probably was – I mean, not that I was a good little Samaritan going around making other people happy, but that was probably the role that felt easiest for me to play. I'd been doing it around the home so much. I just didn't stand up for my own convictions, until I don't know whether I have any convictions to stand up for.

C: You feel that for a long time you've been playing the role of kind of smoothing out the frictions or differences or what not . . .

A: M-hum.

C: Rather than having any opinion or reaction of your own in the situation. Is that it?

A: That's it. Or that I haven't been really honestly being myself, or actually knowing what my real self is, and that I've been just playing a sort of false role. Whatever role no one else was playing, and that needed to be played at the time, I'd try to fill it in.

Source: Rogers (1951) pp. 152–3.

As this example illustrates, in Rogers's view, the therapist should not manipulate events but should create conditions under which the client can make their own decisions independently.

Evaluation

Unlike many other clinicians, who prefer to rely on their own judgements concerning the effectiveness of their techniques, Rogers himself stimulated a considerable amount of research on the effectiveness of client-centred therapy. He recorded therapeutic sessions so that various techniques could be evaluated. One researcher, Truax (1966), obtained permission from Rogers (and his clients) to record some therapy sessions, and he classified the statements made by the clients into several categories. One of the categories included statements of improving mental health, such as 'I'm feeling better lately' or 'I don't feel as depressed as I used to'. After each of the patients' statements, Truax noted Rogers's reaction to see whether he gave a positive response. Typical positive responses were 'Oh, really? Tell me more' or 'Uh-huh. That's nice' or just a friendly 'Mm'. Truax found that of the eight categories of client statements, only those that indicated progress

were regularly followed by a positive response from Rogers. Not surprisingly, during their therapy, the clients made more and more statements indicating progress.

This study attests to the power of social reinforcement and its occurrence in unexpected places. Rogers was an effective and conscientious psychotherapist, but he had not intended to single out and reinforce his clients' realistic expressions of progress in therapy. (Of course, he did not uncritically reinforce exaggerated or unrealistic positive statements.) This finding does not discredit client-centred therapy. Rogers simply adopted a very effective strategy for altering a person's behaviour. He used to refer to his therapy as non-directive; however, when he realised that he was reinforcing positive statements, he stopped referring to it as non-directive because it obviously was not.

Gestalt therapy

The development of client-centred therapy owes much to its founder's disenchantment with classical psychoanalysis. For much the same reason, Fritz Perls (1893–1970), although trained in Freudian techniques, disengaged himself from orthodox psychoanalysis and founded gestalt therapy (Perls, 1969). **Gestalt therapy** emphasises the unity of mind and body by teaching the client to 'get in touch' with bodily sensations and emotional feelings long hidden from awareness. Gestalt therapy, which bears no relation to the perception school of the same name which we described in Chapter 6, places exclusive emphasis upon present experience – not on the past – and the gestalt therapist will often be quite confrontational, challenging the client to deal honestly with their emotions.

The therapist often uses the empty chair technique, in which the client imagines that they are talking to someone sitting in the chair beside them. For example, a woman may be asked to say the things that she had always wanted to say to her deceased father but did not while he was alive. The empty chair technique allows her to experience in the here and now the feelings and perceptions that she may have suppressed while her father was alive. It also allows her to express these feelings and to gain insight into how they have influenced her perception of herself and her world. This technique derives from Perls's belief that, for all of us, our memories, fears and feelings of guilt affect our relationships with others.

The gestalt therapist also encourages the client to gain a better understanding of their feelings by talking to their self (to different parts of their personality) and to inanimate objects. Any attempt by the client to avoid the reality of their situation is challenged by the therapist, who constantly attempts to keep the client's attention focused on present problems and tries to guide the client towards an honest confrontation with these problems. Perls argued, 'In the safe emergency of the therapeutic situation, the neu-

rotic discovers that the world does not fall to pieces if he or she gets angry, sexy, joyous, mournful' (1967, p. 331).

Evaluation

Like psychoanalysis and client-centred therapy, gestalt therapy is inappropriate for serious problems such as psychoses. All three therapies are most effective for people who are motivated enough to want to change and who are intelligent enough to be able to gain some insight concerning their problems. Some of these problems include coping with everyday stressors as well as experiencing excessive anxiety and fear.

Behavioural and cognitive behavioural therapies

The fundamental assumption made by behavioural therapists is that people learn maladaptive or self-defeating behaviour in the same way as they learn adaptive behaviour. Undesirable behaviour, such as nail-biting or alcohol abuse, is the problem, not just a reflection of the problem. The methods that behavioural therapists use to induce behaviour change are extensions of classical and operant conditioning principles and work quite successfully.

Remember from Chapter 7 that, in classical conditioning, a previously neutral stimulus (ultimately the conditional stimulus, CS) comes to elicit the same response as a stimulus (unconditional stimulus, UCS) that naturally elicits that response because the CS reliably predicts the UCS. According to Joseph Wolpe (1958), one of the founders of behavioural therapy, many of our everyday fears and anxieties become associated with neutral stimuli through coincidence. Going to the dentist may evoke fear because the last time that you went you were not given enough anaesthetic and the drilling hurt. Although the dental surgery is usually not painful, you associate the dentist with pain because of your past experience. The next sections describe some of the more specific behavioural and cognitive behavioural approaches.

Systematic desensitisation

One behavioural therapy technique, developed by Wolpe, has been especially successful in eliminating some kinds of fear and phobia. This technique, called **systematic desensitisation**, is designed to remove the unpleasant emotional response produced by the feared object or situation and replace it with an incompatible one – relaxation.

The client is first trained to achieve complete relaxation. The essential task is to learn to respond quickly to suggestions to feel relaxed and peaceful so that these suggestions can elicit an immediate relaxation response. Next, client and therapist construct a hierarchy of anxiety-related stimuli.

Finally, the conditional stimuli (fear-eliciting situations) are paired with stimuli that elicit the learned relaxation response. For example, a person with a fear of spiders is instructed to relax and then to imagine hearing from a neighbour that she saw a spider in her garage. If the client reports no anxiety, they are instructed to move to the next item in the hierarchy and to imagine hearing a neighbour say that there is a tiny spider across the street; and so on. Whenever the client begins feeling anxious, they signal to the therapist with some predetermined gesture such as raising a finger. The therapist instructs the client to relax and, if necessary, describes a less threatening scene. The client is not permitted to feel severe anxiety at any time. Gradually, over a series of sessions (the average is 11), the client is able to get through the entire list, vicariously experiencing even the most feared encounters.

Scientific evaluations of systematic desensitisation have been positive, and several experiments have found that all elements of the procedure are necessary for its success (Emmelkamp, 1994). For example, a person will not get rid of a phobia merely by participating in relaxation training or by constructing hierarchies of fear-producing situations. Only pairings of the anxiety-producing stimuli with instructions to relax will reduce the fear.

Whereas practitioners of systematic desensitisation are careful not to permit their clients to become too anxious, practitioners of a procedure called **flooding** attempt to rid their clients of their fears by arousing them intensely until their responses diminish through habituation and they learn that nothing bad happens. The therapist describes, as graphically as possible, the most frightening encounters possible with the object of a client's phobia. The client tries to imagine the encounter and to experience intense fear (thereby 'flooding' the client's mind with anxious thoughts). In some cases, the client actually encounters the object of their fear, in which case the treatment is called *in vivo* (live) **implosion therapy**. Of course, the client is protected from any adverse effects of the encounter (or the encounter is imaginary), so there are no dangerous consequences. Eventually, the fear response begins to subside, and the client learns that even the worst imaginable encounter can become tolerable. In a sense, the client learns not to fear their own anxiety attack, and avoidance responses begin to extinguish.

Aversion therapy

In **aversion therapy**, a negative reaction to a neutral stimulus is caused by pairing it with an aversive stimulus (UCS). Aversion therapy attempts to establish an unpleasant response (such as a feeling of fear or disgust) to the object that produces the undesired behaviour. For example, a person with a fetish for women's shoes might be given painful electrical shocks while viewing colour slides

of women's shoes. Aversion therapy has also been used to treat drinking, smoking, transvestism, exhibitionism and overeating. This technique has been shown to be moderately effective (Marshall *et al.*, 1991). However, because the method involves pain or nausea, the client's participation must be voluntary, and the method should be employed only if other approaches fail or are impractical.

The use of aversive methods raises ethical issues, particularly when the individual is so severely impaired that they are unable to give informed consent to a particular therapeutic procedure. It would seem reasonable that aversive methods involving stimuli such as electric shock should be used as the last resort. In a method called covert sensitisation, instead of experiencing a punishing stimulus after performing a behaviour, the client imagines that they are performing an undesirable behaviour and then imagines receiving an aversive stimulus.

Behaviour modification

Behaviour modification, a general term describing therapy based on operant conditioning principles (see Chapter 7), involves altering maladaptive behaviour by rearranging the contingencies between behaviour and its consequences. Increases in desirable behaviour can be brought about through either positive or negative reinforcement, and undesirable behaviour can be reduced through either extinction or punishment.

In its infancy, behaviour modification was applied chiefly to patients with schizophrenia (described in detail later) and the mentally retarded (Lindsley, 1956; Ayllon and Azrin, 1968; Neisworth and Madle, 1982). In the past three decades, however, use of operant conditioning principles has been extended to a wide array of behaviours and circumstances, for example weight management, anorexia nervosa, bed-wetting, smoking, and compliance with medical regimens (Kazdin, 1994).

Token economies

The behaviour-analytic approach has been used on a large scale in mental institutions with generally good success. Residents are often asked to do chores to engage them in active participation in their environment. In some instances, other specific behaviours are also targeted as desirable and therapeutic, such as helping residents who have more severe problems. To promote these social behaviours, therapists have designed **token economies**. A list of tasks is compiled, and residents receive tokens as rewards for performing the tasks; later, they can exchange these tokens for snacks, other desired articles or various privileges. The tokens become conditioned reinforcers for desirable and appropriate behaviours. The amount of time spent performing the desirable behaviours was high

when reinforcement contingencies were imposed and low when they were not.

Although token economies are based on a simple principle, they are very difficult to implement. A mental institution includes patients, caretakers, housekeeping staff and professional staff. If a token economy is to be effective, all staff members who deal with residents must learn how the system works; ideally, they should also understand and agree with its underlying principles. A token economy can easily be sabotaged by a few people who believe that the system is foolish, wrong or in some way threatening to themselves. If these obstacles can be overcome, token economies work very well.

Modelling

Humans (and many other animals) have the ability to learn without directly experiencing an event. People can imitate the behaviour of other people, watching what they do and, if the conditions are appropriate, performing the same behaviour. This capability provides the basis for the technique of **modelling**. Behaviour therapists have found that clients can make much better progress when they have access to a model providing examples of successful behaviours to imitate.

Social skills training

With social skills training, the client is taught to behave in a desirable and socially appropriate way. They might do this by engaging in **assertiveness training**, which teaches the client to be more direct about their feelings (Oltmans and Emery, 1998). A part of assertiveness training might be **role-playing**, in which the client is taught to act out or rehearse social skills by adopting the identity of another, socially skilled person.

Cognitive behavioural therapy

The first attempts at developing psychotherapies based on altering or manipulating cognitive processes emerged during the 1970s. These attempts were undertaken by behavioural therapists who suspected that maladaptive behaviour, or, for that matter, adaptive behaviour, could be due to more than only environmental variables. They began exploring how their clients' thoughts, perceptions, expectations and self-statements might interact with environmental factors in the development and maintenance of maladaptive behaviour.

The focus of **cognitive behavioural therapy** (CBT) is on changing the client's maladaptive thoughts, beliefs and perceptions. Like behaviour therapists – and unlike most insight psychotherapists – cognitive behaviour therapists are not particularly interested in events that occurred in the client's childhood. They are interested in the here and

now and in altering the client's behaviour so that it becomes more functional. Although they employ many methods used by behavioural therapists, they believe that when behaviours change, they do so because of changes in cognitive processes.

There are many ways in which CBT can be applied to mental disorder. Attribution retraining, for example, involves retraining the client to alter their perception of causes of events or behaviour (attributions are perceived causes). One way in which this can be achieved is by requesting the client to adopt a more scientific approach to their beliefs. For example, it is common in depression for a depressed person to attribute causes for failure to themselves but to attribute successes to others. Attribution retraining should encourage the client to change these 'faulty' attributions and make them more realistic. One form of CBT designed to treat depression requires the patient to assess whether their view of themselves and others is distorted based on a considered analysis of their lives. This approach, based on the clinical work of Beck (1967, 1976; Beck and Emery, 1985), is considered in the section on depression below (see p. 827).

Another CBT approach, **rational-emotive therapy**, was developed in the 1950s by Albert Ellis, a clinical psychologist, and is based on the belief that psychological problems are caused by how people think about upsetting events and situations. In contrast to the other forms of CBT, rational-emotive therapy did not grow out of the tradition of behaviour therapy. Ellis asserts that psychological problems are the result of faulty cognitions; therapy is therefore aimed at changing people's beliefs. Rational-emotive therapy is highly directive and confrontational. The therapist tells their clients what they are doing wrong and how they should change.

According to Ellis and his followers, emotions are the products of cognition. A significant activating event (A) is followed by a highly charged emotional consequence (C), but it is not correct to say that A has caused C. Rather, C is a result of the person's belief system (B).

Therefore, inappropriate emotions (such as depression, guilt and anxiety) can be abolished only if a change occurs in the person's belief system. It is the task of the rational-emotive therapist to dispute the person's beliefs and to convince them that those beliefs are inappropriate. Ellis tries to show his clients that irrational beliefs are impossible to satisfy, that they make little logical sense, and that adhering to them creates needless anxiety, self-blame and self-doubt. The following are examples of the kinds of ideas that Ellis (1973), pp. 152–3 believes to be irrational:

The idea that it is a necessity for an adult to be loved or approved by virtually every significant person in the community.

The idea that one should be thoroughly competent, adequate, and goal-oriented in all possible respects if one is to consider oneself as having worth.

The idea that human unhappiness is externally caused and that people have little or no ability to control their lives.

The idea that one's past is an all-important determinant of one's present behaviour.

The idea that there is invariably a right, precise, and perfect solution to human problems and that it is catastrophic if this perfect solution is not found.

In a review of research evaluating the effectiveness of rational-emotive therapy, Haaga and Davison (1989) concluded that the method has been shown to reduce general anxiety, test anxiety and unassertiveness. Rational-emotive therapy has appeal and potential usefulness for those who can enjoy and profit from intellectual teaching and argumentation. The people who are likely to benefit most from this form of therapy are those who are self-demanding and who feel guilty for not living up to their own standards of perfection. People with serious anxiety disorders or with severe thought disorders, such as schizophrenia and other psychoses, are unlikely to respond to an intellectual analysis of their problems.

Many therapists who adopt an eclectic approach use some of the techniques of rational-emotive therapy with some of their clients. In its advocacy of rationality and its eschewing of superstition, the therapy proposes a common-sense approach to living. However, many psychotherapists disagree with Ellis's denial of the importance of empathy in the relationship between therapist and client.

Of course, all of the treatments described here are examples of psychology 'in action'. However, two recent cognitive-behavioural approaches to treatment are novel enough to warrant some closer attention. One of these you will find in the section on phobia. The other is an approach designed to reduce trauma and this is the topic of the Psychology in Action section below.

Evaluation

Psychotherapists of traditional orientations have criticised behavioural therapy for its focus on the symptoms of a psychological problem to the exclusion of its root causes. Some psychoanalysts even argue that treatment of just the symptoms is dangerous. In their view, the removal of one symptom of an intrapsychic conflict will simply produce another, perhaps more serious, symptom through a process called **symptom substitution**.

There is little evidence that symptom substitution occurs. It is true that many people's behavioural problems are caused by conditions that existed in the past, and often these problems become self-perpetuating. Behavioural

therapy can, in many cases, eliminate the problem behaviour without delving into the past. For example, a child may, for one reason or another, begin wetting the bed. The nightly awakening irritates the parents, who must change the bed sheets and the child's pyjamas. The disturbance often disrupts family relationships. The child develops feelings of guilt and insecurity and wets the bed more often. Instead of analysing the sources of family conflict, a therapist who uses behavioural therapy would install a device in the child's bed that rings a bell when they begin to urinate. The child awakens and goes to the bathroom to urinate and soon ceases to wet the bed. The elimination of bed-wetting causes rapid improvement in the child's self-esteem and in the entire family relationship. Symptom substitution does not appear to occur (Baker, 1969).

Although cognitive behavioural therapists believe in the importance of unobservable constructs such as feelings, thoughts and perceptions, they do not believe that good therapeutic results can be achieved by focusing on cognitions alone. They, like their behaviour-analytic colleagues, insist that it is not enough to have their clients introspect and analyse their thought patterns. Instead, therapists must help clients to change their behaviour. Behavioural changes can cause cognitive changes. For example, when a client observes that they are now engaging in fewer maladaptive behaviours and more adaptive behaviours, the client's self-perceptions and self-esteem are bound to change as a result. Therapy is more effective when attention is paid to cognitions as well as to behaviours.

Psychology in action – How instructions to express reduce distress

Imagine having experienced severe distress or trauma. You may have been physically attacked, robbed or sexually assaulted. Anecdotal evidence suggests that it is best to talk about these events to another person – this allows you to express your feelings about the event that you had previously kept to yourself. It is a form of catharsis, people will say. They might be right.

A novel medicine treatment for trauma has been emotional disclosure (ED) through expressive writing. ED involves asking an individual who has suffered severe trauma or distress to express how they feel about the distress or trauma by writing about it and to write or think about why they feel in the way that they do. This ostensibly simple technique has been found to improve coping, physical health, emotional health and immune system functioning in extremely distressed individuals (Smyth, 1998).

The pioneers of this technique, James Pennebaker and his colleagues (Pennebaker *et al.*, 1988; Pennebaker and Francis, 1996; Pennebaker, 1997), have published several studies showing that when distressed individuals are asked to write down their thoughts and express their emotions, these individuals required fewer visits from the doctor than did those who wrote about trivial topics. Individuals also showed an improvement in their immune system functioning. The participants in these studies were people suffering real distress – Holocaust survivors, the bereaved and the recently unemployed.

Replications by different groups are positive, but mixed. Some improvement in physical health beyond the 'treatment' period has been reported (Lepore, 1997) and survivors of trauma who create narratives about their distress feel better than those who do not (Foa *et al.*, 1995). Arthritic patients who wrote about the emotionally negative aspects of their illness saw an improvement in their condition (Kelley *et al.*, 1997). Sloan and Marx (2004) randomly assigned 49 women

who reported having experienced at least one traumatic event and who showed at least moderate levels of post-traumatic stress disorder to a disclosure condition – where they wrote about a traumatic event in prose as emotionally as possible – or a control condition where no writing occurred. Participants in the disclosure condition reported fewer psychological and physical symptoms a month after testing. The only improvement that was 'clinically' significant, however, was a reduction in depressive symptoms.

A study investigating the effects of ED in patients suffering serious illness found that it had little effect in reducing distress but patients who had little social contact with others or who found that the opportunities for expressing emotions to others were limited, benefited greatly from the process. Zakowski *et al.* (2004) randomly assigned 104 gynaecological and prostate cancer patients to an ED condition, where patients wrote about their trauma for 20 minutes a day for three days, or a non-ED condition (writing about a non-emotional topic). Those in the ED condition who had little opportunity for expressing emotion in social contexts benefited significantly from the ability to write about their illness. The lack of a reduction in stress is comparable to findings from studies of breast cancer which report similarly negative findings (Stanton and Danoff-Burg, 2002). The authors suggest that the benefits of writing in cancer patients might be better revealed in more objective, physical measures rather than subjective, self-report measures.

Some researchers have hypothesised that the benefits of expressive writing arise from the changes in thinking that such writing encourages (Pennebaker, 1997). When individuals write about cause and effect in their expressive writing and show insight into their distress, physical and psychological health improves – their thoughts become more methodically organised (Pennebaker *et al.*, 1997).

Psychology in action – *Continued*

Writing provides an outlet for the negative thoughts and feelings that the writer may be feeling but which they may want to inhibit. That such thoughts might impair day-to-day performance has been shown in some studies of working memory which, as you saw in Chapter 8, allows the brief storage of material for immediate manipulation. Working memory has a limited capacity – irrelevant events and stimuli can impair the action of working memory because attention has to be divided among different tasks. So, ignoring thoughts about a stressful or traumatic event requires paying attention to them in order to inhibit their appearance. The intrusive thoughts involve directing attention to them which takes away resources from other tasks that require working memory.

Research has found that undergraduates who wrote about their stressful thoughts and feelings on entering university showed significantly better working memory performance at the end of the experiment (Klein and Boals, 2001). More ‘cognitive’ than ‘emotion’ words were used at a later session

(compared with earlier sessions). The researchers suggest that this supports Smyth’s (1998) contention that if writing moderates health by changing cognition, changes in tests measuring cognition should be closely associated with the writing process. In a second experiment, students were asked to write about intrusive negative thoughts. They showed significant improvements in working memory than did those who wrote about a positive event or a trivial one.

This last finding suggests that the improvements may be due to the removal of intrusive negative thoughts, rather than intrusive thoughts per se (positive thoughts, for example, which may have been on people’s minds, did not place significant strains on working memory). Of course, this study focused on one type of working memory task and did not measure health outcomes, but the authors hypothesise that the improvements in health as a result of expressive writing may be due to the improvements in working memory capacity.

Other forms of psychotherapy

Group therapy

Group psychotherapy, in which two or more clients meet simultaneously with a therapist to discuss problems, became common during the Second World War. The stresses of combat produced psychological problems in many members of the armed forces, and the demand for psychotherapists greatly exceeded the supply. What began as an economic necessity became an institution once the effectiveness of group treatment was recognised.

Because most psychological problems involve interactions with other people, treating these problems in a group setting may be worthwhile. Group therapy provides four advantages that are not found in individual therapy:

- 1 The group setting permits the therapist to observe and interpret actual interactions without having to rely on clients’ descriptions, which may be selective or faulty.
- 2 A group can bring social pressure to bear on the behaviours of its members. If a person receives similar comments about their behaviour from all the members of a group, the message is often more convincing than if a psychotherapist delivers the same comments in a private session.
- 3 The process of seeing the causes of maladaptive behaviour in other people often helps a person to gain insight into their own problems. People can often learn from the mistakes of others.

- 4 Knowing that other people have problems similar to one’s own can bring comfort and relief. People discover that they are not alone.

The structure of group therapy sessions can vary widely. Some sessions are little more than lectures, in which the therapist presents information about a problem common to all members of the group, followed by discussion. For example, in a case involving a person with severe mental or physical illness, the therapist explains to family members the nature, treatment and possible outcomes of the disorder. Then the therapist answers questions and allows people to share their feelings about what the illness has done to their family. Other groups are simply efficient ways to treat several clients at the same time. Most types of group therapy involve interactions among the participants.

Family therapy and couples therapy

In **family therapy**, a therapist meets with (usually) all the members of a client’s family and analyses the ways in which individuals interact. The therapist attempts to get family members to talk to each other instead of addressing all comments and questions to them. As much as possible, the family therapist tries to collect data about the interactions – how individuals sit in relation to each other, who interrupts whom, who looks at whom before speaking – in order to infer the nature of interrelationships within the family. For example, there may be barriers between certain family members; perhaps a father is unable to communicate with

one of his children. Or two or more family members may be so dependent on each other that they cannot function independently; they constantly seek each other's approval and, through overdependence, make each other miserable.

After inferring the family structure, the therapist attempts to restructure it by replacing maladaptive interactions with more effective, functional ones. The therapist suggests that perhaps all members of the family must change if the client is to make real improvement. They get family members to 'actualise' their transactional patterns – to act out their everyday relationships – so that the maladaptive interactions will show themselves. Restructuring techniques include forming temporary alliances between the therapist and one or more of the family members, increasing tension in order to trigger changes in unstable structures, assigning explicit tasks and homework to family members (for example, making them interact with other members), and providing general support, education and guidance. Sometimes, the therapist visits the family at home. For example, if a child in a family refuses to eat, the therapist will visit during a mealtime in order to see the problem acted out as explicitly as possible.

Behavioural therapists have also applied their methods of analysis and treatment to families. This approach focuses on the social environment provided by the family and on the ways in which family members reinforce or punish each other's behaviour. The strategy is to identify the maladaptive behaviours of the individuals and the ways these behaviours are inadvertently reinforced by the rest of the family. Then the therapist helps the family members find ways to increase positive exchanges and reinforce each other's adaptive behaviours. A careful analysis of the social dynamics of a family often reveals that changes need to be made not in the individual showing the most maladaptive behaviours but in the other members of the family.

All couples will find that they disagree on some important issues. These disagreements necessarily lead to conflicts. For example, they may have to decide whether to move to accommodate the career of one of the partners, they will have to decide how to spend their money, and they will have to decide how to allocate household chores. Their ability to resolve conflict is one of the most important factors affecting the quality and durability of their relationship (Schwartz and Schwartz, 1980).

Controversies in Psychological Science – Does psychotherapy work?

The issue

Evaluation of therapies and therapists is an important issue. It has received much attention, but almost everyone who is involved agrees that too little is known about the efficacy of psychotherapeutic methods, partly because psychotherapeutic effectiveness is difficult to study (Vervaeke and Emmelkamp, 1998). The most well-known psychotherapies, their goals and methods of intervention are summarised in Table 18.2. Given that there are at least 400 types of therapy and over 150 classified mental disorders (Garfield and Bergin, 1994), achieving some consistency across studies is difficult.

Several other factors make it extremely difficult to evaluate the effectiveness of a particular form of therapy or an individual therapist. These include measurement – there are no easily applied, commonly agreed criteria for mental health; and self-selection – clients choose whether to enter therapy, what type of therapy to engage in and how long to stay in therapy, which makes it nearly impossible to establish either a stable sample population or a control group. Self-selection means that certain kinds of people are more likely than others to enter a particular therapy and stick with it, which produces a biased sample. Lack of a stable sample and of a control group makes it difficult to compare the effectiveness of various kinds of therapy. Many patients change therapists or leave therapy altogether. What conclusions can we make about the effectiveness of a therapy by looking only at the progress made by the clients who remain with it?

Yet another problem with scientific evaluation of psychotherapy is the question of an appropriate control group. The effects of therapeutic drugs must be determined through comparison with the effects of placebos (innocuous pills that have no effects on people's thoughts and behaviour) to be sure that the improvement has not occurred merely because the patient thinks that a pill has done some good. Placebo effects can also occur in psychotherapy: people know that they are being treated and get better because they believe that the treatment should lead to improvement. Given these problems, what can we say about the efficacy of psychotherapy?

The evidence

In a pioneering, controversial paper on psychotherapeutic evaluation, Eysenck (1952) examined 19 studies assessing the effectiveness of psychotherapy. He reported that of the people who remained in psychoanalysis as long as their therapists thought they should, 66 per cent showed improvement. Similarly, 64 per cent of patients treated eclectically showed an improvement. However, 72 per cent of patients who were treated only custodially (receiving no psychotherapy) in institutions showed improvement. In other words, people got better just as fast by themselves as they did in therapy.

Subsequent studies were not much more supportive. Some investigators, including Eysenck, concluded that it was unethical to charge a person for psychotherapy because there was little scientific evidence for its effectiveness. Many forms of

Controversies in Psychological Science – *Continued*

Table 18.2 Summary of the basic assumptions, goals and methods involved in traditional forms of psychotherapy

Type of therapy	Basic assumptions	Primary goals	Typical method of analysis or intervention
Psychoanalysis	Behaviour is motivated by intrapsychic conflict and biological urges	To discover the sources of conflict and resolve them through insight	Free association, dream interpretation, interpretation of transference, resistance, memory, and manner of speech
Psychodynamic	Behaviour is motivated by both unconscious forces and interpersonal experiences	To understand and improve interpersonal skills	Interpretation of transference and modification of client's inappropriate schemata about interpersonal relationships
Humanistic and gestalt	People are good and have innate worth	To promote personal growth and self-actualisation and to enhance client's awareness of bodily sensations and feelings	Reduce incongruence through reflection, empathy, unconditional positive regard and techniques to enhance personal awareness and feelings of self-worth
Behavioural and cognitive behavioural	Behaviour is controlled largely by environmental contingencies, people's perception of them, or their combination	To change maladaptive behaviour and thinking patterns	Manipulate environmental variables, restructure thinking patterns and correct faulty thinking or irrational beliefs
Family/couples	Problems in relationships entail everybody involved in them	To discover how interactions influence problems in individual functioning	Analysis of patterns of family/couple's interaction and how others reinforce maladaptive and adaptive thinking and behaving

therapy have never been evaluated objectively because their practitioners are convinced that the method works and deem objective confirmation unnecessary.

Figure 18.4 summarises Smith *et al.*'s (1980) well-known meta-analysis of 475 studies comparing the outcome effectiveness of psychodynamic, gestalt, client-centred, systematic desensitisation, behaviour modification and cognitive behavioural therapies. Relative to no therapy, each of these therapies was shown to be superior in helping people with their problems. As you can see, behavioural and cognitive therapies tended to exceed others in effectiveness, although these differences were often small. More recent research has confirmed these results, indicating that almost all people who enter behavioural or cognitive behavioural therapy tend to improve with regard to the reason that brought them to therapy (Robinson *et al.*, 1990).

Several studies have suggested that the ability to form understanding, warm and empathetic relationships is one of the most important traits that distinguish an effective therapist from an ineffective one (Beutler *et al.*, 1994). For example,

Strupp and Hadley (1979) enlisted a group of lecturers on the basis of their reputation as warm, trustworthy, empathetic individuals. The lecturers (from the departments of English, history, mathematics and philosophy) were asked to hold weekly counselling sessions for students with psychological difficulties. Another group of students was assigned to professional psychotherapists, both psychologists and psychiatrists, and a third group received no treatment at all. Most of the students showed moderate depression or anxiety.

Although there was much variability, with some individual students showing substantial improvement, students who met with the lecturers did as well as those who met with the professional therapists. Both groups did significantly better than the control subjects who received no treatment. These results suggest that sympathy and understanding are the most important ingredients in the psychotherapeutic process, at least for treatment of mild anxiety or depression. In such cases, the therapists' theories of how mental disorders should be treated may be less important than their ability to establish warm, understanding relationships with their clients.

Controversies in Psychological Science – Continued

Figure 18.4 Effectiveness of psychotherapy. The results of Smith *et al.*'s meta-analysis comparing the effectiveness of different therapies.:

In one meta-analysis, Westen and Morrison (2001) scrutinised studies from nine clinical psychology and psychiatric journals published between 1990 and 1999. To be eligible for inclusion, studies had to test the efficacy of a specific psychosocial treatment against a waiting-list control group and an alternative therapy, had a follow-up of at least 12 months, had to include valid measures of outcome and had to be experimental in nature. Thirty-four studies met these inclusion criteria.

The authors found substantial improvement in mental health in up to half of the patients. The majority of patients, however, did not show sustained improvement at one to two years' follow-up, especially those who are depressed or generally anxious. Half of patients who complete a course of treatment will benefit from it, whereas the figure drops to 40 per cent if a patient simply enters treatment (but may not continue). The long-term treatment success for panic disorder is good, but the authors found that the depressed or anxious patient will maintain mild to significant levels of symptoms after treatment. The authors note that follow-up studies at two years were non-existent. In the four studies that did conduct such a follow-up, a quarter of depressed patients who did not abuse alcohol or drugs and were not suicidal will improve two years after treatment. Psychotherapy for panic disorder treatment was the most effective, with 46 per cent of patients showing sustained improvement.

The strict exclusion/inclusion criteria in the study is a plus and a negative. On the plus side, the studies reviewed are carefully selected and well-controlled experimental studies. On the negative side, few studies were included and complications such as co-morbidity (the appearance of one disorder with another) were not addressed because patients in the selected studies suffered exclusively from one disorder. The future should see the inclusion of studies employing other therapies.

Conclusion

The success of psychotherapy (which includes cognitive behavioural therapy as well as the other, humanistic therapies) rests on the type of therapy applied. There are some negative outcomes: an estimated 9–13 per cent of clients worsen after psychotherapy (Beutler and Clarkin, 1990). The application of psychotherapy to schizophrenia has been associated with a deterioration in the client's condition (Lambert and Bergin, 1994). Also, some problems may be inappropriate for psychotherapy: criminal or antisocial behaviour, for example. And some forms of psychotherapy appear to be ineffective in some contexts, such as influencing the survival rate from cancer (Coyne *et al.*, 2007; 2009). For some other problems, however, such as depression, psychotherapy may be quite effective when combined with other treatments.

Biological treatments

The most common biological treatment for mental illness is pharmacological. Psychopharmacological interventions are aimed at treating psychological problems by using chemical agents.

There are four major classes of drugs used to treat mental disorders: antipsychotic drugs, antidepressant drugs, anti-manic drugs and anti-anxiety drugs. We discuss the application and effectiveness of these drugs in the sections describing mental disorders.

Some people with depression do not respond to antidepressant drugs, but a substantial percentage of these people improve after a few sessions of **electroconvulsive therapy (ECT)** in which electrodes are applied to a person's head and a brief surge of electrical current is passed through them. Because antidepressant medications are generally slow-acting, taking ten days to two weeks for their therapeutic effects to begin, severe cases of depression are often treated with a brief course of ECT to reduce the symptoms immediately. These people are then maintained on an antidepressant drug.

There are several problems with ECT treatments. An excessive number of ECT treatments has been associated with permanent memory loss (Squire *et al.*, 1981) with little enduring effect on cognitive performance (Calev *et al.*, 1995; Barnes *et al.*, 1997). Nowadays, ECT is usually administered only to the right hemisphere, in order to minimise damage to people's verbal memories, and is used only when the patient's symptoms justify it. Because ECT undoubtedly achieves its effects through the biochemical consequences of the seizure, pharmacologists may discover new drugs that can produce rapid therapeutic effects without ECT's deleterious ones. Once this breakthrough occurs, ECT can be abandoned.

One other biological treatment for mental disorders is even more controversial than electroconvulsive therapy: psychosurgery or neurosurgery (Fenton, 1998). **Psychosurgery** involves the treatment of a mental disorder, in the absence of obvious organic damage, through brain surgery. In contrast, brain surgery to remove a tumour or diseased neural tissue or to repair a damaged blood vessel is not psychosurgery, and there is no controversy about these procedures.

Psychosurgery has its origins in the late 1930s when, at a conference at University College London, the results of frontal lobectomies on two chimpanzees, Becky and Lucy, were presented. The surgery resulted in an increase in calmness and passivity in the chimps. Egas Moniz, a 59-year-old Portuguese professor of neurology, one of the audience at the meeting, suggested that this technique might also be appropriate for humans. Late in 1935, the first frontal lobotomy operations were performed. While treating some symptoms, such as those in chronic schizo-

phrenia, the prefrontal lobotomies were found to have serious side-effects, such as apathy and severe blunting of emotions, intellectual impairments, and deficits in judgement and planning ability. Nevertheless, the procedure was used for a variety of conditions, most of which were not improved by the surgery. Approximately 40,000 prefrontal lobotomies were performed in the USA alone, most of them from 1935 to 1955. A simple procedure, called 'ice pick' prefrontal lobotomy by its critics, was even performed on an outpatient basis, as seen in Figure 18.5. The development of antipsychotic drugs and the increasing attention paid to the serious side-effects of prefrontal lobotomy led to a sharp decline in the use of this procedure during the 1950s. Today it is no longer performed.

A few surgeons have continued to refine the technique of psychosurgery and now perform a procedure called a **cingulotomy**, which involves cutting the cingulum bundle, a small band of nerve fibres that connects the prefrontal cortex with parts of the limbic system (Ballantine *et al.*, 1987). Cingulotomies have been shown to be effective in helping some people who suffer from severe compulsions (Tippin and Henn, 1982). In a recent study, Baer *et al.* (1995) conducted a long-term follow-up study of 18 people who underwent cingulotomy for severe obsessive-compulsive disorder. For each of these people, other forms of therapy – drug therapy and behavioural therapy – had been unsuccessful in treating their symptoms. However, after their surgeries, the people in Baer's study showed marked improvements in their functioning, decreased symptoms of depression and anxiety, and few negative side-effects.

Figure 18.5 'Ice pick' prefrontal lobotomy. The sharp metal rod is inserted under the eyelid and just above the eye so that it pierces the skull and enters the base of the frontal lobe.

Table 18.3 Drugs commonly used to treat mental disorders

Therapeutic function	Class of drugs	Generic name	Trade name
Antipsychotic	Soporific Non-soporific Phenothiazines	Chlorpromazine	Thorazine
		Acetophenazine	Tindal
		Thioridazine	Mellaril
		Fluphenazine	Permitil
		Trifluoperazine	Stelazine
		Perphenazine	Trilafon
		Haloperidol	Haldol
	Butyrophenones		
Antidepressant	Tricyclics	Imipramine	Tofranil
	Monoamine oxidase inhibitors	Amitryptiline	Elavil
		Phenelzine	Nardil
		Fluoxetine	Prozac
	Serotonin reuptake inhibitors		Miltown
Anti-anxiety	Propanediols	Meprobamate	
	Benzodiazepines	Chlordiazepoxide	Librium
		Diazepam	Valium
Anti-manic	Lithium salts	Lithium carbonate	Eskalith

Drug therapy is the preferred biological treatment for mental disorders although it represents only a possible treatment, not a cure. Usually, the drugs are effective only to the extent that the people for whom they are prescribed actually use them. In some cases, people forget to take their drugs, only to have the disordered symptoms return. In

other cases, people take their drugs, get better, and stop taking the drugs because they feel that they are no longer 'sick'. In this case, too, the symptoms soon return. For some people, this cycle repeats itself endlessly. Table 18.3 lists some of the drugs commonly used to treat mental disorders.

Mental disorders

The previous section described each of the major approaches to treating mental disorder. This section reviews some of the most important mental disorders. Each major class of disorder is described according to its symptoms, its possible causes and the current treatment approach.

Anxiety, somatoform and dissociative mental disorders

Anxiety, somatoform and dissociative mental disorders are often referred to as neuroses. Most neuroses are strategies of perception and behaviour that have become distorted or exaggerated. They are characterised by pathological increases in anxiety or by defence mechanisms applied too rigidly, resulting in mental processes that are maladaptive. Neurotic people are anxious, fearful, depressed and generally unhappy. However, unlike people who are afflicted with psychoses, they do not

suffer from delusions or severely disordered thought processes. Furthermore, they almost universally realise that they have a problem. Most neurotics are only too aware that their strategies for coping with the world are not working. Neurotic behaviour is usually characterised by avoidance rather than confrontation of problems.

Anxiety disorders

Several important types of mental disorders are classified as anxiety disorders, which have fear and anxiety as their most prominent symptoms. **Anxiety** is a sense of apprehension or doom that is accompanied by certain physiological reactions, such as accelerated heart rate, sweaty palms and tightness in the stomach. Anxiety disorders are the most common psychological disorders and the reported rate of anxiety disorder is twice as high in European women than

in men (Weiller *et al.*, 1998). Five of the most important anxiety disorders are generalised anxiety disorder, panic disorder, phobic disorder, obsessive-compulsive disorder and post-traumatic stress disorder.

The most common of these are agoraphobia, panic disorder and generalised anxiety disorder, all of which are described next, together with possible aetiology. There seems to be national variation in the prevalence of these disorders. Generalised anxiety disorder is more frequent in cities such as Paris and Berlin, for example, whereas it is low in Manchester and Groningen (the Netherlands). Panic disorder appears to be more common in Manchester and agoraphobia in Groningen (Weiller *et al.*, 1998).

Generalised anxiety disorder (GAD)

Description

The principal characteristic of **generalised anxiety disorder (GAD)** is excessive worry about all matters relating to the individual's life: health, money, work, relationships and so on. According to DSM-IV TR, these worries must be present on most days and will have occurred over a period of at least six months. The anxious individual finds it difficult to control the worry and shows at least three symptoms out of the following: restlessness, being easily fatigued, difficulty concentrating, irritability, muscle tension and sleep disturbance. Around 12 per cent of anxiety disorders are GAD (American Psychiatric Association, 1994) and most individuals with GAD also experience depression which sometimes makes a clear-cut diagnosis of GAD difficult.

Anxious individuals spend considerably longer making decisions. For example, Tallis *et al.* (1991) asked a group of controls and clinically anxious individuals to respond if a target was present on a computer monitor. Although there was no difference between controls and anxious individuals when the target was present, the anxious group took significantly longer to make a decision when the target was absent. This finding demonstrates that anxious individuals seem to attend more to tasks that require them to make absolutely correct decisions.

Aetiology

Several models exist which try to explain GAD; some of these also apply to other mental disorders but this section limits itself to those which account for GAD explicitly. One explanation (Borkovec, 1994) suggests that GAD arises from the individual's drive to set and anticipate a set of goals that are desirable. In this context, the anxiety arises when a history of a frustrated failure to achieve affects the perception of cues associated with these goals. Anxiety is reflected in the individual's need to anticipate all possible outcomes, for fear of failing or not achieving.

Eysenck (1992) has argued that although Borkovec's model (described in full in Berkovec [1994] might explain pathological worry, it does not explain normal worry. Eysenck's model attempts to explain both by suggesting that worry or anxiety serves as an 'alarm function' which brings information concerning threat-related stimuli into awareness. In a sense, worry acts as a behaviour that will prepare an individual for future behaviour; it prompts the individual to anticipate future situations and their solutions.

Although older than Eysenck's, Gray's (1982) model suggests a similar mechanism but ties it to neurophysiology and certain brain systems. According to Gray, anxiety is evoked by signals of punishment, lack of reward, novel stimuli and innate fear stimuli. The individual detects such threats by means of a **behavioural inhibition system (BIS)** which also generates the anxiety. An important function of the BIS is that it helps the organism (Gray's theory applies to humans and other animals) to evaluate the threat content of a stimulus or event. The neurophysiology of the system is vast and complicated, involving neuroanatomical and neurochemical interaction between a number of brain regions. The BIS is thought to be represented by the septum and hippocampal formation.

Two-factor model

The two-factor model of anxiety suggests that individuals exhibit a vulnerability to anxiety owing to high trait anxiety and poor coping skills. There is a strong correlation between neuroticism and almost all major anxiety disorders (Andrews *et al.*, 1989; Andrews, 1991). There also seems to be a loss of control exhibited by anxious individuals and anxiety is often preceded by stressful life events (Last *et al.*, 1984), as Borkovec's model also suggests. Individuals with panic disorder and GAD have been found to rate their parents as less caring and as overprotective (Silove *et al.*, 1991), indicating perhaps one cause of the perceived lack of control. High trait anxiety individuals have been found to be very similar to clinically anxious patients in terms of their perception that events are out of their control and in terms of parental overprotection (Bennett and Stirling, 1998).

Information-processing models

A number of studies has suggested that individuals high in trait anxiety and those suffering GAD exhibit **attentional biases**. That is, they are significantly biased towards responding to threat- or anxiety-related material. Anxious people are more vigilant when reacting to threatening faces than non-threatening faces, for example (Bradley *et al.*, 1999). There are various ways of measuring this attentional bias and three of the most common

measures are the dot probe, the emotional Stroop and the interpretation of ambiguous sentences (Eysenck *et al.*, 1991; Wells and Mathews, 1994).

The dot probe task involves the presentation of two words, one above the other, on a computer monitor. Individuals are asked to read aloud the word at the top; this word is either neutral or is an anxiety- or threat-related word. After a short pause, the individual is presented with either another pair of words or a dot where the top or bottom word appeared. The individual has to press a key when such a dot appears. MacLeod and his colleagues (MacLeod *et al.*, 1986; Matthews *et al.*, 1990) have reported that latencies are shorter for anxiety-related words in GAD patients.

Similar biases are reported for the emotional Stroop task. In this, individuals have to read the colour in which a word is written. These words are either neutral or anxiety-related. GAD patients and individuals high in trait anxiety exhibit a bias towards the anxiety-related words, although the effects found with the Stroop are not as robust as those seen in the dot probe (Williams *et al.*, 1996). Finally, anxious individuals have a tendency to interpret ambiguous sentences such as ‘The two men watched as the chest was opened’ as threatening, that is, they interpret the chest as being a person’s torso rather than a large box (Eysenck *et al.*, 1991).

Each model of GAD has some merit; that Eysenck’s and Gray’s models flag anxiety as indicating an alarm system that prepares an individual for future action suggests that anxiety results from excessive monitoring for and detection of threat. The findings from attentional bias studies support this view. Why the anxiety should be produced by this appraisal in some individuals and not in others, however, is still unclear. Borkovec’s model is useful in that it specifies previous non-reward and frustration as a cause of being unable to achieve goals. Gray’s model is useful because it ties this appraisal down to one neuropsychological system.

Treatment

The most common form of treatment for GAD is psychopharmacological, with drug administration sometimes coupled with cognitive behavioural therapy. The drugs used to combat anxiety disorder are called **anti-anxiety drugs** or **anxiolytics**, and a list of the most common appears in Table 18.4.

The anxiolytics include barbiturates, benzodiazepines and antidepressants. Barbiturates are sedatives and include drugs such as Phenobarbital. However, because they are highly toxic and foster dependence, they are not widely used. Benzodiazepines are anticonvulsant and sedative drugs, and are the most widely prescribed. Two common benzodiazepines are chlordiazepoxide (Librium) and diazepam (Valium), both of which are low in toxicity.

Table 18.4 Some of the drugs used to treat anxiety

Substance	Generic name	Example
Benzodiazepines	Alprazolam	Xanax
	Chlordiazepoxide	Librium
	Clonazepam	Klonopin
	Clorazepate	Tranxene
	Diazepam	Valium
	Halazepam	Paxipam
	Lorazepam	Ativan
	Oxazepam	Serax, Zaxopam
	Przepam	Centrax
Atypical agent	Buspirone	Buspar

A meta-analysis of 65 studies comparing CBT and/or pharmacological interventions with a control condition for the treatment of generalised anxiety disorder, found that CBT was a significantly better treatment than was no treatment (Mitte, 2005). When studies directly compare CBT with drug intervention, there was no significant difference in efficacy.

Panic disorder

Description

Panic has been described as a fear of fear (Foa *et al.*, 1984). Individuals who experience panic are threatened by the presence or the potential presence of fear-related physical states. People with **panic disorder** suffer from episodic attacks of acute anxiety – periods of acute and unremitting terror that grip them for lengths of time lasting from a few seconds to a few hours. The lifetime prevalence rate for panic disorder is estimated to be about 4 per cent (Katerndahl and Realini, 1993). Panic attacks (without agoraphobia, which is the anxiety disorder we discuss next) are equally likely to appear in men and women (Clarke, 1992). The disorder usually has its onset in young adulthood; it rarely begins after age 35 (Woodruff *et al.*, 1972).

Panic attacks include many physical symptoms, such as shortness of breath, sweating, racing heartbeat (tachycardia), physical tension, cognitive disorganisation, dizziness and fear of loss of support (jelly legs). The individual feels as if he or she is about to collapse and is on the point of death. Such catastrophic thoughts and feelings only exacerbate the physical symptoms and so the individual becomes involved in a self-fulfilling prophecy.

Between panic attacks, people with panic disorder tend to suffer from **anticipatory anxiety** – a fear of having a

panic attack (Ottaviani and Beck, 1987). Because attacks can occur without apparent cause, these people anxiously worry about when the next one might strike them. Sometimes, a panic attack that occurs in a particular situation can cause the person to fear that situation. The anxiety we all feel from time to time is significantly different from the intense fear and terror experienced by a person gripped by a panic attack, as the case study below illustrates.

Aetiology

Genetic models

There seems to be a hereditary component to panic disorders: the concordance rate for the disorder is higher between identical twins than between fraternal twins (Torgerson, 1983). Almost 30 per cent of the first-degree relatives (parents, children and siblings) of a person with panic disorder also have panic disorder (Crowe *et al.*, 1983). According to Crowe *et al.*, the pattern of panic disorder within a family tree suggests that the disorder is caused by a single, dominant gene.

Panic attacks can be triggered in people with histories of panic disorder by giving them injections of lactic acid (a by-product of muscular activity) or by having them breathe air containing an elevated amount of carbon dioxide (Woods *et al.*, 1988; Cowley and Arana, 1990). People with family histories of panic attack are more likely to react to sodium lactate, even if they have never had a panic attack previously (Balon *et al.*, 1989). Some researchers believe that what is inherited is a tendency to react with alarm to bodily sensations that would not disturb most other people.

Clark's model

The most comprehensive (and cognitive) model of panic disorder is that proposed by David Clark. Clark (1986, 1988) argues that panic attacks are produced by the **catastrophic misinterpretation** of bodily events. Slight changes in bodily sensation are interpreted as symptomatic of a physical threat which makes the individual anxious. The more anxious the individual becomes, the more intense the bodily sensations become (the self-fulfilling prophecy referred to above). According to Clark's model, two processes contribute to the maintenance of this misinterpretation. The first is hypervigilance: the individual repeatedly checks for changes in bodily sensations; the second is avoidance strategies: the individual avoids those behaviours they feel will exacerbate the bodily sensations. For example, a person who is afraid that he is about to have a heart attack will avoid exercise (although this prevents the individual from discovering that exercise will not cause a heart attack).

Seligman (1988), however, has argued that the catastrophic misinterpretation theory is questionable on the grounds that the realisation that death will not accompany panic attacks will eventually dawn on these patients. Seligman suggests an alternative suggestion based on **evolutionary preparedness**, the notion that we are evolutionarily predisposed to respond in a specific way to some stimuli because it is to our advantage to do so (Seligman, 1971). Panic, in this context, is the individual's response to biologically prepared bodily sensations. However, as Power and Dalglish (1997) argue, the failure to realise that death does not follow bodily sensations arises because individuals avoid situations and stimuli that would induce such bodily sensations in the first place. Seligman's formulation may not, therefore, be necessary (for the reason he suggests).

Interestingly, some patients maintain that they do not misinterpret their bodily sensations catastrophically and some are more difficult to convince that these sensations will not lead to death (McNally, 1990). These findings point to a degree of variation in panic disorder patients. The anxiety sensitivity hypothesis (Reiss and McNally, 1985), for example, suggests that some individuals are more anxiety-sensitive than others. The degree of sensitivity depends on pre-existing beliefs about the harmfulness of bodily sensations. These pre-existing beliefs predispose the individual to interpret bodily events negatively and erroneously. This leads to panic.

Treatment

Treatment for panic disorder can be both cognitive behavioural or pharmacological. Cognitive behavioural therapy, for example, is effective at reducing panic attacks. Such therapy would involve breathing and relaxation techniques, **cognitive restructuring** (altering misconceptions about the consequences of bodily sensations) and eliciting bodily sensations in the individual to demonstrate the non-harmful nature of such changes (Craske *et al.*, 1997). Antidepressants and anxiolytics are sometimes used to treat panic attacks with some success. Some individuals react badly to the drugs, however, and while they treat the anxiety generated during panic, they do not address the core problem of catastrophic misinterpretation.

Phobic disorders

Phobias – named after the Greek god Phobos, who frightened his enemies – are irrational fears of specific objects or situations. Because phobias can be highly specific, clinicians have coined a variety of inventive names, some of which are summarised in Table 18.5.

Table 18.5 Name and description of some common phobias

Name	Object or situation feared
Acrophobia	Heights
Agoraphobia	Open spaces
Ailurophobia	Cats
Algophobia	Pain
Astraphobia	Storms, thunder, lightning
Belonophobia	Needles
Claustrophobia	Enclosed spaces
Haematophobia	Blood
Monophobia	Being alone
Mysophobia	Contamination or germs
Nyctophobia	Darkness
Ochlophobia	Crowds
Pathophobia	Disease
Pyrophobia	Fire
Siderophobia	Railways
Syphilophobia	Syphilis
Taphophobia	Being buried alive
Triskaidekaphobia	Thirteen
Zoophobia	Animals, or a specific animal

Most individuals have one or more irrational fears of specific objects or situations, and it is difficult to draw a line between these fears and phobic disorders. If someone is afraid of spiders but manages to lead a normal life by avoiding them, it would seem inappropriate to say that the person has a mental disorder. Similarly, many otherwise normal people are afraid of speaking in public. The term ‘phobic disorder’ should be reserved for people whose fear makes their life difficult. The DSM-IV TR recognises three types of phobic disorder: agoraphobia, social phobia and simple phobia.

Agoraphobia

Agoraphobia (*agora* means ‘marketplace’ in Ancient Greek) is a fear of open spaces and is the most serious and common of the phobic disorders. It occurs in between 50 and 80 per cent of phobic disorders (Matthews *et al.*, 1981). It is reported three times as often in women as in men. Onset is sudden and individuals are usually in their early twenties (Clarke, 1992). The term was coined by Westphal in 1871 to describe four (male) cases who feared open spaces.

Most cases of agoraphobia are considered to be caused by panic attacks and are classified with them. Agoraphobia associated with panic attacks is defined as a fear of ‘being in places or situations from which escape might be difficult (or embarrassing) or in which help might not be available in the event of a panic attack . . . As a result of this fear, the person either restricts travel or needs a companion when

away from home’ (American Psychiatric Association, 1994). Agoraphobia can be severely disabling. Some people with this disorder have stayed inside their house for years, afraid to venture outside. Supermarkets and queuing are especially anxiety-provoking for agoraphobics. Features of supermarket layout such as stairways and diminished access, for example, are regarded as anxiety-provoking by agoraphobic individuals (Jones *et al.*, 1996).

Social phobia

Social phobia is an exaggerated ‘fear of one or more situations . . . in which the person is exposed to possible scrutiny by others and fears that he or she may do something or act in a way that will be humiliating or embarrassing’ (American Psychiatric Association, 1994). Most people with social phobia are only mildly impaired, but the situations in which they can operate may be severely curtailed. Social phobics, like patients with GAD, seem to bias their attention towards threat-related stimuli (Rapee and Heimberg, 1997).

At the core of the disorder seems to be conflict regarding the internal representation of their appearance and external indicators which evaluate them negatively. Rapee and Heimberg, therefore, proposed that socially phobic individuals allocate excessive attentional resources towards mental representations of how they are perceived by their audience. In a study in which high and low anxious social phobic individuals gave a five-minute speech in front of an audience that was behaving positively (smiling) or negatively (frowning), Veljaca and Rapee (1998) found that highly anxious individuals were better at detecting negative audience behaviours whereas the low anxiety individuals were better at detecting the positive behaviours. Social phobics also interpret ambiguous social events more negatively, and interpret mildly negative, unambiguous events more catastrophically than do people suffering from anxiety, or a group of healthy controls (Stopa and Clark, 2000).

Specific phobia

Specific phobia includes all other phobias, such as fear of snakes, darkness or heights. These phobias are often caused by a specific traumatic experience and are the easiest of all types of phobia to treat. The Epidemiological Catchment Area (ECA) Study found that insects, mice, snakes and bats were the more frequently cited feared/disgust-provoking stimuli (Robins and Regier, 1994). Animals are a common phobia. Davey (1992), for example, reported that one-third of women and one-quarter of men reported having a spider phobia.

The lifetime prevalence rate for simple phobia is estimated to be about 14 per cent for women and about

8 per cent for men (Robins and Regier, 1991), but approximately one-third of the population sometimes exhibit phobic symptoms (Goodwin and Guze, 1984).

Aetiology

Animal phobias are sometimes surprising because in Europe, for example, there are no indigenous lethally poisonous spiders, although spider phobias are common. One explanation for this anomaly is that we fear animals that have potentially lethal consequences; we are, therefore, predisposed to fear them. This is the preparedness hypothesis (Seligman, 1971) which we encountered in the section on panic disorder. Evidence for this hypothesis comes in the form of the deliberate conditioning of fear of spiders. These conditioning experiences are the most difficult to extinguish – more difficult than non-threatening stimuli (Ohman *et al.*, 1985; McNally, 1987).

However, Seligman's theory has its problems. For example, if we are adaptively predisposed to fear the stimuli producing simple phobias, what adaptive purpose does a fear of snails, moths and slugs serve? As McNally (1995) points out, we can ascribe adaptive significance to a fear of any object if we are creative enough. One theory suggests that phobias develop from a pairing of a phobic object with an aversive stimulus so that phobic stimuli become phobic by association. However, only 40–50 per cent of animal phobias appear to be accounted for in this way. Davey (1992) also reported that only 8 out of 118 spider phobics recall having a traumatic experience with spiders.

Matchett and Davey (1991) suggest an alternative explanation: that some stimuli become the object of phobia because of our inherent fear of contamination or disease. Animals (such as spiders, slugs, cockroaches) become feared because they seem disgusting and we would reject them as food on the basis of this disgust (although some individuals would be immune to such disgust responses; snails are considered a delicacy in certain parts of Europe). In fact, sensitivity to disgust may be an

important determinant of the level of fear (Webb and Davey, 1993). To investigate whether some animal phobias were disgust- or fear-related, Davey *et al.* (1998) conducted a cross-cultural study of phobia in seven countries. An analysis of the data suggested that phobic stimuli could be divided into one of three categories: fear-irrelevant (for example, chicken, hamster, cow), fear-relevant (for example, lion, bear, alligator) and disgust-relevant (for example, cockroach, spider, maggot, worm). Disgust was consistent across cultures (although there were some cross-cultural differences with Indian respondents reporting lower levels of fear to the disgust stimuli and Japanese respondents showing higher levels of fear). This finding suggests that not all stimuli may be feared for the same reasons (perhaps the term 'simple phobia' is too simplistic, as Curtis *et al.* (1998) suggest).

Treatment

Phobias are sometimes treated by *systematic desensitisation* (described in the general section on treatment) or modelling. Bandura (1971), for example, has described a modelling session with people who had a phobic fear of snakes. The therapist himself performed the fearless behaviour at each step and gradually led participants into touching, stroking and then holding the snake's body with gloved and bare hands while the experimenter held the snake securely by head and tail. If a participant was unable to touch the snake following ample demonstration, they were asked to place their hand on the experimenter's and to move their own hand down gradually until it touched the snake's body. After participants no longer felt any apprehension about touching the snake under these secure conditions, anxieties about contact with the snake's head area and entwining tail were extinguished. The therapist again performed the tasks fearlessly, and then he and the participant performed the responses jointly. As participants became less fearful, the experimenter gradually

Cutting edge – Phobia reduction and cortisol

Although the release of the hormone cortisol is common during our response to stressful events and is also cued by exposure to phobic objects in phobic individuals, a group of researchers from Switzerland, Germany and the United States have reported that the administration of the chemical can reduce phobic symptoms (Soravia *et al.*, 2006). When glucocorticoid levels are high, memory can become impaired. The researchers reasoned that the administration of cortisol would lead to the inhibition of fear-related memory in phobia sufferers. This is

what they found, in a group of 20 people with social phobia and 20 people with spider phobia. Cortisone (25 mg) was administered orally one hour before participants were exposed to a social stressor or photograph of a spider (depending on the participant). Self-reported fear was significantly reduced in the cortisol group during the anticipation of the phobic stimulus, exposure to it and recovery from this exposure. Those in the placebo group did not produce this effect.

reduced his participation and control over the snake, until eventually participants were able to hold the snake in their lap without assistance, to let the snake loose in the room and retrieve it, and to let it crawl freely over their body. Progress through the graded approach tasks was paced according to the participants' apprehensiveness. When they reported being able to perform one activity with little or no fear, they were eased into a more difficult interaction. This treatment eliminated fear of snakes in 92 per cent of those who participated.

Modelling is successful for several reasons. Participants learn to make new responses by imitating those of the therapist and their behaviour in doing so is reinforced. When they observe a confident person approaching and touching a feared object without showing any signs of emotional distress, they probably experience a vicarious extinction of their own emotional responses. In fact, Bandura (1971, p. 684) reports that 'having successfully overcome a phobia that had plagued them for most of

their lives, subjects reported increased confidence that they could cope effectively with other fear-provoking events', including encounters with other people.

Cognitive behavioural therapy has also been applied to agoraphobia (Ost *et al.*, 1993). In an experiment in which the effect of exposure (graded exposure to the phobic stimuli) was compared with exposure and CBT (combating negative thoughts and dysfunctional attitudes), Burke *et al.* (1997) found no difference in the effectiveness of the two therapies at six months following the therapy: both were equally effective. Similar combinations have also been found to be effective for social phobia (Scholing and Emmelkamp, 1996).

A recently developed treatment has taken the idea of exposure but added a technological element: virtual reality technology. This has many practical benefits. The fear of flying, for example, would be more efficiently treated using simulated or virtual stimuli rather than taking sufferers to airports. This approach is evaluated in the Psychology in Action section.

Psychology in action – Virtual planes can relieve real fear of flying

The fear may be more common than people imagine. According to one German study, 15 per cent of respondents reported having a fear of flying and around 60 per cent of those try to cope with this fear by drinking alcohol or taking tranquillisers (Wilhelm and Roth, 1997).

In many cases, treatment may take the form of cognitive behavioural therapy which exposes the patient to the fear-eliciting stressor with the aim of attenuating the fear that such stressors cause. For example, a patient may be exposed to real aeroplanes or may be walked around a stationary plane. Recently, however, psychologists have harnessed new technology to help people combat their fear of flying: virtual reality or VR (Klein, 1998). VR technology allows researchers to simulate events, locations or stimuli effectively using computer software. Consequently, it is a very convenient and inexpensive approach to treatment.

Rothbaum *et al.* (2000) randomly assigned 49 patients who expressed a fear of flying to one of three conditions: virtual reality (VR) training, standard exposure therapy or no therapy where patients were on a waiting list for treatment.

The VR training involved exposing the participant to a virtual aircraft (sitting in it while it took off and landed); standard exposure involved direct exposure to an airport and a stationary plane. Both experimental conditions were preceded by four sessions of anxiety management. Patients received treatment over eight weeks and a post-treatment flight was set up after this period to examine the efficacy of the VR treatment, as measured by willingness to fly and self-reported anxiety about the first flight.

Both VR and standard exposure treatments were better than the control condition in reducing fear of flying. The beneficial effects of exposure were still seen at a six-month follow-up. Ninety-three per cent of VR patients and 93 per cent of standard exposure patients had flown after treatment. The results show that VR may be an inexpensive and more convenient way of reducing the fear of flying than is actual exposure to real aeroplanes. If given the choice, patients indicated that they would opt for the VR treatment rather than real exposure.

Exposure to virtual reality also appears to be more effective at reducing flight anxiety than is relaxation therapy, a common

Figure 18.6 Fear of flying scores for people in the VR exposure group (black line) and the relaxation group (orange line).

Psychology in action – Continued

psychological intervention that some flyers adopt. Muhlberger *et al.* (2001) found that while exposure to VR flights increased feelings of fear, these feelings gradually attenuated and to a greater extent than they did in people undergoing relaxation training. Both approaches reduced flight anxiety, but VR was better, as Figure 18.6 shows.

Virtual reality technology of this kind has now been successfully used to treat arachnophobia (Carlin *et al.*, 1997) and claustrophobia (Botella *et al.*, 1998). As with all treatments, its success is measured by its long-term effects. A recent 12-month

follow-up study suggests that VR flight exposure has lasting effects on anxiety relief. Rothbaum's team followed up 24 patients who were either exposed to actual planes and an airport or to VR flying. As you saw in the section at the beginning, both interventions were successful at the first testing point. The follow-up study showed that the initial improvements were maintained. The results suggest that a very short-term treatment that imposes fewer practical demands than real exposure to planes and airports can have sustainable benefits.

Post-traumatic stress disorder (PTSD)

Description

Post-traumatic stress disorder (PTSD) is a relatively new anxiety disorder (it made its first appearance in DSM-III in 1980) and refers to anxiety that follows a traumatic event. This event poses a threat to the individual's life or the lives of others. Symptoms of the disorder include the re-experiencing of feelings related to the event (such as intrusive memories, thoughts and images related to the event), avoidant behaviour (such as denial and emotional numbing) and arousal (such as hypervigilance for trauma-related information). Sadness, guilt and anger are also associated with the disorder (Shore *et al.*, 1989). These latter symptoms are important because PTSD seldom appears alone but with other disorders or additional diagnoses (McFarlane, 1992; Bleich *et al.*, 1997). PTSD is a controversial inclusion in DSM-IV TR because its validity has been challenged. Some researchers point to the ease with which PTSD symptoms can easily be faked (Burgess and McMillan, 2001).

The prevalence rate is around 25–30 per cent in the general population, and rape is associated with the greatest prevalence (Green, 1994). Other events which can produce PTSD are road traffic accidents (Stallard *et al.*, 1998; Murray *et al.*, 2002), bank robberies (Kamphuis and Emmelkamp, 1998), war (Fontana and Rosenheck, 1993), and natural or human-made disasters (Freedy *et al.*, 1994). Onset of the disorder may be delayed by many years (Blank, 1993). As with generalised anxiety disorder and panic disorder, there is a greater Stroop interference for words related to the trauma (Thrasher *et al.*, 1994).

The emergency services, especially its members who respond to disasters, may be more prone to developing the disorder because of the type of work they engage in. In the UK, ambulance drivers answer more calls than do the police and fire service combined. It might be expected, therefore, that the incidence of PTSD is high. In fact, the prevalence lies between 10 and 20 per cent. Clohessy and Ehlers (1999) asked 56 ambulance drivers in the UK to

describe the most distressing aspects of their work and administered questionnaires which tapped their ability to cope with this distress and the degree to which the thoughts about the distress were intrusive. They found that 21 per cent of the sample met the criteria set by the DSM-IV TR for PTSD. Predictors of the severity of the post-traumatic stress were poor coping strategy, efforts to suppress intrusive thoughts and dwelling on previous distressing events.

In a study of 96 victims of physical or sexual assault, Dunmore *et al.* (1999) found that some factors were common to both onset and maintenance whereas others were specific to onset. Factors associated with both were appraising the event and the consequences of the event (dwelling on the assault and its aftermath) and adopting poor coping strategies (such as avoidance). Factors which were related to onset were feeling detached during the assault and being unable to perceive positive responses from others. The researchers suggest that these cognitive factors may contribute to PTSD in a number of ways. They may prevent recovery by encouraging poor coping strategy or by generating a sense of immediate threat.

Aetiology

Horowitz's (1979, 1986) model suggests that information about the trauma in PTSD is processed because of a mechanism called *completion tendency*. Completion tendency refers to the need for new information to be integrated into existing patterns of thought and memory. Power and Dalgleish (1997) describe how there is first a stunned reaction to the traumatic event and then a feeling of information overload as the individual realises the enormity of the trauma. Such information cannot be accommodated by existing mental schemata, and defence mechanisms, such as denial and numbing, provide a means of coping with this lack of accommodation. Completion tendency, however, insists on keeping the memory of the event alive (Horowitz calls this 'active memory') through flashbacks and nightmares. The anxiety results from the vacillation

between these two processes: defence mechanisms and completion tendency. Although an honourable attempt at explaining PTSD, Power and Dalgleish (1997) query whether the model explains some features of the disorder. Why do only some individuals develop PTSD, for example? And why is PTSD delayed in some individuals?

An alternative model suggests that in PTSD the individual's beliefs about the world have been shattered. According to the model, the individual is assumed to view themselves as personally invulnerable, that the world is meaningful and comprehensible, and that the individual views themselves positively (Janoff-Bulman, 1989, 1992). These assumptions provide the bedrock of our life and give it structure. This structure is shattered after the traumatic event which gives rise to PTSD. The process by which this structure breakdown occurs, however, is not explained by the model.

Treatment

Various forms of treatment have been attempted with PTSD with varying success (Shalev *et al.*, 1996; Foa and Meadows, 1997). Debriefing appears to be ineffective (Deahl *et al.*, 1994) but drug treatment meets with mixed success (O'Brien and Nutt, 1998). Treatment based on exposure seems to be effective (Foa and Meadows, 1997).

Obsessive-compulsive disorder

Description

Individuals with **obsessive-compulsive disorder (OCD)** suffer from **obsessions** – thoughts that will not leave them – and **compulsions** – behaviours that they cannot keep from performing. In one study, impaired control of mental activities, checking, urges involving loss of motor control, and feeling contaminated were found to be the major classes of obsession and compulsion among a large sample of American college students (Sternberger and Burns, 1990). The lifetime prevalence rate is estimated to be about 2.5 per cent (Robins and Regier, 1991; Bebbington, 1998).

Unlike people with panic disorder, people with obsessive-compulsive disorder have a defence against anxiety – their compulsive behaviour. Unfortunately, the need to perform this compulsive behaviour often becomes more and more demanding of their time until it interferes with their daily life. Obsessions are seen in many mental disorders, including schizophrenia. However, unlike persons with schizophrenia, people with obsessive-compulsive disorder recognise that their thoughts and behaviours are senseless and wish that they would go away. The types of obsession and compulsion seen in these individuals are summarised in Table 18.6.

Table 18.6 The number and percentage of obsessive and compulsive symptoms reported by 70 children and adolescents diagnosed with obsessive-compulsive disorder

	Reported symptom at initial interview	
	Number	%
Obsessions		
Concern with dirt, germs or environmental toxins	28	40
Something terrible happening (fire, death or illness of self or loved one)	17	24
Symmetry, order or exactness	12	17
Scrupulosity (religious obsessions)	9	13
Concern or disgust with bodily wastes or secretions (urine, stools, saliva)	6	8
Lucky or unlucky numbers	6	8
Forbidden, aggressive or perverse sexual thoughts, images or impulses	3	4
Fear might harm others or oneself	3	4
Concern with household items	2	3
Intrusive nonsense sounds, words or music	1	1
Compulsions		
Excessive or ritualised handwashing, showering, bathing, toothbrushing or grooming	60	85
Repeating rituals (going in or out of a door, up or down from a chair)	36	51
Checking (doors, locks, cooker, appliances, emergency brake on car, homework)	32	46
Rituals to remove contact with contaminants	16	23
Touching	14	20
Measures to prevent harm to self or others	11	16
Ordering or arranging	12	17
Counting	13	18
Hoarding or collecting rituals	8	11
Rituals of cleaning household or inanimate objects	4	6
Miscellaneous rituals (such as writing, moving, speaking)	18	26

Consider the case of Sergei, a 17-year-old ex-student:

Only a year ago, Sergei seemed to be a normal adolescent with many talents and interests. Then, almost overnight he was transformed into a lonely outsider, excluded from social life by his psychological disabilities. Specifically, he was unable to stop washing. Haunted by the notion that he was dirty – in spite of the contrary evidence of the senses – he began to spend more and more of his time cleansing himself of imaginary dirt. At first his ritual ablutions were confined to weekends and evenings and he was able to stay in school while keeping them up, but soon they began to consume all his time, forcing him to drop out of school, a victim of his inability to feel clean enough.

Source: Rapoport (1989) p. 63.

Women are slightly more likely than men to have this diagnosis. Like panic disorder, obsessive-compulsive disorder most commonly begins in young adulthood (Robbins *et al.*, 1984). People with this disorder are unlikely to marry, perhaps because of the common obsessional fear of dirt and contamination or because the shame associated with the rituals they are compelled to perform causes them to avoid social contact (Turner *et al.*, 1985).

There are two principal kinds of obsession: obsessive doubt or uncertainty, and obsessive fear of doing something prohibited (Salkovskis *et al.*, 1998). Uncertainties, both trivial and important, preoccupy some people with obsessive-compulsive disorder almost completely. Others are plagued with the fear that they will do something terrible – swear aloud in church, urinate in someone's living room, kill themselves or a loved one, or jump off a bridge – although they seldom actually do anything antisocial. And even though they are often obsessed with thoughts of killing themselves, fewer than 1 per cent of them actually attempt suicide.

Most compulsions fall into one of four categories: counting, checking, cleaning and avoidance. For example, people might repeatedly check burners on the stove to see that they are off and windows and doors to be sure that they are locked. Some people wash their hands hundreds of times a day, even when they become covered with painful sores. Other people meticulously clean their homes or endlessly wash, dry and fold their clothes. Some become afraid to leave home because they fear contamination and refuse to touch other members of their families. If they do accidentally become 'contaminated', they usually have lengthy purification rituals.

Aetiology

Several possible causes have been suggested for obsessive-compulsive disorder. Unlike simple anxiety states, this disorder can be understood in terms of defence mechanisms. Some cognitive investigators have suggested that obsessions serve as devices to occupy the mind and displace painful thoughts.

Cognitive researchers also point out that persons with obsessive-compulsive disorder believe that they should be competent at all times, avoid any kind of criticism at all costs, and worry about being punished by others for behaviour that is less than perfect (Sarason and Sarason, 1993). Thus, one reason people who have obsessive-compulsive disorder may engage in checking behaviour is to reduce the anxiety caused by fear of being perceived by others as incompetent or to avoid others' criticism that they have done something less than perfectly.

If painful, anxiety-producing thoughts become frequent, and if turning to alternative patterns of thought reduces anxiety, then the principle of reinforcement predicts that the person will turn to these patterns more frequently. Just as an animal learns to jump a hurdle to escape a painful foot shock, a person can learn to think about a 'safe topic' in order to avoid painful thoughts. If the habit becomes firmly established, the obsessive thoughts may persist even when the original reason for turning to them – the situation that produced the anxiety-arousing thoughts – no longer exists. A habit can thus outlast its original causes.

Family studies have found that obsessive-compulsive disorder is associated with a neurological disorder called **Gilles de la Tourette's syndrome**, which appears during childhood (Janowicz, 1993). Gilles de la Tourette's syndrome is characterised by muscular and vocal tics, including making facial grimaces, squatting, pacing, twirling, barking, sniffing, coughing, grunting or repeating specific words (especially vulgarities). It is not clear why some people with the faulty gene develop Gilles de la Tourette's syndrome early in childhood and others develop obsessive-compulsive disorder later in life.

Treatment

There are usually two forms of treatment employed in obsessive-compulsive disorder. The first is behavioural therapy in which the individual may be exposed to the object, situation or event that provokes the ritualistic behaviour (Emmelkamp, 1993). One example may be to deliberately dirty the hands of an individual who ritualistically washes their hands 20 or 30 times a day and not allow them to wash their hands (Rapoport, 1989). This type of therapy has met with some success in serious cases

of obsessive-compulsive disorder. However, behavioural treatment appears to be more successful at eliminating compulsive than obsessive behaviour (Emmelkamp, 1993). Drug treatment appears to eliminate both successfully. These drugs are two serotonin-specific reuptake inhibitors (described in more detail in the section on depression below) and act by increasing the amount of the neurotransmitter, serotonin, in the brain.

Somatoform disorders

The primary symptoms of **somatoform disorder** are a bodily or physical (*soma* means ‘body’) problem for which there is no physiological basis. The two most important somatoform disorders are somatisation disorder and conversion disorder.

Somatisation disorder

Description

Somatisation disorder occurs mostly among women and involves complaints of wide-ranging physical ailments for which there is no apparent biological basis (the complaints must include at least 13 symptoms from a list of 35, which fall into the following categories: gastrointestinal symptoms, pain symptoms, cardiopulmonary symptoms, pseudoneurological symptoms, sexual symptoms, and female reproductive symptoms). This disorder used to be called hysteria. The older term derives from the Greek word *hysteria*, meaning ‘uterus’, because of the ancient belief that various emotional and physical ailments in women could be caused by the uterus wandering around inside the body, searching for a baby.

It is true that somatisation disorder is seen almost exclusively in women; however, modern use of the term ‘hysteria’ does not imply any gynaecological problems. Moreover, this disorder is rare even among women: Regier *et al.* (1988) found that the incidence of somatisation disorder in a sample of over 18,000 people was less than 1 per cent in women and non-existent in men. Somatisation disorder is often chronic, lasting for decades.

Aetiology

Somatisation disorder is most common in poorly educated women of low socio-economic status (Guze *et al.*, 1971). The disorder also runs in families. Coryell (1980) found that approximately 20 per cent of first-degree female relatives of people with somatisation disorder also had the disorder. In addition, many studies have shown that somatisation disorder is closely associated with antisocial

personality disorder. First-degree male relatives of women with somatisation disorder have an increased incidence of alcoholism or antisocial behaviour, and first-degree female relatives of convicted male criminals have an increased incidence of somatisation disorder (Guze *et al.*, 1967; Woerner and Guze, 1968). These findings suggest that a particular environmental or genetic history leads to different pathological manifestations in men and women.

Conversion disorder

Description

Conversion disorder is characterised by physical complaints that resemble neurological disorders but have no underlying organic pathological basis. The symptoms include blindness, deafness, loss of feeling, and paralysis. According to the DSM-IV TR, a conversion disorder must have some apparent psychological reason for the symptoms; the symptoms must occur in response to an environmental stimulus that produces a psychological conflict, or they must permit the person to avoid an unpleasant activity or to receive support and sympathy. Unlike somatisation disorder, conversion disorder can afflict both men and women.

The term ‘conversion’, when applied to a mental disorder, derives from psychoanalytical theory, which states that the energy of an unresolved intrapsychic conflict is converted into a physical symptom. Hofling (1963, pp. 315–16) described one such case:

The patient had taken the day off from work to be at home with his wife and [newborn] baby. During the afternoon, he had felt somewhat nervous and tense, but had passed off these feelings as normal for a new father . . .

. . . The baby awoke and cried. Mrs L. said that she would nurse him . . . As she put the baby to her breast, the patient became aware of a smarting sensation in his eyes. He had been smoking heavily and attributed the irritation to the room’s being filled with smoke. He got up and opened a window. When the smarting sensation became worse he went to the washstand and applied a cold cloth to his eyes. On removing the cloth, he found that he was completely blind . . . Psychotherapy was instituted . . . The visual symptoms disappeared rather promptly, with only very mild and fleeting exacerbations during the next several months . . .

. . . He had been jealous of the baby – this was a difficult admission to make – and jealous on two distinct counts. One feeling was, in essence, a sexual jealousy, accentuated by his own sexual deprivation during the last weeks of the pregnancy. The other was . . . a jealousy of the maternal solicitude shown the infant by its mother.

Although the sensory deficits or paralyses of people with conversion disorders are not caused by damage to the nervous system, these people are not faking their illnesses. People who deliberately pretend they are sick in order to gain some advantage (such as avoiding work) are said to be malingering. Malingering is not defined as a mental disorder by the DSM-IV TR. Although it is not always easy to distinguish malingering from a conversion disorder, two criteria are useful. First, people with conversion disorders are usually delighted to talk about their symptoms in great detail, whereas malingerers are reluctant to do so for fear of having their deception discovered. Secondly, people with conversion disorders usually describe the symptoms with great drama and flair but do not appear to be upset about them.

Somatisation disorder consists of complaints of medical problems, but the examining physician is unable to see any signs that would indicate physical illness. In contrast, a patient with conversion disorder gives the appearance of having a neurological disorder such as blindness or paralysis. Psychophysiological disorders (also called psychosomatic disorders) are not the result of fictitious or imaginary symptoms; they are real, organic illnesses caused or made worse by psychological factors. For example, stress can cause gastric ulcers, asthma or other physical symptoms; ulcers caused by stress are real, not imaginary. Successful therapy would thus require reduction of the person's level of stress as well as surgical or medical treatment of the lesions in the stomach.

Aetiology

Psychoanalytical theory suggests that the psychic energy of unresolved conflicts (especially those involving sexual desires the patient is unwilling or unable to admit to having) becomes displaced into physical symptoms. In other words, psychoanalysts regard conversion disorders as primarily sexual in origin.

In contrast, behaviour analysts have suggested that conversion disorders can be learned for many reasons. This assertion gains support from the finding that people with these disorders usually suffer from physical symptoms of diseases with which they are already familiar (Ullman and Krasner, 1969). A patient often mimics the symptoms of a friend. Furthermore, the patient must receive some kind of reinforcement for having the disability: they must derive some benefit from it.

Treatment

Early treatment of somatoform disorders had concentrated on allowing the patient to explore past or previous traumas, although there was no evidence that this helped to treat the disorder. A method that seems to meet with

some success is behavioural therapy. This may be especially relevant to those experiencing pain or sickness. The treatment involves not rewarding those behaviours which reinforce expressions of illness and pain, and rewarding ways of adapting to life and coping with it.

Dissociative disorders

In somatoform disorders, anxiety is avoided by the appearance of the symptoms of serious physical disorders. In **dissociative disorders**, anxiety is reduced by a sudden disruption in consciousness, which in turn produces changes in one's sense of identity.

Description

Like conversion disorder, the term 'dissociative disorder' comes from Freud. According to psychoanalytical theory, a person develops a dissociative disorder when a massive repression fails to keep a strong sexual desire from consciousness. As a result, the person resorts to dissociating one part of their mind from the rest.

The most common dissociative disorder is **psychogenic amnesia**, in which a person 'forgets' all their past life, along with the conflicts that were present, and begins a new one. The term 'psychogenic' means 'produced by the mind'. Because amnesia can also be produced by physical means – such as epilepsy, drug or alcohol intoxication, and brain damage – clinicians must be careful to distinguish between amnesias of organic and psychogenic origin.

A **psychogenic fugue** is a special form of amnesia in which a person deliberately leaves home and starts a new life elsewhere (fugue means 'flight'). You read about this in the memory at the movies section in Chapter 8.

Dissociative identity disorder is a very rare, but very striking, dissociative disorder that is marked by the presence of two or more separate personalities within the individual, either of which may be dominant at any given time. Only about 100 cases of dissociative identity disorder have been documented, and some investigators believe that many, if not most of them, are simulations, not actual mental disorders.

An interesting example of dissociative identity disorder is the case of Billy Milligan as told in the book *The Minds of Billy Milligan* (Keyes, 1981). Milligan was accused of rape and kidnapping but was deemed not guilty by reason of insanity. His psychiatric examination showed him to have 24 different personalities. Two were women and one was a young girl. There was a Briton, an Australian and a Yugoslav. One woman, a lesbian, was a poet, while the Yugoslav was an expert on weapons and munitions, and the Briton and Australian were minor

criminals. Dissociative identity disorder has received much attention; people find it fascinating to contemplate several different personalities, most of whom are unaware of each other, existing within the same individual. Bliss (1980) suggests that dissociative identity disorder is a form of self-hypnosis, established early in life and motivated by painful experiences. In fact, the overwhelming majority of people diagnosed as having multiple personality disorder report having been physically abused when they were a child (Kluft, 1984).

Aetiology

Dissociative disorders are usually explained as responses to severe conflicts resulting from intolerable impulses or as responses to guilt stemming from an actual misdeed. Partly because they are rare, dissociative disorders are among the least understood of the mental disorders. In general, the dissociation is advantageous to the person. Amnesia enables the person to forget about a painful or unpleasant life. A person with fugue not only forgets but also leaves the area to start a new existence. And a dissociative identity disorder allows a person to do things that they would really like to do but cannot because of the strong guilt feelings that would ensue. The alternative personality can be one with a very weak conscience.

Treatment

Like early treatment for the somatoform disorders, early treatment for the dissociative disorders involved the patient recounting past and present traumas. It is assumed that the disorder arises from a failure to accept these traumas and the pain they caused. Acknowledging and expressing the trauma, therefore, is a means of accepting it and avoiding the need to dissociate (Oltmans and Emery, 1998). There is little evidence to suggest that the treatment is successful. Anti-anxiety drugs may also be prescribed to alleviate the patients' distress.

Personality disorders

The DSM-IV TR classifies abnormalities in behaviour that impair social or occupational functioning as **personality disorders**. There are several types of personality disorder which the DSM has grouped into three clusters. Cluster A, for example, refers to the 'eccentric cluster' of schizotypal and paranoid personality disorder; Cluster B (the dramatic cluster) includes the narcissistic and antisocial personality disorders; and Cluster C (the anxious cluster) includes avoidant and dependent personality disorders (Van

Velzen and Emmelkamp, 1996). Another general cluster accounts for other personality disorders not covered by these clusters. Because there are so many personality disorders, this chapter focuses on just one in depth: antisocial personality disorder. Table 18.7 provides a description of the several other personality disorders.

Antisocial personality disorder and psychopathy

Antisocial personality disorder refers to a failure to conform to standards of decency, repeated lying and stealing, a failure to sustain long-lasting and loving relationships, low tolerance of boredom and a complete lack of guilt. Prichard (1835) used the term 'moral insanity' to describe people whose intellect was normal but in whom the 'moral and active principles of the mind are strongly perverted and depraved . . . and the individual is found to be incapable . . . of conducting himself with decency and propriety'. Koch (1889) introduced the term 'psychopathic inferiority', which soon became simply psychopathy; a person who displayed the disorder was called a psychopath. The first edition of the DSM used the term 'sociopathic personality disturbance', which was subsequently replaced by the present term, 'antisocial personality disorder'. Most clinicians still refer to such people as psychopaths or sociopaths but this is probably incorrect. There is good evidence, for example, that antisocial personality disorder/sociopathy and psychopathy are different disorders; the former is characterised by antisocial behaviour, usually criminal, whereas the latter is characterised by these antisocial activities plus other, more emotive factors such as lack of empathy for others, remorselessness and manipulateness.

Description

People with antisocial personality disorder cause a considerable amount of distress in society. Many criminals can be diagnosed as psychopaths, and most psychopaths have a record of criminal behaviour. The offending psychopath commits more offences than the average criminal (Hare, 1981; Kosson *et al.*, 1990) and is significantly more violent. Hare and McPherson (1984) report that psychopaths are convicted of three-and-a-half times more violent crime than are non-psychopathic criminals. Because of data such as these, psychologists have made attempts to identify the chronic psychopathic offender early on in life. However, these studies have met with mixed success (Lynam, 1996; Raine *et al.*, 1996).

The diagnostic criteria of the DSM-IV TR include evidence of at least three types of antisocial behaviour before age 15 and at least four after age 18. The adult forms of antisocial behaviour include inability to sustain

Table 18.7 Descriptions of various personality disorders

Personality disorder	Description
Paranoid	Suspiciousness and extreme mistrust of others; enhanced perception of being under attack by others
Schizoid	Difficulty in social functioning – poor ability and little desire to become attached to others
Schizotypal	Unusual thought patterns and perceptions; poor communication and social skills
Histrionic	Attention-seeking; preoccupation with personal attractiveness; prone to anger when attempts at attracting attention fail
Narcissistic	Self-promoting; lack of empathy for others; attention-seeking; grandiosity
Borderline	Lack of impulse control; drastic mood swings; inappropriate anger; becomes bored easily and for prolonged periods; suicidal
Avoidant	Oversensitivity to rejection; little confidence in initiating or maintaining social relationships
Dependent	Uncomfortable being alone or in terminating relationships; places others' needs above one's own in order to preserve the relationship; indecisive
Obsessive-compulsive	Preoccupation with rules and order; tendency towards perfectionism; difficulty relaxing or enjoying life
Passive-aggressive	Negative attitudes; negativity is expressed through passive means; complaining, expressing envy and resentment towards others who are more fortunate
Depressive	Pervasive depressive cognitions and self-criticism; persistent unhappiness; feelings of guilt and inadequacy

Note: The anti social personality disorder, not listed here, is described in detail in the text.

Source: Adapted from Carson, R.C., et al., *Abnormal Psychology and Modern Life*, 10th edn. Published by Allyn & Bacon, Boston, MA. Copyright © 1996 by Pearson Education. By permission of the publisher.

consistent work behaviour; lack of ability to function as a responsible parent; repeated criminal activity, such as theft, pimping or prostitution; inability to maintain enduring attachment to a sexual partner; irritability and aggressiveness, including fights or assault; failure to honour financial obligations; impulsiveness and failure to plan ahead; habitual lying or use of aliases; and consistently reckless or drunken driving. In addition to meeting at least four of these criteria, the person must have displayed a 'pattern of continuous antisocial behaviour in which the rights of others are violated, with no intervening period of at least five years without antisocial behaviour'. The lifetime prevalence rate for antisocial personality disorder is estimated to be about 3.5 per cent (Robins and Regier, 1994), although estimates of prevalence reported in the DSM-IV TR are lower: about 3 per cent for men and less than 1 per cent for women.

Cleckley (1976) has listed 16 characteristics of antisocial personality disorder, seen in Table 18.8. Cleckley's list of features provides a good picture of what most psychopaths are like. They are unconcerned for other people's feelings and suffer no remorse or guilt if their actions hurt others. Although they may be superficially charming, they do not form real friendships; thus, they often become swindlers or confidence artists. Both male and female psychopaths are sexually promiscuous from an early age, but these encounters do not seem to mean much to them. Female psychopaths tend to marry early, to be unfaithful to their husbands, and soon become separated or divorced.

Not a typical psychopath.

Table 18.8 Cleckley's primary characteristics of antisocial personality disorder

- 1 Superficial charm and good 'intelligence'
- 2 Absence of delusions and other signs of irrational thinking
- 3 Absence of 'nervousness'
- 4 Unreliability
- 5 Untruthfulness and insincerity
- 6 Lack of remorse or shame
- 7 Inadequately motivated antisocial behaviour
- 8 Poor judgement and failure to learn by experience
- 9 Pathological egocentricity and incapacity for love
- 10 General poverty in major affective reactions
- 11 Specific loss of insight
- 12 Unresponsiveness in general interpersonal relations
- 13 Fantastic and uninviting behaviour
- 14 Suicide rarely carried out
- 15 Sex life impersonal, trivial and poorly integrated
- 16 Failure to follow any life plan

Source: Cleckley, H., *The Mask of Sanity*, pp. 337–8. St Louis: C.V. Mosby, 1976. Reprinted with permission.

They tend to marry other psychopaths, so their husbands' behaviour is often similar to their own. Psychopaths habitually tell lies, even when there is no apparent reason for doing so and even when the lie is likely to be discovered. They steal things they do not need or even appear to want. When confronted with evidence of having lied or cheated, psychopaths do not act ashamed or embarrassed and usually shrug the incident off as a joke.

Psychopaths do not easily learn from experience; they tend to continue committing behaviours that get them into trouble. They also do not appear to be driven to perform their antisocial behaviours; instead, they usually give the impression that they are acting on whims. When someone commits a heinous crime such as a brutal murder, normal people expect that the criminal had a reason for doing so. However, criminal psychopaths are typically unable to supply a reason more compelling than 'I just felt like it'. They do not show much excitement or enthusiasm about what they are doing and do not appear to derive much pleasure from life.

Aetiology

Cleckley (1976, p. 371) suggested that the psychopath's defect 'consists of an unawareness and a persistent lack of ability to become aware of what the most important experiences of life mean to others . . . The major emotional accompaniments are absent or so attenuated as to count for little.' Some investigators have hypothesised that this lack of involvement is caused by an unresponsive autonomic nervous system. If a person feels no anticipatory fear of punishment, they are perhaps more likely to commit acts that normal people would be afraid to commit. Similarly, if a person feels little or no emotional response to other people and to their joys and sorrows, they are unlikely to establish close relationships with them.

Many experiments have found that psychopaths do show less reactivity in situations involving punishment. For example, Hare (1965) demonstrated that psychopaths show fewer signs of anticipatory fear. All participants in Hare's study watched the numerals 1 through 12 appear in sequential order in the window of a device used to present visual stimuli. They were told that they would receive a very painful shock when the numeral 8 appeared. Psychopathic subjects showed much less anticipatory responsiveness than did normal control subjects or non-psychopathic criminals.

Psychopaths appear to be selectively aroused by some emotions. When viewing slides of facial expression of distress or threat, psychopaths are less responsive than a control group to the distress faces but are no different from controls when responding to the threatening faces (Blair *et al.*, 1997). Psychopaths also appear to respond differently to emotional words when these are presented to the left (analytical) or right (emotional) hemisphere. Psychopaths do not show the right-hemisphere advantage for recognising emotion (Day and Wong, 1996).

The quality of parenting is strongly related to the development of antisocial personality disorder. In particular, children whose parents ignore them or who leave them unsupervised for prolonged periods, often develop patterns of misconduct and delinquency (Lynam, 1996). When the parents do pay attention to their children, it tends to be in the form of harsh punishment or verbal abuse in response to their misdeeds. Thus, the children of these parents live in an environment that ranges from no attention at all to attention in the form of physical punishment and scoldings. In response, the children develop a pattern of behaviour that is characterised by increased aggression, distrust of others, concern only for themselves, and virtually no sense of right and wrong.

According to Hare (1996, p. 46), 'In some respects, it is as if psychopaths lack a central organiser to plan and keep track of what they think and say. The part of the brain that is more responsible than any other for monitoring,

organising and integrating sensory input and behaviour, is the frontal cortex. People with damage to the frontal cortex have also been shown to exhibit irregularities in autonomic nervous system functioning such as a lack of heart rate responsiveness and galvanic skin response in contexts that require an assessment of risk.

Over many years, Adrian Raine and colleagues in the US have published controversial data linking frontal lobe dysfunction with psychopathic behaviour and antisocial personality disorder. In general, psychopaths tend to show less activity or less volume in this area, a region known to mediate some aspects of emotional and social behaviour, as you saw in Chapter 13. In what they describe as a study showing the 'first evidence for a structural brain deficit in antisocial personality disorder' (APD), Raine *et al.* (2000) compared the brain volume of 21 community volunteers with the DSM-IV TR ratified APD, with control groups and found that prefrontal brain volume of the APD group was 11 per cent less than other groups. They also showed little autonomic response when undertaking the social stressor task – they had their behaviour videotaped as they talked about their faults.

These findings are consistent with evidence from brain-damaged individuals showing that frontal patients have social problems and are unresponsive to threatening or risky behaviour when this response is measured autonomically. Commenting on Raine's findings, Damasio (2000) cautions against drawing too bold a conclusion from the study: 'One must be careful not to fall in the phrenological trap set behind every new identification of a brain area with some putative role', he says; 'the normal or pathologic effects associated with that certain area can be properly understood only in the context of multicomponent neural systems.'

To date, neuroimaging studies have focused on 'unsuccessful' psychopaths, i.e. those who have been caught and jailed. It has been suggested that successful psychopaths – those who are not caught and jailed – are behaviourally very similar to their incarcerated counterparts but are physiologically different (Widom, 1978). Ishikawa *et al.* (2001) recruited people from temporary employment agencies and administered the Hare Psychopathy Checklist to determine the degree of psychopathy in the sample. On the basis of individuals' responses, those scoring in the top (most psychopathic) and bottom third were selected. The top third were divided into those who had been convicted of a crime and those who had not. Heart rate and electrodermal response were measured.

The researchers found that, when compared with the control group, the successful psychopaths showed heightened heart rate activity and performed better than the unsuccessful psychopaths at a test of frontal lobe function. The authors suggest that this reactivity reflects the successful psychopath's greater awareness of changes in the social environment – they are better than unsuccessful

psychopaths at assessing or making risky decisions; unsuccessful psychopaths show little autonomic nervous system (ANS) reaction to risk and it may be this lack of feedback from the ANS that leads to their slipping up.

Treatment

There is no standard, effective treatment for antisocial personality disorder or psychopathy and the treatments used have normally been designed for other purposes such as anger management or reducing deviant sexual behaviour (Oltmans and Emery, 1998). Whereas evidence suggests that there is some temporary effect on the behaviour, the effect does not generalise to other settings in the long term. One predictor of success, when it does happen, is a person's adherence to a treatment programme: the more successful complete the programme (Reid and Gacono, 2000).

Schizophrenic disorders

Schizophrenia, the most common psychosis, includes several types, each with a distinctive set of symptoms. There is some controversy over whether schizophrenia is a unitary disorder with various sub-types or whether each sub-type constitutes a distinct disorder. Because the prognosis differs for the various sub-types of schizophrenia, each would appear to differ at least in severity. An individual may, at different times, meet the criteria for different sub-types, although the diagnosis of schizophrenia seems valid and reliable (Mason *et al.*, 1997).

Description

Schizophrenia refers to a group of psychological disorders involving distortions of thought, perception and emotion, bizarre behaviour and social withdrawal. Around 8 to 40 cases per 1,000 are reported per year worldwide and the disorder appears to recognise no cultural or international boundaries. It is higher in urban areas and there is a lifetime risk of 0.7 per cent of developing the illness (and this is greater in men). It is highest in people of lowest socio-economic status, has its onset in adolescence or early adulthood, and genetic factors account for 80 per cent of the disorder's appearance (Tandon *et al.*, 2008a). Schizophrenia is probably the most serious of the mental disorders.

Descriptions of symptoms in ancient writings indicate that the disorder has been around for thousands of years (Jeste *et al.*, 1985). The word 'schizophrenia' literally means 'split mind', although it is commonly misinterpreted as 'split personality'. The schizophrenic does not suffer from split personality or multiple personality (those are other mental

disorders) but from disordered thought and affect. The man who invented the term, Eugen Bleuler (in 1911), intended it to refer to a break with reality caused by such disorganisation of the various functions of the mind that thoughts and feelings no longer worked together normally.

Many studies of people who become schizophrenics in adulthood have found that they were different from others even in childhood. One study obtained home movies of people with adult-onset schizophrenia that showed them and their siblings when they were children (Walker and Lewine, 1990). Although the schizophrenia did not manifest itself until adulthood, viewers of the films (six graduate students and one professional clinical psychologist) did an excellent job of identifying the children who were to become schizophrenic. The viewers commented on the children's poor eye contact, relative lack of responsiveness and positive affect, and generally poor motor coordination.

There are also degrees of cognitive impairment seen in schizophrenia. Verbal fluency – the ability to name as many objects beginning with a particular letter or belonging to the same category – appears to be impaired in schizophrenic individuals (Gruzelier *et al.*, 1988), although the category version of this test appears to be better performed (Joyce *et al.*, 1996). Semantic memory and performance on 'frontal lobe' tasks is also impaired in schizophrenic individuals (Shallice *et al.*, 1991; Tamlyn *et al.*, 1992).

The prognosis for schizophrenia is described by the 'law of thirds'. Approximately one-third of the people who are diagnosed as having it will require institutionalisation for the rest of their lives. About one-third show remission of symptoms and may be said to be cured of the disorder. The final third are occasionally symptom-free (sometimes for many years) only to have the symptoms return, requiring more treatment and perhaps even institutionalisation.

Schizophrenia is characterised by two categories of symptoms: positive and negative. **Positive symptoms** include thought disorders, hallucinations and delusions. A **thought disorder** – a pattern of disorganised, irrational thinking – is probably the most pronounced symptom of schizophrenia. People with schizophrenia have great difficulty arranging their thoughts logically and sorting out plausible conclusions from absurd ones. In conversation, they jump from one topic to another as new associations come up. Sometimes, they utter meaningless words or choose words for their rhyme rather than for their meaning. **Delusions** are beliefs that are obviously contrary to fact. **Delusions of persecution** are false beliefs that others are plotting and conspiring against oneself. **Delusions of grandeur** are false beliefs in one's power and importance, such as a conviction that one has god-like powers or has special knowledge that no one else possesses. **Delusions of control** are related to delusions of persecution; the person believes, for example, that they are being controlled by

others through such means as radar or tiny radio receivers implanted in their brain.

The third positive symptom of schizophrenia is **hallucinations**, which are perceptions of stimuli that are not actually present. The most common schizophrenic hallucinations are auditory, but such hallucinations can also involve any of the other senses. The typical schizophrenic hallucination consists of voices talking to the person. Sometimes, they order the person to act; sometimes, they scold the person for their unworthiness; sometimes, they just utter meaningless phrases. Sometimes, those with schizophrenia may also hear a voice that keeps a running commentary on their behaviour, or they hear two or more voices.

In contrast to the positive symptoms, the **negative symptoms** of schizophrenia are known by the absence of normal behaviours: flattened emotional response, poverty of speech, lack of initiative and persistence, inability to experience pleasure, and social withdrawal (Crow, 1980; Frith, 1987).

Types of schizophrenia

The DSM-IV TR identifies four types of schizophrenia: undifferentiated, catatonic, paranoid and disorganised. Most cases of schizophrenia, however, do not fit exactly into one of these categories. Many individuals are diagnosed with **undifferentiated schizophrenia**, that is, the patients have delusions, hallucinations and disorganised behaviour but do not meet the criteria for catatonic, paranoid or disorganised schizophrenia. In addition, some patients' symptoms change after an initial diagnosis, and their classification changes accordingly.

Catatonic schizophrenia (from the Greek *katateinein*, meaning 'to stretch or draw tight') is characterised by

various motor disturbances, including catatonic postures – bizarre, stationary poses maintained for many hours – and waxy flexibility, in which the person's limbs can be moulded into new positions, which are then maintained. Catatonic schizophrenics are often aware of all that goes on about them and will talk about what happened after the episode of catatonia subsides.

The pre-eminent symptoms of **paranoid schizophrenia** are delusions of persecution, grandeur or control. The word 'paranoid' has become so widely used in ordinary language that it has come to mean 'suspicious'. However, not all paranoid schizophrenics believe that they are being persecuted. Some believe that they hold special powers that can save the world or that they are Christ, or Napoleon or the president of the USA.

Paranoid schizophrenics are among the most intelligent of psychotic patients, so, not surprisingly, they often build up delusional structures incorporating a wealth of detail. Even the most trivial event is interpreted in terms of a grand scheme, whether it is a delusion of persecution or one of grandeur. The way a person walks, a particular facial expression or movement, or even the shapes of clouds can acquire special significance. An example of a case study of paranoid schizophrenia appears in the Psychology in Action section.

Disorganised schizophrenia is a serious progressive and irreversible disorder characterised primarily by disturbances of thought. People with disorganised schizophrenia often display signs of emotion, especially silly laughter, that are inappropriate to the circumstances. Also, their speech tends to be a jumble of words: 'I came to the hospital to play, gay, way, lay, day, bray, donkey, monkey' (Snyder, 1974, p. 132). This sort of speech is often referred to as a word salad.

Psychology in action – Treating paranoid schizophrenia

Bill McClary, a 25-year-old unemployed man, did not go to the therapist willingly. His sister Coleen, with whom he had been living for 18 months, suggested that Bill receive professional help for behaviour that had become increasingly unusual. He would spend most of his time in social isolation, daydreaming, talking to himself and saying things that did not make sense. Although most people engage in such behaviour at some time, Bill's was constant and this is what worried his sister.

On seeking professional help, Bill appeared quiet and hesitant. During therapy, he was friendly but shy and ill-at-ease. It was only later that his therapist learned of even stranger and unusual behaviour reported by Bill's brother Roger.

It transpired that Bill had had occasional but not long-lasting heterosexual and homosexual relationships. After moving

in with his sister, he became convinced that people were talking about him, especially about his sexuality. He came to believe that a group of conspirators had implanted microphones and cameras in the house to spy on his sexual encounters with men. These recordings were released as a film which Bill believed had grossed \$50 million at the box office; this money was used to fund the activity of the Irish Republican Army in Northern Ireland and he would often feel deeply guilty and responsible for the deaths there because his money was used to buy arms and ammunition.

Bill also heard voices discussing his sexual behaviour in unpleasant terms. Often, these discussions would involve an element of punishment, such as 'He's a faggot; we've got to kill him'. The successfully released film was called *Honour Thy*

Psychology in action – Continued

Father and Bill's name in the film was Gay Talese. Although Bill did not acknowledge the fact, this name actually belonged to a real novelist who wrote about organised crime. He maintained that his photograph had appeared on the cover of *Time* magazine in the previous year with the name Gay Talese printed clearly on it.

Bill was the youngest of four children born to Irish-American parents. He was very close to his mother and his father blamed him for the break-up of his marriage; he was often excluded from his father's activities. At the age of 12, Bill's father fell ill and Bill remembered wanting to see him dead. His school work was good and he eventually became a bank clerk – a stop-gap job while he thought of which career to pursue. He was quiet and polite but eccentric; he resigned after two years to become a lift operator, a job which afforded even more thinking time, but he was sacked after a year for being disorganised. He moved in with his mother shortly after this but because each made the other anxious, he moved out and moved in with his sister, her husband and their three children. It was at this point that Bill's unusual behaviour became noticeable.

Bill did not seem to enjoy life very much – he did not like interacting with others, was ambivalent about relationships and described sex in very impersonal terms. Initial therapy sessions targeted Bill's indifference and time-keeping and his sister was advised to ignore inappropriate behaviour. If he missed break-

fast, then he would not have a snack cooked for him at eleven, as had previously happened. This strategy and others like it resulted in Bill keeping time and domestic appointments. He enjoyed helping his niece with her homework and so this pleasant activity was encouraged. Eventually, his schedule approached those of the house and he began to help more with domestic chores. Mumbling and lack of social contact was tackled next. The therapist advised Bill to move to one area of the house whenever he felt the need to mumble and talk to himself. This was partly but not totally successful. His shyness with other people was tackled by asking Bill to rehearse mentally conversations that might occur with other people.

When the 'film fantasy' was made aware to the therapist, however, Bill was prescribed thioridazine, a standard antipsychotic medication. This was successful in reducing the self-talk but his delusions remained. To try and eliminate these delusions, Bill was told to visit a local library and find the cover of *Time* with his photograph on. This he did and obviously did not find such a cover. However, he believed that the covers had been switched by conspirators. He was told to go to two more libraries but he was still convinced that the covers had been switched. Over the next few weeks, he began to believe that he might just have imagined the *Time* incident and his delusions managed to recede a little.

Aetiology

Research into the causes of all kinds and forms of schizophrenia throughout this century and the last reflects the challenge that psychologists face in attempting to understand how psychological and biological factors interact to influence behaviour. The diathesis-stress model of mental disorders, discussed earlier in the chapter, appears to describe accurately the causes of schizophrenia: schizophrenia appears to result from one or more inherited, biological predispositions that are activated by environmental stress. In fact, this is currently the predominant view of schizophrenia.

Genetic causes

The heritability of schizophrenia, or more precisely the heritability of a tendency towards schizophrenia, has now been firmly established by both twin studies and adoption studies. Identical (monozygotic) twins are much more likely to be concordant for schizophrenia than are fraternal (dizygotic) twins, and the children of parents with schizophrenia are more likely

themselves to become schizophrenic, even if they were adopted and raised by non-schizophrenic parents (Kety *et al.*, 1968; Farmer *et al.*, 1987). Twin studies of schizophrenia compare the concordance rates of monozygotic twins with the concordance rates of siblings of different genetic relatedness who were reared either together or apart. The risk of one MZ twin developing the disorder if the other has it is between 50 and 70 per cent; in DZ twins, this is between 9 and 18 per cent. If both of a child's parents are affected, it has a 40–60 per cent of chance of developing the illness (Tanda *et al.*, 2008b).

If a person has been diagnosed with schizophrenia, there exists the possibility that other family members have the disorder, too. It is important to note that although the likelihood of developing schizophrenia increases if a person has schizophrenic relatives, this disorder is not a simple trait, like eye colour, that is inherited. Even if both parents are schizophrenic, the probability that their child will develop schizophrenia is 30 per cent or less.

Current findings provide strong evidence that schizophrenia is heritable, and they also support the conclusion that carrying a 'schizophrenia gene' does not mean that a person will necessarily become schizophrenic (see Figure 18.7).

These figures suggest that the environment may be an important trigger for the activation of the biological predisposition.

Several chromosomal regions have been identified as being involved in schizophrenia, around 20 (Lewis *et al.*, 2003), and the total number of genes linked with the disorder is 4,000, a quarter of all known genes (Keshavan *et al.*, 2008). The specific genes involved are likely to be *Sp21–22* and *22q 11–12*.

Neurochemical causes

Two classes of drug have been found to affect the symptoms of schizophrenia. Cocaine and amphetamine can cause symptoms of schizophrenia, both in schizophrenics and in non-schizophrenics; antipsychotic drugs, on the other hand, can reduce them. Because both types of drug affect neural communication in which dopamine serves as a transmitter substance, investigators have hypothesised that abnormal activity of these neurons is the primary cause of schizophrenia. That is, the **dopamine hypothesis** states that the positive symptoms of schizophrenia are produced by overactivity of synapses that use dopamine as a transmitter substance.

Amphetamine and related substances make naturally occurring schizophrenia worse: paranoids become more suspicious, disorganised schizophrenics become sillier, and catatonics become more rigid or hyperactive. Davis (1974) injected an amphetamine-like drug into schizophrenic patients whose symptoms had abated. Within one minute, each patient's condition changed 'from a mild schizophrenia into a wild and very florid schizophrenia'.

Chlorpromazine and other antipsychotic drugs are remarkably effective in alleviating the positive symptoms of schizophrenia but produce little consistent improvement in the negative symptoms. Hallucinations diminish or disappear, delusions become less striking or cease altogether, and the patient's thought processes become more coherent. These drugs are not merely tranquillisers; for example, they cause a patient with catatonic immobility to begin moving again as well as cause an excited patient to quieten down. In contrast, true tranquillisers such as

Librium or Valium only make a schizophrenic patient slow-moving and lethargic.

Amphetamine, cocaine and the antipsychotic drugs act on synapses – the junctions between nerve cells – in the brain. One neuron passes on excitatory or inhibitory messages to another by releasing a small amount of transmitter substance from its terminal button into the synaptic cleft. The chemical activates receptors on the surface of the receiving neuron, and the activated receptors either excite or inhibit the receiving neuron. Drugs such as amphetamine and cocaine cause the stimulation of receptors for dopamine. In contrast, antipsychotic drugs block dopamine receptors and prevent them from becoming stimulated. The focus of the drugs appears to be the D2 receptor in the striatum: around 70 per cent of these receptors are occupied by antipsychotic medication which blocks their action (Lidow *et al.*, 1998). Cocaine, conversely, activates this receptor.

Neurological causes

Ventricular enlargement/tissue loss

Weinberger and Wyatt (1982) found that the ventricles in the brains of schizophrenic patients were, on average, twice as large as those of normal subjects. This enlargement has been confirmed in 50 studies (Lewis, 1990); MRI studies further indicate that the medial temporal lobes may be affected (Chua and McKenna, 1995), although there appears to be a reduction in whole-brain size together with an increase in the occipital areas of the ventricles (Lawrie and Abukmeil, 1998). The most consistent finding is a reduction in the lateral or third ventricle (Tanda *et al.*, 2008a; Keshavan *et al.*, 2008).

There is a loss of total brain volume as well as reduced grey matter in the temporal lobe, the prefrontal cortex and the thalamus (Keshavan *et al.*, 2008). The caudate nucleus is larger in those who respond to treatment (Keshavan *et al.*, 2008). Loss of brain tissue, as assessed by CT scans, appears to be related to negative symptoms of schizophrenia but not to positive ones (Johnstone *et al.*, 1978). In

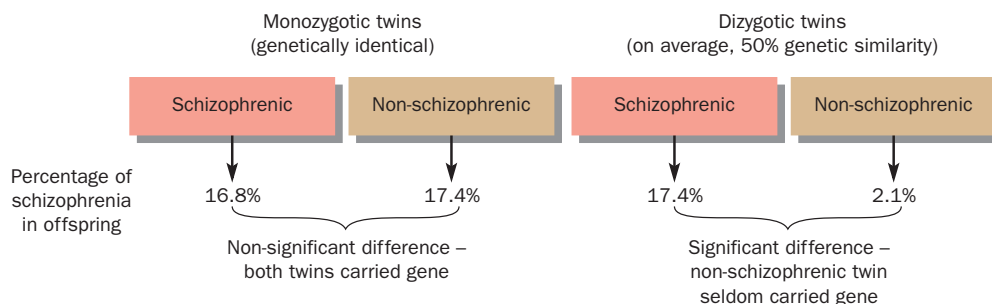

Figure 18.7 Heritability of schizophrenia. An explanation for evidence that people can have an unexpressed 'schizophrenia gene'.

addition, patients with loss of brain tissue respond poorly to antipsychotic drugs (Weinberger *et al.*, 1980). These studies suggest that positive and negative symptoms of schizophrenia have different causes: positive symptoms are a result of overactivity of dopamine synapses, whereas negative symptoms are produced by actual loss of brain tissue.

The prefrontal cortex

Metabolism in the prefrontal cortex is reduced in schizophrenia, a condition called hypofrontality (Kindermann *et al.*, 1997; Pae *et al.*, 2004) and which appears regardless of the patient's drug-taking status (Andreasen *et al.*, 1997).

PET studies of schizophrenic patients suggest that there is a decrease in dopamine receptors in the prefrontal cortex (Okubo *et al.*, 1997) and a decrease of N-acetyl aspartate in the frontal and temporal lobe (Keshavan *et al.*, 2008). There is also evidence that the neuronal density in the prefrontal cortex is 17 per cent higher compared with patients with Huntington's chorea and patients with schizophrenia-related disorders (Selemon *et al.*, 1995). These researchers suggested that this 'squashing' of neurons results from abnormal brain development and may account for the frontal lobe deficits. Keefe *et al.* (1995) found that schizophrenic patients performed poorly at keeping information in working memory over 30-second and 60-second delay periods, a frontal lobe function. Executive function and episodic memory performance, in general, is poor (Reichenberg and Harvey, 2007). These abnormalities are milder in the relatives of schizophrenic patients (Reichenberg and Harvey, 2007).

Crow (1998, 2002) has controversially suggested that a deficit in the functional lateralisation of the brain, especially the lateralisation of language, may be the cause of schizophrenia, although the evidence for this is mixed. A recent study found a significant reduction in the superior (top) part of the left temporal lobe in schizophrenic patients as well as a general reduction in the size of the temporal lobe, although this last finding was not statistically significant (Highley *et al.*, 1999). The researchers also found a relationship between this asymmetrical reduction and the time of onset of the disorder: the later the onset, the greater the reduction. Another study, this time of frontal lobe asymmetry, found that the planum temporale and Sylvian fissure were less lateralised in schizophrenic patients (Sommer *et al.*, 2001). As you saw in Chapter 10, asymmetry of these structures is associated with language processing.

Finally, Gray and colleagues have proposed that schizophrenia may be the result of abnormal connections between the limbic forebrain (especially the hippocampal formation) and the basal ganglia, the region of the brain implicated in the regulation of movement (Gray *et al.*, 1991; Gray, 1995). These neuroanatomical abnormalities correspond to increases in dopamine in a part of the basal

ganglia called the nucleus accumbens. A disruption in these connections means that steps in a motor programme are not confirmed by the brain, leading to the expected outcome of each step being perceived as novel or unexpected.

Neurodevelopmental impairment

Various neurodevelopmental factors have been implicated in schizophrenia from cannabis use to obstetric complications (Keshavan *et al.*, 2008). Another possible neurological cause of schizophrenia is interference with normal prenatal brain development (Weinberger, 1996; Hultman *et al.*, 1997). Several studies have shown that people born during the winter months are more likely to develop schizophrenia later in life. Torrey *et al.* (1977) suggest that the causal factor could be seasonal variations in nutritional factors, or, more likely, variations in toxins or infectious agents in air, water or food. Several diseases known to be caused by viruses, such as measles, German measles and chicken pox, show a similar seasonality effect. The seasonality effect is seen most strongly in poor, urban locations, where people are at greater risk of viral infections (Machon *et al.*, 1983).

A seasonally related virus could affect either a pregnant woman or her newborn infant. Two pieces of evidence suggest that the damage is done prenatally. First, brain development is more susceptible to disruption prenatally than post-natally. Secondly, a study of the offspring of women who were pregnant during an epidemic of type A2 influenza in Finland occurring in 1957 showed an elevated incidence of schizophrenia (Mednick *et al.*, 1990). The increased incidence was seen only in the children of women who were in the second term of their pregnancy when the epidemic occurred. Presumably, the viral infection produced toxins that interfered with the brain development of some of the foetuses, resulting in the development of schizophrenia later in life. Weinberger (1996) has explicitly stated the neurodevelopmental hypothesis as follows: 'Schizophrenia is related to a defect in brain development. This defect predisposes to a characteristic pattern of brain malfunction in early adult life and to symptoms that respond to antidopaminergic drugs.' In a review of the evidence to suggest that this malfunction does occur and does have the consequences the hypothesis states, he suggests that the hypothesis is broadly supported although it has provoked more questions than answers.

Related to the viral hypotheses of schizophrenia are obstetric complications. Complications at birth have been associated with later development of schizophrenia (Hultman *et al.*, 1999) and infants who experience these complications are twice as likely to develop schizophrenia than is a control group (Geddes and Lawrie, 1995). Hultman *et al.*'s Swedish study of birth records of schizophrenic and control group infants report the same

pattern: increased risk of schizophrenia is associated with complications during pregnancy and birth, especially in boys (Hultman *et al.*, 1997). Why these complications should be a risk factor, however, is unclear.

Cognitive and environmental causes

Family and expressed emotion

A study carried out in Finland has suggested that being raised by a 'mentally healthy' family helps to protect against the development of schizophrenia (Tienari *et al.*, 1987). The researchers examined the children of schizophrenic mothers who had been adopted away early in life. Following interviews and psychological tests, the families who adopted the children were classified as well-adjusted, moderately maladjusted or severely maladjusted. The children adopted by the well-adjusted families were least likely to show signs of mental disturbance, including schizophrenia. These findings suggest that the environment may be either an important cause or mediator of schizophrenia.

The personality and communicative abilities of either or both parents appear to play an influential role in the development of schizophrenic symptoms in children. Several studies have shown that children raised by parents who are dominating, overprotective, rigid and insensitive to the needs of others later develop schizophrenia (Roff and Knight, 1981). In many cases, a parent may be verbally accepting of the child yet in other ways reject them, which establishes a conflict for the child called a **double-bind**. For example, a mother may encourage her son to become emotionally dependent on her yet continually reject him when he tries to hug her or sit on her lap.

Schizophrenia also seems to occur at a higher than average rate among children who were reared in families characterised by verbal violence and disharmony. In a study of 14 schizophrenic individuals, Lidz *et al.* (1965) found that each of these individuals had a family that underwent either chronic discord in which the integrity of the parents' marriage was perpetually threatened, or marital problems in which the bizarre behaviour of one family member was tolerated by the other members. Children in families in which parents treat them with hostility or in which parents present confusing communication to them are at risk of developing schizophrenia. However, it is unclear whether marital discord, family hostility, and confusing communications are a cause or an effect of children's schizophrenia.

Another environmental factor which could account for the development of schizophrenia is **expressed emotion** or EE (Hooley *et al.*, 1996). Brown *et al.* (1966; Brown, 1985) identified a category of behaviours of families of individuals recovering from schizophrenia that seemed to be related to the patients' rates of recovery. They labelled

this variable expressed emotion, which consists of expressions of criticism, hostility and emotional over-involvement by the family members towards the patient. Patients living in a family environment in which the level of expressed emotion was low were more likely to recover, whereas those in families in which it was high were likely to continue to exhibit schizophrenic symptoms. The finding that low EE is associated with better outcome has since been replicated (Strachan *et al.*, 1989). Perceived criticism also appears to be important: in depressed patients, perceived criticism predicted a relapse in the mental disorder more reliably than did actual criticism (Hooley and Teasdale, 1989); mood disorder patients with high-EE families appear to be more non-verbally negative than patients from low-EE families (Simoneau *et al.*, 1998).

Jenkins and Karno (1992) report that in the past decade over 100 studies have investigated expressed emotion in countries ranging from North America, England, Denmark, and Italy to France, Spain, Germany, Taiwan, India, Egypt and Australia. Despite differences in the ways that people of different cultures perceive mental illness and express themselves, expressed emotion does not seem to be culture-bound. Two elements appear to be common to all cultures: critical comments and emotional over-involvement. If these elements are present in families of schizophrenics at low levels, patients are likely to recover quickly; if they are present at high levels, patients are less likely to recover quickly.

Jenkins and Karno also found that expressed emotion tends to be higher in industrialised cultures than in non-industrialised cultures. In other words, people in non-industrialised countries are more supportive of family members with schizophrenia than are people in industrialised countries. The reasons for this difference are many and appear to focus on the role that individuals play in the two environments.

Treatment

The commonest form of treatment for schizophrenia is psychopharmacological. The only effective means of treating the disorder is by D2 antagonists. These **antipsychotic drugs** help to reduce the effects of schizophrenia apparently by blocking dopamine receptors in the brain. Presumably, overactivity of dopamine synapses is responsible for the positive symptoms of schizophrenia, which is why treatment is effective at combating the positive symptoms but has limited success in combating the negative symptoms (Keshavan *et al.*, 2008). Although dopamine-secreting neurons are located in several parts of the brain, most researchers believe that the ones involved in the symptoms of schizophrenia are located in the cerebral cortex and parts of the limbic system near the front of the brain. There is evidence that the education of the

family/patient about the disorder reduces the likelihood of a relapse and that social skills training also improves outcome (Keshavan *et al.*, 2008).

A different system of dopamine-secreting neurons in the brain is involved in the control of movement. Occasionally, this system of neurons degenerates in older people, producing Parkinson's disease. Symptoms of this disorder include tremors, muscular rigidity, loss of balance, difficulty in initiating movement, and impaired breathing that makes speech indistinct. In severe cases the person is bedridden.

The major problem with antipsychotic drugs is that they do not discriminate between these two systems of dopamine-secreting neurons. The drugs interfere with the activity of both the circuits involved in the symptoms of schizophrenia and the circuits involved in the control of movements. Consequently, when a person with schizophrenia begins taking an antipsychotic drug, they often exhibit a movement disorder. Fortunately, the disorder is usually temporary and soon disappears.

However, after taking the antipsychotic drug for several years, some people develop a different, more serious, movement disorder known as **tardive dyskinesia** (tardive means late developing; dyskinesia refers to a disturbance in movement), an often irreversible and untreatable syndrome characterised by continual involuntary lip smacking, grimacing and drooling (Cummings and Wirshing, 1989). Severely affected people have difficulty talking, and occasionally the movements interfere with breathing. The risk of developing this syndrome increases with age, dose and duration of use (Hughes and Pierattini, 1992). For example, approximately 20 per cent of older people develop tardive dyskinesia. The symptoms can be alleviated temporarily by increasing the dose of the antipsychotic drug, but doing so only serves to increase and perpetuate the person's dependence on the medication (Baldessarini and Tarsy, 1980).

Clozapine, an anti-schizophrenic drug, is more effective than other antipsychotic drugs in helping cases of almost untreatable schizophrenia (Kane *et al.*, 1988). It improves the symptoms of about 30–50 per cent of those people who have not responded to traditional antipsychotic drugs. Because about 2 per cent of those taking clozapine suffer an inhibition of white blood cell production, which can be fatal, weekly blood tests have to be conducted. People with schizophrenia have not yet received clozapine for a long enough time for researchers to be sure that the drug will not eventually produce tardive dyskinesia.

Mood disorders

Everyone experiences moods varying from sadness to happiness to elation. We are excited when our team wins a game, saddened to learn

Stephen Fry, who has publicly discussed his bipolar disorder.

that a friend's father has had a heart attack, thrilled at news of a higher than expected grade in an exam, and devastated by the death of a loved one. Some people, though, experience more dramatic mood changes than these. Significant shifts or disturbances in mood that affect normal perception, thought and behaviour are called mood disorders. They may be characterised by a deep, foreboding depression or by a combination of depression and euphoria.

Mood disorders are primarily disorders of emotion. The most severe mood disorders are bipolar disorder and major depression. **Bipolar disorder** is characterised by alternating periods of mania (wild excitement) and depression. **Major depression** involves persistent and severe feelings of sadness and worthlessness accompanied by changes in appetite, sleeping and behaviour. The life-time prevalence rates for major depression are about 13 per cent for males and about 21 per cent for females (Kessler *et al.*, 1994a).

A less severe form of depression is called **dysthymic disorder**. The term comes from the Greek words *dus*, 'bad' and *thymos*, 'spirit'. The primary difference between this disorder and major depression is its relatively low severity. Similarly, **cyclothymic disorder** resembles bipolar disorder but is much less severe.

Mania

Mania (the Greek word for madness) is characterised by wild, exuberant, unrealistic activity unprecipitated by environmental events. During manic episodes, people are usually elated and self-confident; however, contradiction or interference tends to make them very angry. Their speech (and, presumably, their thought processes) becomes very rapid. They tend to flit from topic to topic and are full of

Author, creativity researcher and manic-depressive, Kay Jamison
Source: Getty Images

grandiose plans, but their thoughts are not as disorganised as those of people with schizophrenia. Manic patients also tend to be restless and hyperactive, often pacing around ceaselessly. They often have delusions and hallucinations, typically of a nature that fits their exuberant mood. Impairments in 'frontal lobe' function such as set-shifting, verbal memory and sustained attention have been reported (Clark *et al.*, 2002), and the experience of the disorder has been related to an oversensitive frontal cortex (Harmon-Jones *et al.*, 2002).

The usual response that manic speech and behaviour evokes in another person is one of sympathetic amusement. In fact, when an experienced clinician starts to become amused by a patient, the clinician begins to suspect the presence of mania. Because very few patients exhibit only mania, the DSM-IV TR classifies all cases in which mania occurs as bipolar disorder. Patients with bipolar disorder usually experience alternate periods of mania and depression. Each of these periods lasts from a few days to a few weeks, usually with several days of relatively normal behaviour between. Around 40 per cent of bipolar disorder patients will have been diagnosed with major depression previously (Bowden, 2001). Even according to DSM-IV TR, 'the specific diagnostic categories are meant to serve as guidelines to be informed by clinical judgement and are not meant to be used in a cookbook fashion'. Many therapists have observed that there is often something brittle and unnatural about the happiness during the manic phase, as though the patient

is making themselves be happy to ward off an attack of depression. Indeed, some manic patients are simply hyperactive and irritable rather than euphoric.

Depression

Description

It was the worst experience of my life. More terrible even than watching my wife die of cancer. I am ashamed to admit that my depression felt worse than her death but it's true. I was in a state that bears no resemblance to anything I had experienced before. I was not just feeling very low. I was seriously ill. I was totally self-involved, negative and thought about suicide most of the time. I could not think properly let alone work, and wanted to remain curled up in bed all day.

These were the opening words of Professor Lewis Wolpert, Professor of Developmental Biology at University College London in his book, *Malignant Sadness*. Depressed people are extremely sad and are usually full of self-directed guilt, but not because of any particular environmental event. Depressed people cannot always state why they are depressed. Around 17 per cent of people will experience a major episode of depression at some point in their lives (Kessler *et al.*, 1994b) and a similar percentage experiences disability at work due to the illness (Goldberg and Steury, 2001). Beck (1967) identified five cardinal symptoms of depression: (1) a sad and apathetic mood; (2) feelings of worthlessness and hopelessness; (3) a desire to withdraw from other people; (4) sleeplessness and loss of appetite and sexual desire; and (5) change in activity level, to either lethargy or agitation. Major depression must be distinguished from grief, such as that caused by the death of a loved one. People who are grieving feel sad and depressed but do not fear losing their minds or have thoughts of self-harm. Because many people who do suffer from major depression or the depressed phase of bipolar disorder commit suicide, these disorders are potentially fatal. The fatality rate by suicide for major depression is estimated at 15 per cent (Guze and Robins, 1970). According to Elizabeth Wurtzel, author of *Prozac Nation*:

one day, you realise that your entire life is just awful, not worth living, a horror and a black blot on the white terrain of human existence. One morning, you wake up afraid you are going to live . . . for all intents and purposes, the deeply depressed are just the walking, waking dead.

Depression knows no social or intellectual barriers. Lewis Wolpert, Professor of Developmental Biology, Winston Churchill, British Prime Minister (both pictured here) and the late Stuart Sutherland, Professor of Psychology, have all suffered from major depression or bipolar disorder.

Sources: Courtesy Lewis Wolpert, Press Association Images.

The ‘walking, waking dead’, according to the World Health Organization (2002b), account for 4.4 per cent of the world’s disease burden, a percentage similar to that for ischaemic heart disease and asthma and pulmonary disease combined. According to one study, depressive disorders are likely to be the second most common diseases by the year 2020 (Brown, 2001). Successful treatment, therefore, is vital. Interventions can reduce the burden of depression by as much as 10–30 per cent (Chisholm *et al.*, 2004).

The UK Office for National Statistics estimates that 2.6 million people suffered depression in England in 2000 (Thomas and Morris, 2003), 72 per cent of whom were girls/women and 20 per cent of whom were aged between 35 and 44 years. The direct cost to the National Health Service was estimated at almost £370 million. The total cost, which includes economic costs such as days taken off work and disability benefit, was estimated to be £9 billion. The cost of treatment, therefore, was a drop in the ocean compared to the other costs involved. Some 109.7 million working days were lost through depression and 2,615 deaths resulted from the disorder.

A Canadian study of 1,281 employees who had claimed depression-related absences from work found that 60 per cent who claimed disability benefit took antidepressants. Those who took the recommended drugs and at the right

dosage were less likely to claim long-term disability benefits or to leave work completely. The researchers estimated that early intervention would reduce the appearance of depression by three weeks, representing a financial saving of \$3,500 per person. If early intervention had occurred in people who started taking the drugs 30 days after the start of the first episode of depression, savings of around \$539,000 could have been made.

Of course, perhaps more important than the financial cost is the human, psychological cost. As Thomas and Morris (2003) conclude (p. 518), ‘the intangible elements of pain and suffering of people with depressive disorders and their families and the effects on quality of life cannot be quantified in monetary terms’.

Aetiology

Cognitive causes

People with mood disorders do not have the same outlook on life as others. Specifically, they make negative statements about themselves and their abilities: ‘Nobody likes me’, ‘I’m not good at anything’, ‘What’s the point in even trying, I’ll just mess it up anyway’. Because they are so negative about themselves, depressed people are particularly unpleasant to be around. The problem is that the

depressed individual is caught in a vicious circle: negative statements strain interpersonal relationships, which result in others withdrawing or failing to initiate social support, which, in turn, reinforces the depressed individual's negative statements (Klerman and Weissman, 1986).

Beck (1967, 1991) suggested that the changes in affect seen in depression are not primary but instead are secondary to changes in cognition. That is, the primary disturbance is a distortion in the person's view of reality. For example, a depressed person may see a scratch on the surface of their car and conclude that the car is ruined; or a person whose recipe fails may see the unappetising dish as proof of their unworthiness; or a nasty letter from a creditor is seen as a serious and personal condemnation. According to Beck, depressed people's thinking is characterised by self-blame (things that go wrong are always their fault), overemphasis on the negative aspects of life (small problems are blown out of proportion), and failure to appreciate positive experiences (pessimism). This kind of pessimistic thinking involves negative thoughts about the self, about the present and about the future, which Beck collectively referred to as the **cognitive triad**. In short, depressed people blame their present miserable situation on their inadequacies and a lack of hope for improving the situation in the future.

The negative view of the self and events, however, seems to be time-specific. Depressed individuals who are asked to describe themselves 'right now' use negative terms, but use less negative terms when they describe how they usually feel (Brewin *et al.*, 1992). Depressed patients are also likely to be negative when discussing things globally but not when discussing specific issues (Wycherley, 1995).

Beck's original model argued that cognition caused the emotional disorder, but his later reformulation of the theory suggested that cognition is part of a set of interacting mechanisms that include biological, psychological and social factors (Kovacs and Beck, 1978). In the reformulation, Beck argued that people might be predisposed to develop depression under certain circumstances. He called this a diathesis-stress theory. Central to the theory is that there is a set of schema – a stored collection of knowledge that affects encoding and understanding of all other processed information – which, when activated, sets off a series of negative thoughts and experiences. If the schema is depressogenic – characterised by depressive features – then an event which might activate these schemata leads to the person processing information very negatively. However, if a person is not exposed to these triggers, they will think or behave no more depressively than a person who does not possess depressogenic schemata. A study of undergraduates found that students with dysfunctional attitudes – those who were identified as having depressogenic schemata – felt more depressed after learning they had been refused a place at a univer-

sity of their choice than when learning that they had, a pattern not seen in students whose attitudes were not dysfunctional (Abela and D'Allessandro, 2002).

Beck also distinguished between two types of depression: sociotropic depression in which the abnormal belief derived from a dependence on others, and autonomous depression in which the individual was goal-oriented and relied little on others. The evidence for these two types as distinct varieties of depression, however, is mixed (Power and Dalgleish, 1997).

Another causal factor in depression appears to involve the attributional style of the depressed person (Abramson *et al.*, 1978, 1989). According to this idea, it is not merely experiencing negative events that causes people to become depressed: what is more important are the attributions people make about why those events occur. People who are most likely to become depressed are those who attribute negative events and experiences to their own shortcomings and who believe that their life situations are never going to get any better. A person's attributional style, then, serves as a predisposition or diathesis for depression. In other words, people prone to depression tend to have a hopeless outlook on their life: 'I am not good at anything I try to do and it will never get any better. I am always going to be a useless person.' According to this view, depression is most likely when people with pessimistic attributional styles encounter significant or frequent life stressors (Abramson *et al.*, 1989). The pessimistic attributions are then generalised to other, perhaps smaller, stressors, and eventually a deep sense of hopelessness and despair sets in. Thus, the original formulation of the theory was called the helplessness theory whereas the later reformulation became known as the hopelessness theory.

Such people also appear to suffer a double dose of hopelessness. Not only do they perceive negative outcomes as being their own fault, but they also perceive positive outcomes as being due to circumstance or to luck. In addition, they apply pessimistic attributions to a wide range of events and experiences and apply positive attributions only to a very narrow range of events and experiences, if any.

However, there is mixed evidence for a strong version of the hopelessness attribution theory. Swendsen (1998) reported that attributional style did not predict immediate depressed or anxious mood in a group of 91 individuals who were asked to report negative events, cognitions, anxiety and depression five times a day for one week. However, attributional style did predict 'individual' specific causal attributions made to negative events. Similar findings have been reported in other studies (Kapci, 1998). Lynd-Stevenson (1996, 1997) reports that hopelessness does not mediate the relationship between attributional style and depression but that there is a mediating effect

when measures of hopelessness are relevant to the individual's ongoing life (in Lynd-Stevenson's sample's case, hopelessness related to unemployment). Attributional style, therefore, seems to apply only in certain, relevant contexts.

Genetic causes

Like schizophrenia, the mood disorders appear to have a genetic component. People who have first-degree relatives with a serious mood disorder are ten times more likely to develop these disorders than are people without afflicted relatives (Rosenthal, 1970). Furthermore, the concordance rate for bipolar disorder is 72 per cent for monozygotic twins, compared with 14 per cent for dizygotic twins. For major depression, the figures are 40 per cent and 11 per cent, respectively (Allen, 1976). Thus, bipolar disorder appears to be more heritable than major depression, and the two disorders appear to have different genetic causes. Recent studies, however, have cast doubt on the heritability of major depressive disorder (Andrew *et al.*, 1998).

Neurochemical causes

Drug treatments for depression (which are described in detail below) have shed some light on the biochemical causes of schizophrenia. Antidepressants such as imipramine, for example, stimulate synapses that use two transmitter substances, norepinephrine and serotonin. Other drugs such as reserpine, which is used to treat high blood pressure, can cause episodes of depression. Reserpine lowers blood pressure by blocking the release of norepinephrine in muscles in the walls of blood vessels, thus causing the muscles to relax. However, because the drug also blocks the release of norepinephrine and serotonin in the brain, a common side-effect is depression. This side-effect strengthens the argument that biochemical factors in the brain play an important role in depression.

Such data have suggested a biological amine theory of depression: depression results from a depletion in the monoamines, dopamine, norepinephrine or serotonin. The serotonin hypothesis is a variant of this general theory. The serotonin hypothesis suggests that this neurotransmitter (the lack of it) may be more involved in depression because blocking reuptake of serotonin is more effective than blocking norepinephrine. Given that most antidepressants augment serotonin (perhaps by different mechanisms), perhaps the involvement of other neurotransmitters is peripheral.

In addition to the amines, levels of the neurotransmitter Gamma amino butyric acid (GABA) have been found to be lower in the cerebrospinal fluid and plasma of individuals with unipolar depression (Brambila *et al.*, 2003). When depressed individuals are given drugs which increase the level of serotonin at serotonergic neurons or are given

ECT, the decrease in GABA concentration seen in the occipital cortex is reversed (Sanacora *et al.*, 2002, 2004). The roles of the two classes of GABA (the a and b classes) in depression, however, is unclear.

Neuropathological causes

In a neuroimaging study, activity in the prefrontal cortex near the top of the corpus callosum was reduced in individuals with unipolar and bipolar depression (Drevets *et al.*, 1997). This part of the prefrontal cortex is called the anterior cingulate cortex and a specific region within the cingulate – which has been called subgenual region sg24 – is less active in people with mood disorder, as Figure 18.8 shows.

Drevets *et al.* found that the volume of this region was lateralised to the left hemisphere, which is consistent with

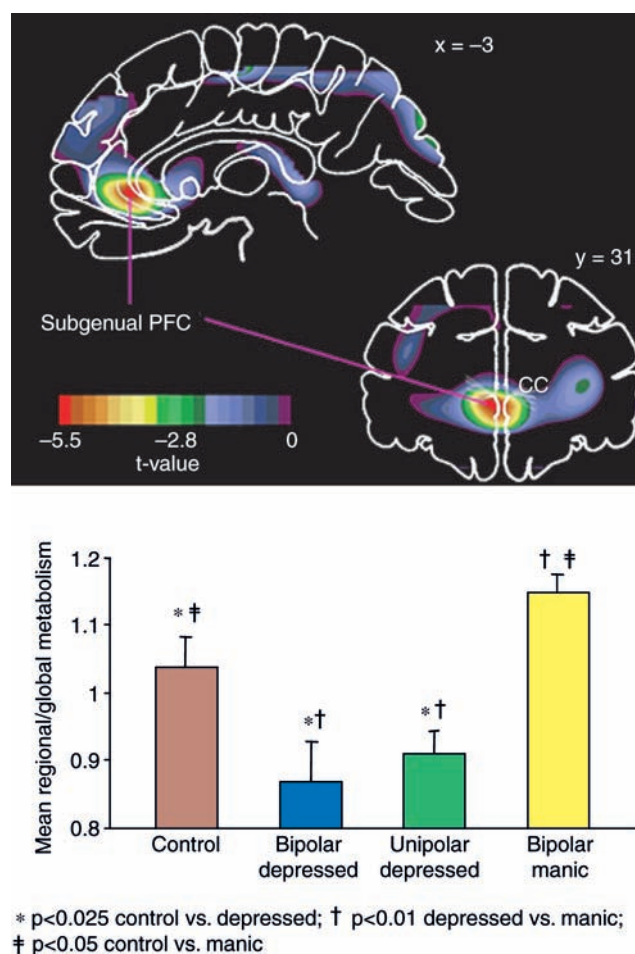

Figure 18.8 Decreases in activation in the prefrontal cortex seen in individuals with mood disorders.

Source: Drevets, W.C., Neuroimaging and neuropathological studies of depression: Implications for the cognitive-emotional features of mood disorders. *Current Opinion in Neurobiology*, 2001, 11, 240–49. Copyright 2001, with permission from Elsevier.

the data and model of normal emotion described in Chapter 13. These findings were subsequently replicated in a group of people with severe mood disorder (Hirayasu *et al.*, 1999).

When Drevets and his colleagues went on to explore the cellular nature of this region in people with mood disorder, they found the typical reduction in sg24 but also a reduction in the density of cells and in the number of glial cells (see Ongur *et al.*, 1998). A further study, using a larger sample, found that same pattern of cell reduction in a group of individuals with major and bipolar depression but only in a subset with a family history of the disorder (Torrey *et al.*, 2000). These cells carry neurotransmitter receptors and help to transport neurotransmitters, which may explain why their reduction is associated with depression; the reduction might also explain why this area is seen as smaller in people with depression and bipolar depression.

Studies have also implicated a dysfunction in the functioning of the hypothalamus (Bao *et al.*, 2008; Swaab and Bar 2005). For example, cortisol levels (the glucocorticoid you read about in the stress section of Chapter 17) are thought to be worse in the morning than in the afternoon (and depressed people are at their worst in the morning). Levels of cortisol are higher in depressed individuals than controls and an increase in the number of neurons in the hypothalamus that release corticotrophin-releasing hormone

is found in these patients; the levels of CRH in cerebrospinal fluid is also higher and people on cortisol-increasing drugs report symptoms of depression. Serotonin is reduced in the presence of CRH and as the principal action of antidepressants is to make more serotonin available in the brain, these two factors may be linked.

Geography

Some studies suggest that depression and psychosis are more common in urban than rural areas but others report no such difference. To attempt to determine whether such a difference was real and consistent, Sundquist *et al.* (2004) followed up the entire Swedish population aged between 25 and 64 years who had been admitted to hospital with a diagnosis of depression and psychosis. Level of urbanisation was defined by population density.

They found that those patients who lived in the most densely populated areas were 68–77 per cent more likely to be at risk of developing psychosis and 12–20 per cent more likely to be at risk of developing depression than were patients who lived in the least densely populated areas.

Why such a difference should emerge is unknown. It may be that living in densely populated areas produces more adverse living circumstances, such as stressful events and little social support.

Cutting edge – Cold summers, depressed Swedes and antidepressants

Working on the hypothesis that restricted leisure activities of an outdoor nature would lead to increased stress and unhappiness, researchers at Uppsala and California Universities investigated the use of antidepressants during unseasonable cold summer

weather in Sweden that would inhibit normal outdoor activity (Hartig *et al.*, 2007). In total, prescriptions administered between 1991 and 1998 were examined. More antidepressants were dispensed during cold Julys to men and women.

Suicide – An international perspective

Migration, low intelligence and substance use may separately be important risk factors for depression and suicide. In some countries, suicide rates have increase by over 60 per cent in the past five decades and you can see this pattern and the international incidence in Figure 18.9 a and b.

A study of immigration into Estonia, which had been part of the Soviet Union until independence in 1991 and had, therefore, a significant Russian population (about 30 per cent of the population were Russians in 1989), found that while the rate of suicide was lower in the Russian minority during Soviet rule, this pattern changed during the period of stabilisation following independence (Varnik *et al.*, 2005). The rate was higher than that found in Estonians in Estonia or in Russians in

Russia, reflecting a change in status from privileged minority to non-privileged minority. The rates converged in 1998, suggesting to the authors that this may reflect the efforts by the Estonian government to integrate the Russian minority.

In a separate study of Swedish servicemen, Gunnell *et al.* (2005) found that of 987,308 Swedish men followed up for up to 26 years risk of suicide was 2–3 times higher in men with the lowest cognitive test scores compared to those with the highest. The greatest suicide risk emerged from the test of logic – this was the test correlating most significantly with suicide. Perhaps this reflects an inability to solve problems in real life; problems which, if left unresolved, lead to self-harm and death.

Suicide – Continued

Suicide attempts in adolescence are associated with heavy or frequent drinking and illegal drug-taking (Shaffer and Pfeffer, 2001; Gould *et al.*, 2003). A group of Norwegian researchers monitored the correlation between substance use and suicide in two surveys (in 1992 and 2002) of 23,000 13–19-year-olds

(Rossow *et al.*, 2005). There was a significant relationship between increased substance use and suicide, but only in girls. For boys, the effect of substance use seemed to be less pronounced in 2002 than in 1992. For both sexes, the substance most significantly associated with suicide attempts was alcohol.

Treatment

The two principal treatments for clinical depression are cognitive therapy and antidepressant medication.

Cognitive (behavioural) therapy

Beck's cognitive therapy begins by arguing that the negative beliefs held by depressed individuals are seen as conclusions based on faulty logic (Beck, 1967). A depressed person concludes that they are 'deprived, frustrated, humiliated, rejected or punished' (Beck *et al.*, 1979, p. 120). Beck views the cognitions of the depressed individual in terms of a cognitive triad: a negative view of the self ('I am worthless'), of the outside world ('The world makes impossible demands on me'), and of the future ('Things are never going to get better').

Even when confronted with evidence that contradicts their negative beliefs, depressed individuals often find an illogical means of interpreting good news as bad news (Lewinsohn *et al.*, 1980). For example, a student who receives an A grade on an exam might attribute the high grade to an easy, unchallenging exam rather than to their own mastery of the material. The fact that few others in the class received a high grade does little to convince the depressed person that they deserve congratulations for having done well. The depressed student goes on believing, against contrary evidence, that the good grade was not really deserved.

Once the faulty logic is recognised for what it is, therapy entails exploring means for correcting the distortions. The therapist does not accept the client's conclusions and inferences at their face value. Instead, those conclusions resulting from faulty logic are discussed so that the client may understand them from another perspective, changing their behaviour as a result.

Meta-analyses suggest that CBT can be a very effective means of combating depression and may even be more effective than tricyclic antidepressants (see below) in the long term (Hensley *et al.*, 2004).

Antidepressant drugs

Tricyclic antidepressants

Antidepressant drugs are a class of drugs used to treat the symptoms of major depression and the most common of these are listed in Table 18.9. **Antimanic drugs** are used to treat the symptoms of bipolar disorder and mania. The earliest used antidepressant drugs were derived from the family of chemicals known as **tricyclics**, which refers to their 'three-ring' chemical structure (Lickey and Gordon, 1983).

Although the biology of depression is not well understood, the most widely accepted theory is that depression may result from a deficiency of the catecholamine neurotransmitters norepinephrine and serotonin. Each of these neurotransmitters may be involved in different types of depression, although researchers are not sure how. Antidepressant drugs seem to slow down the reuptake of these neurotransmitters by presynaptic axons. Although tricyclic antidepressants do not work for all people, about 60–80 per cent of those whose depression has brought despair to their lives gradually return to normal after having been placed on tricyclics for 2–6 weeks (Hughes and Pierattini, 1992). Unfortunately, tricyclics have many side-effects, including dizziness, sweating, weight gain, constipation, increased heart rate, poor concentration and dry mouth.

Monoamine oxidase inhibitors

Another class of antidepressants, introduced in the late 1950s, is the **monoamine oxidase inhibitors (MAOIs)**, which take 1–3 weeks to begin alleviating depression. MAOIs prevent enzymes in the synaptic gap from destroying dopamine, norepinephrine and serotonin that have been released by presynaptic neurons. These drugs can have many side-effects, many of them fatal. The **tyramine cheese reaction**, for example, arises from the eating of foods containing tyramine such as some wines, milk products, coffee and chocolate. Because the monoamine oxidase does not oxidise tyramine, tyramine displaces epinephrine at epinephrine receptors. This produces severe hypertension and blurred vision, impotence, insomnia and nausea. It can also be fatal if leading to a haemorrhage. MAOIs also have been shown to be more effective in treating atypical depressions such as those involving hypersomnia (too much sleep) or mood swings (Hughes and Pierattini, 1992).

Serotonin-specific reuptake inhibitors

A relatively new class of drugs is **serotonin-specific reuptake inhibitors (SSRIs)**, which, as their name suggests, block the reuptake of serotonin in nerve cells. As a result, the common feature of all SSRIs is that they enhance the transmission of serotonin. Perhaps the most common SSRI is fluoxetine (Prozac), first authorised for medical use in 1988. Fluoxetine inhibits the reuptake of serotonin, leaving more of that neurotransmitter in the synaptic cleft to stimulate post-synaptic receptors, and is the drug of first choice when tricyclic drug treatment has failed. SSRIs produce fewer negative side-effects than do tricyclics and the MAOIs, although some individuals do experience headache, gastrointestinal discomfort, insomnia, tremor and sexual dysfunction.

Table 18.9 Some of the drugs used to treat depression

Substance	Generic name	Example
Norepinephrine-reuptake inhibitors (Tertiary amine tricyclics)	Amitriptyline	Elavil
	Clomipramine	Anafranil
	Doxepin	Adapin, Sinequa
	Imipramine	Tofranil
	Trimipramine	Surmontil
Norepinephrine-reuptake inhibitors (Secondary amine tricyclics)	Amoxapine	Asendin
	Desipramine	Norpramin, Pertofrane
	Maprotiline	Ludiomil
	Nortriptyline	Pamelor
	Protriptyline	Vivactil
Serotonin-reuptake inhibitors	Fluoxetine	Prozac
	Fluvoxamine	Luvox
	Paroxetine	Paxil
	Sertraline	Zoloft
	Venlafaxine	Effexor
Atypical antidepressants	Bupropion	Wellbutrin
	Nefazodone	Serzone
	Trazodone	Desyrel
Monoamine oxidase inhibitors	Phenelzine	Nardil
	Tranylcypromine	Parnate
	Selegiline	Eldepryl

Recent pharmacological treatments

Two developments in the psychopharmacology of depression have been second generation (atypical) depressants which block either norepinephrine reuptake or dopamine reuptake, and **dual-action antidepressants** which block certain serotonin receptors while inhibiting its reuptake. An example of the former, nefazodone, was released in 1995; an example of the latter, mirtazapine, was released in 1997. Neither type of drug has been authorised in all European countries and, because of their youth, little research is available evaluating their long-term efficacy.

The important factor in assessing the effect of antidepressant medication is the maintenance phase of the treatment. In the initial period of drug-taking, there is an acute phase in which the acute symptoms begin to stabilise. This period can last up to three months (Hirschfeld, 2001). The next period extends between the end of the acute period and the end of the depression itself, a period that can take up to 6 to 12 months. The danger is that if patients had stabilised in the acute phase, then they would have medication withdrawn. According to Hirschfeld (2001), however, around one-third to one-half of people who successfully stabilise in the acute phase, will relapse if medication is not sustained,

hence the importance of monitoring behaviour closely during this period.

Lithium carbonate

Lithium carbonate is most effective in the treatment of bipolar disorders or simple mania (Young and Newham, 2006). People's manic symptoms usually decrease as soon as their blood level of lithium reaches a sufficiently high level (Gerbino *et al.*, 1978). In bipolar disorder, once the manic phase is eliminated, the depressed phase does not return. People with bipolar disorder have remained free of their symptoms for years as long as they have continued taking lithium carbonate. This drug can have some side-effects, such as a fine tremor or excessive urine production; but in general, the benefits far outweigh the adverse symptoms. However, an overdose of lithium is toxic, which means that the person's blood level of lithium must be monitored regularly. Psychotherapy has also been associated with some benefits, but this treatment is more successful for depression than mania (Scott, 2006).

The major difficulty with treating bipolar disorder is that people with this disorder often miss their 'high'.

The Blue Room at the Dana Centre in the Science Museum, London.

Source: Science and Society Picture Library.

When medication is effective, the mania subsides along with the depression. But most people enjoy at least the initial phase of their manic periods, and some believe that they are more creative at that time. In addition, many of these people say that they resent having to depend on a chemical 'crutch'. As a consequence, many people suffering from bipolar disorder stop taking their medication. Not taking their medication endangers the lives of these people because the risk of death by suicide is particularly high during the depressive phase of bipolar disorder.

Seasonal affective disorder (SAD)

Some people become depressed during the winter season, when days are short and nights are long. The symptoms of this form of depression, called **seasonal affective disorder**, are slightly different from those of major depression (Rosenthal *et al.*, 1984). Both forms include lowered mood, lethargy and sleep disturbances, but seasonal depression includes a craving for carbohydrates and an accompanying weight gain.

The original study of SAD found a pattern of depression during winter and hypomania during the spring/summer in 29 individuals (Rosenthal *et al.*, 1984). A high percentage of these individuals exhibited bipolar disorder (92 per cent). Similar percentages have been reported elsewhere (Thompson, 1989). Although various mechanisms have been advanced, the most interesting has been the proposal that the light-sensitive hormone melatonin

is dysfunctional in individuals with SAD. Seasonal affective disorder can be treated by exposing people to bright light for several hours a day, for example, or early in the morning (Rosenthal *et al.*, 1985; Thompson *et al.*, 1997). The direct evidence for the role of melatonin, however, appears to be inconclusive (Rosenthal and Wehr, 1992; Dalglish *et al.*, 1996).

Sexual dysfunctions

The DSM-IV TR lists a number of sex-related disorders which have severe psychological consequences and causes. **Male sexual dysfunction**, for example, refers to the man's inability to achieve an erection, in the absence of impaired sexual desire – the desire is there, but the erection is not. Some authors have argued that this failure to achieve erection is due to some form of performance anxiety and that combating this anxiety will eliminate the problem; there is some evidence for this view (Munjack *et al.*, 1984). **Female sexual dysfunction** – the inability of the woman to achieve orgasm although the desire for orgasm is present – is sometimes treated by systematic desensitisation or masturbation training and both have been successful (Emmelkamp, 1994). Other disorders classified as sexual dysfunctions are the paraphilias.

Paraphilia

According to the DSM-IV TR, **paraphilia** constitutes a mental or behavioural disorder that has a sexual content. The individuals must be distressed by the urges or behaviour they exhibit and social or occupational functioning must be impaired. The paraphilias include: **fetishism** (the use of non-living objects for sexual excitement), **transvestic fetishism** (cross-dressing), **paedophilia** (sex with pre-pubescent children), **voyeurism** (looking at people without their knowledge while they are undressing/having sex), **sexual masochism** (the individual derives sexual gratification from being made to suffer), **sexual sadism** (the individual derives sexual gratification from inflicting suffering), **exhibitionism** (exposure of genitalia in public), **frotteurism** (rubbing against a person in public) and paraphilias not otherwise specified. The Psychology in Action section highlights just one of these paraphilias and shows how clinical psychologists can help treat the disorders.

Psychology in action – Treating exhibitionism

‘Steve’, a 34-year-old married man, was arrested for sexually assaulting a woman after attempting to help her fix her broken-down car. He fixed the woman’s fan belt, pulled her to him and began fondling her buttocks. She pushed him away, but he exposed himself and began masturbating. After the woman contacted the police, Steve was arrested and charged.

Psychiatric assessment determined that Steve had a history of exhibitionism and frottage. As an adolescent, he would rub up against women in crowded places and, when he obtained his driver’s licence, he used to park in car parks, watch women and covertly masturbate. When he was 16 years old, Steve remembered watching football in a park while sitting next to a female acquaintance. As he sat next to her, he began masturbating, eventually ejaculating. At the age of 13, he remembered playing with three young women and had an orgasm while wrestling with one of them when rubbing against her buttocks. He would repeat the behaviour with his 8-year-old sister, rubbing her buttocks until he orgasmed. When his sister threatened to tell their mother, he would masturbate to fantasies of buttock rubbing. After this, he would expose himself about 15 to 20 times a year, especially during times of stress. His sexual fantasy involved a woman catching him masturbating; the woman would be aroused by his erect state. This, however, never happened in real life. At the age of 24, he married Helen, a secretary. She gave birth to a son, who was 5 years old at the time of his father’s arrest.

Steve’s family history is a complex affair. His father changed jobs often and so the family moved frequently. Such frequent movement meant that Steve formed very few lasting relationships or friendships. He felt rejected by his father and clung to his mother, who was smothering and overprotective. She bathed him up until the age of 15. She would clean his penis by stroking it with a wet bar of soap and would enjoy seeing the erection this produced.

After the arrest, his wife complained of his lack of affection and of their poor sexual relations, but she knew nothing of his deviance. He did minimal parenting or household duties and his wife had little respect for him. Steve’s treatment was initially aimed at stopping public masturbation and frottage. These behaviours were linked to car parks, shopping centres and subways; he was, therefore, told to avoid these places. He abstained for two months, but he still experienced urges to exhibit. To combat these urges, he was instructed to distract himself whenever he felt them – by imagining himself on a beach, feeling drowsy and soaking up the sun.

To change his fantasies and improve sexual relations with his wife, Steve was instructed to masturbate only while fantasising about intercourse. When he could not do this, he was told to masturbate while fantasising about frottage but at the point of orgasm, he should switch his fantasy to intercourse. This fantasy was then encouraged to appear earlier on during masturbation. By the fourth week of therapy, he could masturbate without having deviant fantasies. He was still turned on by seeing women’s buttocks in tight jeans, however, and so was asked to imagine a non-sexual fantasy when seeing these, such as thinking about the woman’s occupation or looking at her face instead.

During marital therapy, he was shocked that his wife viewed him so negatively. So shocked was he that he began to help more around the house and got a new job as a camera salesman. The usual foreplay (rubbing his wife’s buttocks) was replaced with manual or oral stimulation and his sexual relations with his wife improved. Although Steve’s deviant behaviour had not been ‘cured’, it had been contained.

Chapter review

Classification and diagnosis of mental disorders

- Psychologists and other mental health professionals view the causes of mental disorders from several different perspectives:
 - The psychodynamic perspective argues that mental disorders arise from intrapsychic conflict that overwhelms the mind’s defence mechanisms.
 - The medical perspective asserts that mental disorders have an organic basis, as physical illnesses do.
 - The cognitive behavioural perspective maintains that mental disorders are learned patterns of maladaptive thinking and behaving.
- The humanistic perspective suggests that mental disorders arise from an oversensitivity to the demands of others and because positive regard from others is conditional on meeting those demands.
- The sociocultural perspective focuses on how cultural variables influence the development of mental disorders and people’s subjective reactions to them.
- Many elements of these perspectives are integrated into the diathesis-stress model of mental disorders which suggests that biological inheritance and early learning experiences predispose us to develop mental disorders; these disorders are

expressed only if we encounter stressors that overwhelm our capacity to cope with them.

- The two major manuals for diagnostic mental disorder are the *Diagnostic and Statistical Manual of Mental Disorders IV* (American Psychiatric Association, 1994) and the *International Classification of Diseases 10* (World Health Organization, 1992).
- There is strong cross-cultural agreement for the diagnosis of disorder such as schizophrenia, although anxiety and social phobia are not as uniformly diagnosed; there are also culture-bound disorders which are not universal.
- Research indicates that lay people continue to show poor understanding of the symptoms, possible causes and treatment of mental illness.

Treatment of mental disorders

- Historically, people suffering from emotional or behavioural problems were believed to be possessed by demons or were accused of being witches. They were often subjected to torture, including trephining, in which a small hole was punctured in the skull of the afflicted person to allow demonic spirits to escape. Mental patients in sixteenth- and seventeenth-century asylums encountered abject humiliation. Philippe Pinel, a French physician, is often credited with changing the asylum environment in the late eighteenth century.
- Modern therapy adopts an eclectic approach – the borrowing of methods from different treatments and blending them in a way that will work best in treating the patient's problem. There are, however, different types of treatment approaches that have specific characteristics.
- Insight psychotherapy is based primarily on conversation between therapist and client. The oldest form of insight psychotherapy, psychoanalysis, was devised by Freud.
- Psychoanalysis attempts to discover the forces that are warring in the client's psyche and to resolve these inner conflicts by bringing to consciousness the client's unconscious drives and the defences that have been established against them. Insight is believed to be the primary source of healing.
- Humanistic therapy emphasises conscious, deliberate mental processes.
- Client-centred therapy is based on the premise that people are healthy and good and that their problems result from faulty thinking. Instead of evaluating themselves in terms of their own self-concepts, they judge themselves by other people's standards. This tendency is rectified by providing an environment of unconditional positive regard in which clients can find their own way to good mental health.
- Gestalt therapy focuses on convincing clients that they must deal honestly with their present feelings in order to become more mentally healthy. According to gestalt therapists, the key to becoming happier is to confront one's fears and guilt and to keep one's emotions in proper perspective.
- The range of people that may benefit from insight therapy is limited and narrow. In general, those most likely to benefit are those who are intelligent and able to articulate their problems.
- Insight psychotherapies are not effective with persons with serious mental disorders such as schizophrenia. There are also difficulties with evaluating their effectiveness.
- Behavioural therapists attempt to use the principles of classical and operant conditioning to modify behaviour – fears are eliminated or maladaptive behaviours are replaced with adaptive ones.
- Systematic desensitisation uses classical conditioning procedures to condition relaxation to stimuli that were previously producing fear. In contrast, implosion therapy attempts to extinguish fear and avoidance responses. Aversion therapy attempts to condition an unpleasant response to a stimulus with which the client is preoccupied, such as a fetish.
- The most formal system of therapy based on operant conditioning involves token economies, which arrange contingencies in the environment of people who reside in institutions.
- Some operant treatment is vicarious – people can imagine their own behaviour with its consequent reinforcement or punishment.
- Modelling involves using others as role models for behaviour.
- The major problem with behaviour therapy is the failure of patients to transfer behaviour outside the therapy setting. Techniques to promote generalisation include the use of intermittent reinforcement and recruitment of family and friends as adjunct therapists.
- Cognitive behavioural therapies attempt to change overt behaviour and unobservable cognitive processes.
- Rational-emotive therapy is based on the assumption that people's psychological problems stem from faulty cognitions. Its practitioners use many forms of persuasion, including confrontation, to encourage people to abandon faulty cognitions in favour of logical and healthy ones.
- Beck has developed ways to help depressed people correct errors of cognition that perpetuate self-defeating thoughts.
- Group therapy is based on the belief that certain problems can be treated more efficiently and more effectively in group settings.
- Practitioners of family therapy, couples therapy and some forms of group behaviour therapy observe people's interactions with others and attempt to help them learn how to establish more effective patterns of behaviour. Treatment of groups, including families and couples, permits the therapist to observe clients' social behaviours, and it uses social pressures to help convince clients of the necessity for behavioural change. It permits clients to learn from the mistakes of others and to observe that other people have similar problems, which often provides reassurance.
- The effectiveness of psychotherapeutic methods is difficult to assess: outcomes are difficult to measure objectively, ethical considerations make it hard to establish control groups for some types of disorder, and self-selection and drop-outs make it impossible to compare randomly selected groups of participants. Research suggests that behavioural therapy and cognitive behavioural therapy are effective.
- Biological treatments for mental disorders include drugs, electroconvulsive therapy and psychosurgery.

- Research has shown that treatment of the positive symptoms of schizophrenia with antipsychotic drugs, of major depression with antidepressant drugs, and of bipolar disorder with lithium carbonate are the most effective ways to alleviate the symptoms of these disorders.
- Tricyclic antidepressant drugs can also alleviate severe anxiety that occurs during panic attacks and agoraphobia and can reduce the severity of obsessive-compulsive disorder.
- Although electroconvulsive therapy is an effective treatment for depression, its use is reserved for cases in which rapid relief is critical because the seizures may produce brain damage.
- The most controversial treatment, psychosurgery, is rarely performed today. Its only accepted use, in the form of cingulotomy, is for treatment of crippling compulsions that cannot be reduced by more conventional means.

Mental disorders

Anxiety, somatoform and dissociative mental disorders

- Anxiety disorders refer to mental disorders which are characterised by excessive worry or fear and include generalised anxiety disorder, panic disorder, simple phobia, obsessive-compulsive disorder and post-traumatic stress disorder.
- Generalised anxiety disorder is characterised by excessive worry about all aspects of life; the most explanatory models suggest that anxiety serves as an alarm function preparing an organism for future action. It is best treated by anxiolytic (anti-anxiety) drugs.
- Panic disorder results from a fear of fear. A patient misinterprets bodily sensations catastrophically.
- Cognitive behavioural therapy and anti-anxiety drugs are effective treatments.
- Social phobia refers to an excessive pathological fear of speaking or performing in public.
- Agoraphobia, the most common phobia, is the fear of open spaces. Simple phobia is a fear of specific stimuli such as spiders and snakes.
- Recent research has applied virtual reality technology (exposure to computer-simulated events, objects or locations) to the treatment of the fear of flying and fear of spiders, with long-term success.
- Post-traumatic stress disorder refers to anxiety generated by an astonishing event or trauma (such as natural catastrophe, war or rape).
- Somatoform disorders include somatisation disorder and conversion disorder.
- Somatisation disorder refers to complaints of symptoms of illness without underlying physiological causes. Almost all people with this disorder are women.
- Conversion disorder involves specific neurological symptoms, such as paralysis or sensory disturbance, that are not produced by a physiological disorder.
- Dissociative disorders include psychogenic amnesia (with or without fugue) – a withdrawal from a painful situation or from intolerable guilt; multiple personalities – the adoption of several distinct and complete personalities.

Personality disorders

- Antisocial personality disorder refers to a pathological impairment in social and personal behaviour. It is also known as psychopathy or sociopathy, but antisocial personality is qualitatively different from psychopathy. Psychopaths are indifferent to the effects of their behaviour on other people, are impulsive, fail to learn from experience, are sexually promiscuous, lack commitment to a partner and are habitual liars. Some psychopaths are superficially charming and psychopathy tends to run in families.
- Evidence suggests that the frontal lobe is either dysfunctional or smaller in psychopaths.
- There is a significant association between psychopathy and alcohol abuse.

Schizophrenic disorders

- Schizophrenia is a mental illness characterised by distortions of thought, perception and emotion.
- The main positive symptoms of schizophrenia include thought disorders; delusions of persecution, grandeur and control; and hallucinations. The main negative symptoms include withdrawal, apathy and poverty of speech.
- DSM-IV TR classifies schizophrenia into several sub-types, including undifferentiated, catatonic, paranoid and disorganised.
- The diathesis-stress model suggests that some people seem to inherit a predisposition for the disorder, which is expressed when environmental stressors outweigh the person's attempts to cope with them.
- Recent research suggests that a low level of expressed emotion (including critical comments and emotional over-involvement) by family members facilitates the recovery of a patient with schizophrenia.
- Positive symptoms of schizophrenia can be made worse in schizophrenic patients by drugs that stimulate dopamine synapses (cocaine and amphetamine) and can be reduced or eliminated by drugs that block dopamine receptors (antipsychotic drugs).
- These findings have led to the dopamine hypothesis, which states that schizophrenia is caused by an inherited biochemical defect that causes dopamine neurons to be overactive.
- Enlargement of the ventricles is a consistent finding in schizophrenic patients and is unrelated to drug use; there is also evidence of reduced frontal lobe activation.
- Some researchers have suggested that lateralisation of function does not occur normally in schizophrenia.
- More recent studies indicate that schizophrenia can best be conceived of as two different disorders.
- The positive symptoms are produced by overactivity of dopamine neurons and can be treated with antipsychotic drugs. These positive symptoms are associated with limbic and sublimbic neural activation during verbal hallucination and verbal disorganisation.

- The negative symptoms, which do not respond to these drugs, are caused by brain abnormality. Investigators have found direct evidence of brain damage by inspecting CT scans of living patients' brains.
- Researchers have suggested three possible causes of the brain abnormality: a virus that triggers an autoimmune disease, which causes brain damage later in life; a virus that damages the brain early in life; and obstetric complications.

Mood disorders

- Mood disorders refer to a severe disturbance in emotion.
- Bipolar disorder consists of alternating periods of mania and depression; major depression consists of depression alone.
- Beck has noted that although mood disorders involve emotional reactions, these reactions may be, at least in part, based on faulty and negative cognition. Others such as Abramson and co-workers suggest that depressed individuals are characterised by a negative attributional style which promotes helplessness and hopelessness.
- Heritability studies strongly suggest a biological component to mood disorders. This possibility receives support from the finding that biological treatments effectively reduce the symptoms of these disorders, while reserpine, a drug used to treat hypertension, can cause depression.
- Biological treatments include lithium carbonate for bipolar disorder and electroconvulsive therapy and antidepressant drugs (including monoamine oxidase inhibitors and tricyclic antidepressants) for depression.
- Neuroimaging research has shown that an area in the frontal cortex, sg24, is smaller in people suffering from depression.
- Recently developed drugs for depression, called serotonin-specific reuptake inhibitors, act by preventing reuptake of serotonin and blocking serotonin receptors.

Suggestions for further reading

Abnormal psychology – general reading

- Bentall, R.P. and Beck, A.T. (2004) *Madness Explained: Psychosis and human nature*. New York: Penguin.
- Carson, R.C., Butcher, J.N., Mineka, S. and Hooley, J.M. (2003) *Abnormal Psychology and Modern Life* (12th edn). New York: HarperCollins.
- Davison, G.C. and Neale, J.M. (2006) *Abnormal Psychology* (10th edn). Chichester: Wiley.
- Kramer, G.P., Bernstein, D.S. and Phares, V. (2009) *Introduction to Clinical Psychology* (7th edn). Boston: Prentice Hall.
- Nevid, J. (2006) *Abnormal Psychology in a Changing World* (6th edn). Boston: Allyn & Bacon.
- Oltmans, T.F. and Emery, R.E. (2010) *Abnormal Psychology* (6th edn). Upper Saddle River, NJ: Prentice Hall.

Abnormal psychology is one of the most popular areas of study in psychology. As a result, there are many good textbooks which are in their fourth editions (and beyond). The books listed here are very good introductions to the general area of mental disorder and are recommended for more information on topics covered in this chapter.

Specific mental illnesses

- Arkowitz, H. and Lillienfeld, S.O. (2007) The best medicine? *Scientific American Mind*, 18, 5, 80–3.

- Tandon, R., Keshavan, M.S. and Nasrallah, H.A. (2008) Schizophrenia, 'Just the facts': What we know in 2008, Part 1: Overview. *Schizophrenia Research*, 100, 4–19.
- Tandon, R., Keshavan, M.S. and Nasrallah, H.A. (2008). Schizophrenia, 'Just the facts': What we know in 2008, Part 2; Epidemiology and etiology. *Schizophrenia Research*, 100, 1–18.
- Walker, E., Kestler, L., Bollini, A. and Hochman, K.M. (2004) Schizophrenia: Etiology and course. *Annual Review of Psychology*, 55, 401–30.
- Special issue of *Cognition and Emotion* on cognitive biases in anxiety and depression (2002) 16, 3.
- A number of books treat mental disorders separately, and the texts and papers here are some of the best covering anxiety, depression and schizophrenia.

Case studies and papers in mental illness

- Jamison, K.R. (1993) *Touched with Fire*. New York: Free Press.
- Jamison, K.R. (1995) *The Unquiet Mind*. London: Picador.
- Jamison, K.R. (2004) *Exuberance*. New York: Knopf.
- Meyer, R.G., Chapman, L.K. and Weaver, C.M. (2009) *Case Studies in Abnormal Behaviour* (8th edn). Boston: Allyn & Bacon.

Oltmans, T.F., Martin, M. Neale, J.M. and Davison, G. (2006) *Case Studies in Abnormal Psychology* (7th edn). Chichester: Wiley.

Sutherland, S. (1987) *Breakdown*. London: Weidenfeld & Nicolson.

Wolpert, L. (1999) *Malignant Sadness: The anatomy of depression*. London: Faber.

The impact of mental disorder (on the individual and on the people around the individual) is seen vividly in personal accounts of mental illness. These books present case studies of mental disorder but from slightly different perspectives. Oltmans *et al.*'s book complements the DSM-IV TR and presents case studies of each of the major disorders listed in the manual. Sutherland's book is remarkable. It is an account of bipolar disorder suffered by the late Stuart Sutherland and recounts the various treatments and therapies he underwent in a search for a cure. He describes the events surrounding the disorder with often painful honesty, and the account is made all the more provocative by the fact that Sutherland was Professor of Psychology at the University of Sussex. Wolpert, another distinguished academic, suffered from major episodes

of depression. In his book, he describes the episodes vividly and reviews current understanding of the disorder and its treatment.

Other topics

Hinshaw, S.P. (2005) The stigmatization of mental illness in children and parents: Developmental issues, family concerns, and research needs. *Journal of Child Psychology and Psychiatry*, 46, 7, 714–34.

Pennebaker, J.W., Mehl, M.R. and Niederhoffer, K.G. (2003) Psychological aspects of natural language use: Our words, our selves. *Annual Review of Psychology*, 54, 547–77.

Wedding, D., Boyd, M.A. and Niemiec, R.M. (2005) *Movies and Mental Illness* (2nd edn). Cambridge, MA: Hogrefe.

Three articles giving an overview of the stigma attached to mental illness, a review of how the use of language can influence the way we feel, and a comprehensive and highly engaging account of how mental illness is portrayed in film (the last one would be very good for seminar discussion)

Appendix

Understanding research results

In almost all the studies described in this book, the behaviour of groups of participants was observed and measured. Once a study is finished, we need some way to compare these measurements. To do so, we use descriptive statistics and these are very useful tools: they show us patterns in data that are not readily accessible by looking at individual participants' scores alone.

This section describes some of the most common types of descriptive statistics and what is meant by correlation when describing statistical data. You can find more detail about the topics here in the further reading suggested in Chapter 2.

Descriptive statistics

Descriptive statistics, or summary statistics, are mathematical procedures that permit us to summarise sets of numbers. Using these procedures, we will calculate measures that summarise the performance of the participants in each group. Then we can compare these measures to see whether the groups of participants behaved differently (step 4 of the scientific method). We can also use these measures to describe the results of the experiment to others (step 5 of the scientific method). You are already familiar with some descriptive statistics. For example, you know how to calculate the average of a set of numbers; an average is a common measure of central tendency. You might be less familiar with measures of variability, which tell us how groups of numbers differ from one another, and with measures of relations, which tell us how closely related two sets of numbers are.

Measures of central tendency

When we say that the average weight of an adult male in Europe is 77 kg or that the average density of population in Wales is 40 people per square mile, we are using a **measure of central tendency**, a statistic that represents many observations. There are several different measures of central tendency (summarised in Table A.1), but the

most common is the average, also called the mean. The **mean** of a set of observations is calculated by adding the individual values and dividing by the number of observations. The mean is the most frequently used measure of central tendency in reports of psychological experiments.

Although the mean is usually selected to measure central tendency, it is not the most precise measure, especially if a set of numbers contains a few abnormally high or low values. The most representative measure of central tendency is the **median**. For this reason, we usually read 'median family income' rather than 'mean family income' in newspaper or magazine articles. To calculate the median of a set of numbers, we arrange them in numerical order and find the midpoint. For example, the median of the numbers 1, 2 and 6 is 2. The other measure of central tendency is the **mode**. The mode is the most frequently occurring value in a set of values.

To understand why the median is the best representative of a set of numbers that contains some extreme values, consider a small town of one hundred families. Ninety-nine of the families, all of whom work in the local textile factory, make between £15,000 and £20,000 per year. However, the income of one family is £2 million per year. This family consists of a popular novelist and her husband, who moved to the area because of its mild climate. The mean income for the town as a whole, considering the novelist as well as the mill workers, is £37,325 per year. In contrast, the median income for the town is £17,500 per year. Clearly, the median represents the typical family income of the town better than the mean does.

Why, then, would we ever bother to use the mean rather than the median? As we will see later in this chap-

Table A.1 Measures of central tendency

Measure	Description
Mean	The sum of a group of values divided by their number
Median	The midpoint of a group of values arranged numerically
Mode	The most frequently occurring value in a set of values

ter, the mean is used to calculate other important statistics and has special mathematical properties that often make it more useful than the median.

Measures of variability

Many experiments produce two sets of numbers, one consisting of the experimental group’s scores and one of the control group’s scores. If the mean scores of these two groups differ, the experimenter can conclude that the independent variable had an effect. However, the experimenter must decide whether the difference between the two groups is larger than what would probably occur by chance. To make this decision, the experimenter calculates a **measure of variability**, a statistic that describes the degree to which scores in a set of numbers differ from each other. This measure can be used as a basis for comparing the means of the two groups.

Two sets of numbers can have the same mean or median and still be very different. For example, the mean and median of both sets of numbers listed in Table A.2 are the same, but the numbers are clearly different. The variability of the scores in set B is greater.

Table A.2 Two sets of numbers having the same mean and median but different ranges

Sample A	Sample B
8	0
9	5
10 Median	10 Median
11	15
12	20
Total 50	Total 50
Mean 50/5 = 10	Mean 50/5 = 10
Range 12 – 8 = 4	Range 20 – 0 = 20

One way of stating the difference between the two sets of numbers in Table A.2 is to say that the numbers in set A range from 8 to 12 and the numbers in set B range from 0 to 20. The range of a set of numbers is simply the largest number minus the smallest. Thus, the range of set A is 4 and the range of set B is 20.

The range is not commonly used to describe the results of psychological experiments because another measure of variability – the standard deviation – has more useful mathematical properties. To calculate the standard deviation of a set of numbers, you first calculate the mean and then find the difference between each number and the mean. These difference scores are squared (that is, multiplied by themselves) and then summed. The mean of this total is called the **variance**; the **standard deviation** is the square root of the variance. The more different the numbers are from each other, the larger the standard deviation will be. This can be seen from the workings illustrated in Table A.3.

Measurement of relations

In correlational studies, the investigator measures the degree to which two variables are related. For example, suppose that a psychologist has developed a new aptitude test and wants to sell the test to university admissions committees for screening applicants. Before the committees will consider buying the test, the psychologist must show that a person’s score on the test is related to their subsequent success at university. To do so, the psychologist will give the test to a group of first-year undergraduates entering university and later obtain their average course grades. The psychologist will then measure the relation between test scores and grades.

Imagine that we give the test to ten students entering university and later obtain their average grades. We will have two scores for each person. We can examine the relation between these variables by plotting the scores on

Table A.3 Calculation of the variance and standard deviation of two sets of numbers having the same mean

Sample A			Sample B		
Score	Difference between score and mean	Difference squared	Score	Difference between score and mean	Difference squared
8	10 – 8 = 2	4	0	10 – 0 = 10	100
9	10 – 9 = 1	1	5	10 – 5 = 5	25
10	10 – 10 = 0	0	10	10 – 10 = 0	0
11	11 – 10 = 1	1	15	15 – 10 = 5	25
12	12 – 10 = 2	4	20	20 – 10 = 10	100
Total 50		Total 10	Total 50		Total 250
Mean 50/5 = 10		Mean (variance) 10/5 = 2	Mean 50/5 = 10		Mean (variance) 250/5 = 25
		Square root			Square root
		(standard deviation) 1.41			(standard deviation) 5

a graph. For example, student R.J. received a test score of 14 and earned an average grade of 3.0 (corresponding to a good class of degree). We can represent this student's score as a point on the graph shown in Figure A.1.

The horizontal axis represents the test score, and the vertical axis represents the average grade. We put a point on the graph that corresponds to R.J.'s score on both of these measures.

We do this for each of the remaining students and then look at the graph, called a **scatterplot**, to determine whether the two variables are related. When we examine the scatterplot, we see that the points tend to be located along a diagonal line that runs from the lower left to the upper right, indicating that a rather strong relationship

exists between a student's test score and average grade, as seen in Figure A.1. High scores are associated with good grades, low scores with poor grades.

Although scatterplots are useful, we need a more convenient way to communicate the results to others, so we calculate the **correlation coefficient**, a number that expresses the strength of a relation. Calculating this statistic for the two sets of scores gives a correlation of +0.9 between the two variables.

The size of a correlation coefficient can vary from 0 (no relation) to 1.0 (perfect relation). A perfect relation means that if we know the value of a person's score on one measure, then we can predict exactly what his or her score will be on the other. Thus, a correlation of +0.9 is very close to perfect; our hypothetical aptitude test is an excellent predictor of how well a student will do at university.

Correlations can be negative as well as positive. A negative correlation indicates that high values on one measure are associated with low values on the other and vice versa. An example of a negative correlation is the relation between people's mathematical ability and the amount of time it would take them to solve a series of maths problems. People with the highest level of ability will take the least amount of time to solve the problems. For purposes of prediction, a negative correlation is just as good as a positive one. A correlation of -0.9 is an almost perfect relation, but in this case high scores on one measure predict low scores on the other. Examples of scatterplots illustrating high and low correlations, both positive and negative, are shown in Figure A.2.

If the points in a scatterplot fall along a line, the relation is said to be linear. But many relations are non-linear. For example, consider the relation between level of illumination and reading speed. Obviously, it is impossible to read in the dark. As the light level increases, people's reading speed will increase, but once an adequate amount of light falls on a page, further increases in light will have no effect. Finally, the light becomes so bright and dazzling that people's reading speed will decline, as seen in Figure A.3.

Figure A.1 A scatterplot of the test scores and average grades of ten students. An example of graphing one data point (student R.J.) is shown.

Figure A.2 Scatterplots of variables having several different levels of correlation.

Figure A.3 A non-linear relation. Results of a hypothetical experiment investigating the relation between level of illumination and reading speed. A correlation coefficient cannot adequately represent this kind of relation.

A correlation coefficient cannot accurately represent a non-linear relation such as this because the mathematics involved in calculating this measure assume that the relation is linear. Scientists who discover non-linear relations in their research usually present them in graphs or express them as non-linear mathematical formulae.

Inferential statistics: are the results significant?

When we perform an experiment, we select a sample of participants from a larger population. In doing so, we hope that the results will be similar to those we might have obtained had we used all members of the population in the experiment. We randomly assign the participants to groups in an unbiased manner, alter only the relevant independent variables, and measure the dependent variable using a valid and reliable method. After the experiment is completed, we must examine the results and decide whether a relation really exists between independent and dependent variables. That is, we must decide whether the results have **statistical significance** and are not simply due to chance. To do so, we will use inferential statistics. As we saw, descriptive statistics enable us to summarise our data. **Inferential statistics** enable us to determine whether the results are statistically significant.

For example, if we conduct an experiment and find that individuals low in self-esteem engage in fewer social interactions than do individuals with high self-esteem, how great does the difference between our two groups

have to be before it is meaningful? How different is different? Suppose that we tested another two groups of people, both treated in exactly the same way. Would the mean scores of the two groups be precisely the same? Well, no, because, by chance, they would be at least slightly different. Imagine that we find that the mean score for the group that was subjected to a loss of self-esteem is lower than the mean score for the control group. How much lower would it have to be before we could correctly conclude that the difference between the groups was significant? The obvious way to determine whether two group means differ significantly is to look at the size of the difference. If it is large, then we can be fairly confident that the independent variable had a significant effect. If it is small, then the difference is probably due to chance. What we need are guidelines to help us to determine when a difference is large enough to be statistically significant. This can be done using inferential statistics.

Psychologists can calculate the mean and standard deviation for each group and consult a table that statisticians have already prepared for them. The table (which is based upon mathematical properties of the mean and standard deviation) will tell them how likely it is that their results could have been obtained by chance. In other words, the table tells them how likely it is that low self-esteem is not related to the number of social interactions. Note that the table tells them how likely it is that there will be *no* effect of our independent variable. This is known as the null hypothesis: there is no relationship between variable X and variable Y. The experimental hypothesis suggests that there is a difference between variable X and variable Y and will specify the direction of the difference (X will make Y increase, for example). If the likelihood of accepting the null hypothesis is low enough, psychologists will conclude that the results they obtained are statistically significant. Most psychologists consider a 5 per cent probability to be statistically significant but are much more comfortable with 1 per cent or less.

Statistical tests help us decide whether results are representative of the larger population but not whether they are important. In general usage, the word 'significant' does mean important, but statistical significance simply means that the results appear not to be caused by chance. Why might the results of a study be statistically significant but nevertheless unimportant? What if you had performed an experiment but found non-significant results? Does this mean that your experimental hypothesis is wrong? Can you think of alternative explanations for your negative results?

Glossary

A

absolute threshold The minimum value of a stimulus that can be detected.

accommodation (1) Changes in the thickness of the lens of the eye that focus images of near or distant objects on the retina. (2) In developmental psychology, the process by which existing schemata are modified or changed by new experiences.

achromatopsia A form of colour blindness in which the world is seen in shades of grey.

acquired dyslexia Reading impairment which results from brain injury.

acquisition In classical conditioning, the time during which a conditioned stimulus first appears and increases in frequency.

action potential A brief electrochemical event that is carried by an axon from the soma of the neuron to its terminal buttons; causes the release of a transmitter substance.

activational effect The effect of a hormone on a physiological system that has already developed. If the effect involves the brain, it can influence behaviour. An example is facilitation of sexual arousal and performance.

actor–observer effect The tendency to attribute one's own behaviour to situational factors but others' behaviour to dispositional factors.

adaptation The ability of generations of species to adapt effectively to changes in the environment.

adaptive significance The effectiveness of behaviour in aiding organisms to adjust to changing environmental conditions.

adjacency/proximity principle A Gestalt principle of organisation; elements located closest to each other are perceived as belonging to the same figure. Also called proximity principle.

aerobic exercise Physical activity that expends considerable energy, increases blood flow and respiration and thereby stimulates and strengthens the heart and lungs and increases the body's efficient use of oxygen.

affect In emotion research, the term given to a prolonged, general mood state (e.g. 'positive affect').

affix A sound or group of letters added to the beginning of a word (prefix) or its end (suffix).

affordances Features of the perceptual environment which give it its meaning or signify its use.

aggression The intent to inflict harm on others.

agoraphobia A mental disorder characterised by fear of and avoidance of being alone in public places; this disorder is often accompanied by panic attacks.

agrammatism A language disturbance; difficulty in the production and comprehension of grammatical features, such as proper use of function words, word endings and word order. Often seen in cases of Broca's aphasia.

alcoholism An addiction to ethanol, the psychoactive agent in alcoholic beverages.

algorithm A procedure that consists of a series of steps that will solve a specific type of problem.

alien hand After split-brain operation, the feeling that patients report of one hand not belonging to them.

alleles Alternative forms of the same gene.

allesthesia In spatial neglect, where patients transfer features of the right-hand side of an object/environment to the left when drawing. Also called allochiria.

allochiria See allesthesia.

alpha activity Rhythmical, medium-frequency activity of the electroencephalogram, usually indicating a state of quiet relaxation.

altruism The unselfish concern of one individual for the welfare of another.

Alzheimer's disease A degenerative brain disorder characterised by neuronal abnormalities which leads to confusional states and cognitive impairment.

amygdala A part of the limbic system of the brain located deep in the temporal lobe; damage causes changes in emotional and aggressive behaviour.

anal stage The second of Freud's psychosexual stages, during which the primary erogenous zone is the anal region. Freud argued that during this time, children take pleasure in retaining or expelling faeces.

anatomical coding A means by which the nervous system represents information; different features are coded by the activity of different neurons.

androgen insensitivity syndrome An inherited condition caused by a lack of functioning androgen receptors. Because androgens cannot exert their effects, a person with XY sex chromosomes develops as a female, with female external genitalia.

androgens The primary class of sex hormones in males. The most important androgen is testosterone.

androstenone A chemical secreted by wild boars and thought to be a pheromone.

animism The belief that all animals and all moving objects possess spirits providing their motive force.

anomalous trichromacy A deficit in colour vision in which a photopigment is altered.

anorexia nervosa An eating disorder characterised by attempts to lose weight, sometimes to the point of starvation.

anterior Towards the front.

anterograde amnesia A disorder caused by brain damage that disrupts a person's ability to form new long-term memories of events that occur after the time of the brain damage.

anti-anxiety (anxiolytic) drug A 'tranquilliser', which reduces anxiety. The most common include chlordiazepoxide (Librium) and diazepam (Valium).

antibodies Proteins in the immune system that recognise antigens and help kill invading micro-organisms.

anticipatory anxiety A fear of having a panic attack; may lead to the development of agoraphobia.

antidepressant drugs Drugs used to treat depression.

antigen The unique proteins found on the surface of bacteria; these proteins are what enable the immune system to recognise the bacteria as foreign substances.

antimanic drugs Drugs used to treat bipolar disorder and mania.

antipsychotic drugs The pharmacological agents used to treat severe mental illness such as schizophrenia.

antisocial personality disorder A disorder characterised by a failure to conform to standards of decency; repeated lying and stealing; a failure to sustain lasting, loving relationships; low tolerance of boredom; and a complete lack of guilt.

anxiety A sense of apprehension or doom that is accompanied by many physiological reactions, such as accelerated heart rate, sweaty palms and tightness in the stomach.

anxiolytic drug See anti-anxiety drug.

aphasia Language impairment seen after brain damage and usually involves an inability to produce or comprehend speech.

appeasement gesture A stereotyped gesture made by a submissive animal in response to a threat gesture by a dominant animal; tends to inhibit an attack.

apperceptive agnosia An inability to recognise objects visually.

archetypes Universal thought forms and patterns that Jung believed resided in the collective unconscious.

articulatory loop The component of working memory which stores verbal/auditory information. Also called phonological loop.

artificial intelligence The construction of computer programs that simulate mental function.

Asperger's syndrome A disorder similar to autism but characterised by a narrow and obsessional range of interests.

assertiveness training A technique which trains an individual to be more direct about his/her feelings.

assimilation The process by which new information about the world is modified to fit existing schemata.

associative agnosia An inability to make meaningful associations to visually presented objects.

attachment A social and emotional bond between infant and carer that spans both time and space.

attention deficit hyperactivity disorder (ADHD) A conduct disorder characterised by poor sustained attention, impulsiveness and hyperactivity in children.

attentional bias A tendency to attend to certain stimuli more than others.

attitude A relatively enduring set of beliefs, feelings and intentions towards an object, person, event or symbol.

attribution The process by which people infer the causes of other people's behaviour.

attribution theory Group of theories about how people assign causes to their own or others' behaviour.

attributional ambiguity Tendency of members of stigmatised groups continually to read prejudice and discrimination into innocuous behaviours and even into behaviours favouring them.

attributional style An individual (personality) predisposition to make a certain type of causal attribution for behaviour.

auditory hair cell The sensory neuron of the auditory system; located on the basilar membrane.

authoritarian personality Personality syndrome originating in childhood that predisposes individuals to be prejudiced.

autism Developmental disorder characterised by abnormal social behaviour, language abnormalities and stereotypical and repetitive patterns of behaviour.

autobiographical memory See episodic memory.

autokinetic effect Optical illusion in which a point of light shining in complete darkness appears to move about.

automatic processing The formation of memories of events and experiences with little or no attention or effort.

automaticity Tendency for categories and associated stereotypes to be activated on the basis of cues, very rapidly and without conscious awareness.

autonomic nervous system (ANS) The portion of the peripheral nervous system that controls the functions of the glands and internal organs.

autotopagnosia An inability to name body parts following damage to the left parietal association cortex.

availability heuristic A general rule for social judgement by which a person judges the likelihood or importance of an event by the ease with which examples of that event come to mind.

aversion therapy A form of treatment in which the client is trained to respond negatively to a neutral stimulus that has been paired with an aversive stimulus.

avoidance response An operant response acquired through negative reinforcement that prevents an aversive stimulus from occurring.

avoidant attachment A kind of attachment in which infants avoid or ignore their mothers and often do not cuddle when held.

axes The criteria used in DSM-IV for classifying mental disorder.

axon A long, thin part of a neuron attached to the soma; divides into a few or many branches, ending in terminal buttons.

B

B lymphocytes Cells that develop in bone marrow and release immunoglobulins to defend the body against antigens.

backward masking The ability of a stimulus to interfere with the perception of a stimulus presented just before it.

barbiturate A drug that causes sedation; one of several derivatives of barbituric acid.

bariatric surgery Surgery of the intestine to reduce weight loss.

Barnum effect Individuals' acceptance that vague and generalised descriptions of personality that apply to almost all individuals are an accurate reflection of their own personality.

basal ganglia A collection of brain structures underneath the cortex which play an important role in motor behaviour.

base-rate fallacy The failure to consider the likelihood that a person, place or thing is a member of a particular category – some categories are simply larger than others.

basic level categories Default categories that people tend to use most of the time because they are neither too inclusive nor too exclusive.

basic-level concept A concept that makes important distinctions between different categories.

basic orientations Karen Horney's sets of personality characteristics that correspond to the strategies of moving towards others, moving against others and moving away from others.

basic rest–activity cycle (BRAC) The suggestion that our behaviour patterns for drinking, feeding, sleeping and so on follow 90-minute cycles of rest and activity. The cycle is controlled by a biological clock in the pons; during sleep, it controls cycles of REM sleep and slow-wave sleep.

basilar membrane A membrane that divides the cochlea of the inner ear into two compartments. The receptive organ for audition resides here.

behaviour genetics The branch of psychology that studies the role of genetics in behaviour.

behaviour modification Behaviour therapy based on the principles of operant conditioning.

behavioural inhibition system (BIS) The brain system which allows the organism to evaluate how threatening the environment is.

behaviourism A movement in psychology that asserts that the only proper subject matter for scientific study in psychology is observable behaviour.

belief in a just world The belief that people get what they deserve in life – good things happen to good people and bad things happen to bad people.

benzodiazepine A class of drug having anxiolytic ('tranquillising') effects.

beta activity The irregular, high-frequency activity of the electroencephalogram, usually indicating a state of alertness or arousal.

between-groups design See independent groups design.

bilingualism The ability to communicate in two or more languages.

Binet–Simon Scale An intelligence test developed by Binet and Simon in 1905; the precursor of the Stanford–Binet Scale.

biological evolution Changes that take place in the genetic and physical characteristics of a population or group of organisms over time.

biological reductionism The belief that behaviour can be explained and described primarily by biological processes.

bipedalism The ability to move about the environment on two feet.

bipolar cell A neuron in the retina that receives information from photoreceptors and passes it on to the ganglion cells, from which axons proceed through the optic nerves to the brain.

bipolar disorder Alternating states of depression and mania separated by periods of relatively normal affect.

blending After segmenting a word, the putting together of these segments to pronounce a word.

blindsight A disorder resulting from occipital cortex damage in which patients seem to show awareness of objects but declare being consciously unaware of them.

bottom-up processing A perception based on successive analyses of the details of the stimuli that are present.

brain stem The 'stem' of the brain, including the medulla, pons and midbrain.

brainstorming Uninhibited generation of as many ideas as possible in a group, in order to enhance group creativity.

brightness A perceptual dimension of colour, most closely related to the intensity or degree of radiant energy emitted by a visual stimulus.

brightness constancy The tendency to perceive objects as having constant brightness even when they are observed under varying levels of illumination.

bulimia nervosa A loss of control over food intake characterised by gorging binges followed by self-induced vomiting or use of laxatives; also accompanied by feelings of guilt and depression.

bystander intervention The intervention of a person in a situation that appears to require their aid.

C

c The features which families share in common and can contribute to intelligence.

callosal syndrome The behavioural consequences of lesioning the largest bundle of nerve fibres connecting the two hemispheres, the corpus callosum.

Cartesian dualism See dualism.

case study Observation of the behaviour of individuals having special characteristics, such as psychological or neurological disorders.

cataplexy A neurological disorder in which the person collapses, becoming temporarily paralysed but not unconscious; usually triggered by anger or excitement; apparently related to the paralysis that normally accompanies REM sleep.

catastrophic misinterpretation The interpretation of bodily sensations as physical threat.

catatonic schizophrenia A form of schizophrenia characterised primarily by various motor disturbances, including catatonic postures and waxy flexibility.

causal event or determinant An event that causes another event to occur.

central executive The component of working memory that coordinates the other elements of working memory such as the phonological loop and the visuospatial scratchpad.

central nervous system The brain and the spinal cord.

central traits Descriptive traits that are significantly more important than other traits in organising information about a person into an impression.

cerebellum A pair of hemispheres resembling the cerebral hemispheres but much smaller and lying beneath and at the back of them; controls posture and movements, especially rapid ones.

cerebral cortex The outer layer of the cerebral hemispheres of the brain, approximately 3 mm thick.

cerebral hemisphere The largest part of the brain; covered by the cerebral cortex and containing parts of the brain that evolved most recently.

cerebrospinal fluid (CSF) The liquid in which the brain and spinal cord float; provides a shock-absorbing cushion.

chemosensation The process of sensing chemical stimuli by the chemosenses (olfaction and gustation).

chemosense One of the two sense modalities (gustation and olfaction) that detect the presence of chemical molecules present in the environment.

child-directed speech The speech of an adult directed towards a child; differs in important features from adult-directed speech and tends to facilitate learning of language by children.

cholesterol A lipid, a chemical made of fat, present in the body which is necessary but which, in excess, can be a risk factor for ill-health.

chromosomal aberration The rearrangement of genes within chromosomes or a change in the total number of chromosomes.

chromosomes Rod-like structures in the nuclei of living cells; contain genes.

chunking A process by which information is simplified by rules which make it easily remembered once the rules are learned. For example, the string of letters TWAIBMBBC is easier to remember if a person learns the rule that organises them into smaller 'chunks': TWA, IBM and BBC.

cilia Hairlike appendages of a cell; involved in movement or in transducing sensory information. Cilia are found on the receptors in the auditory and vestibular systems.

cingulotomy The surgical destruction of the cingulum bundle, which connects the prefrontal cortex with the limbic system; helps to reduce intense anxiety and the symptoms of obsessive-compulsive disorder.

circadian rhythm A daily rhythmical change in behaviour or physiological process.

classical conditioning The process by which a response normally elicited by one stimulus (the UCS) comes to be controlled by another stimulus (the CS) as well.

client-centred therapy A form of therapy in which the client is allowed to decide what to talk about without strong direction and judgement from the therapist.

clinical judgements Diagnoses of mental disorders or predictions of future behaviour based largely on experts' experience and knowledge.

clinical neuropsychology The branch of psychology concerned with the identification and treatment of the behavioural consequences of nervous system disorders and injuries.

clinical psychology The branch of psychology concerned with the investigation and treatment of abnormal behaviour and mental disorders.

cochlea A snail-shaped chamber set in bone in the inner ear, where audition takes place.

cocktail-party phenomenon The ability to attend selectively to auditory material against a background of competing auditory stimuli.

cognitive algebra Approach to the study of impression formation which focuses on how people combine attributes that have valence into an overall positive or negative impression.

cognitive behavioural therapy A treatment method that focuses on altering the client's maladaptive thoughts, beliefs and perceptions.

cognitive dissonance theory The theory that changes in attitude can be motivated by an unpleasant state of tension caused by a disparity between a person's beliefs or attitudes and their behaviour, especially beliefs or attitudes that are related to the person's self-esteem.

cognitive interview Technique of applying the principles of cognitive psychology to the purpose of enhancing memory retrieval in real-life settings (such as witnessing and reporting a crime).

cognitive neuroscience The branch of neuroscience which seeks to localise cognitive functions (such as memory, attention, language, etc.) in the brain.

cognitive psychology The branch of psychology that studies complex behaviours and mental processes, such as perception, attention, learning and memory, verbal behaviour, concept formation and problem-solving.

cognitive reappraisal Any coping strategy in which one alters one's perception of the threat posed by a stressor to reduce stress.

cognitive rehabilitation Specific form of rehabilitation in which patients are encouraged to recover functions such as memory and language which have been impaired by brain injury.

cognitive restructuring Altering misconceptions about the consequences of bodily sensation.

cognitive science The branch of psychology which seeks to understand human cognitive function by using artificial intelligence and computer models.

cognitive structures According to Piaget, mental representations or rules, such as schemata or concepts, that are used for understanding and dealing with the world and for thinking about and solving problems.

cognitive triad Pessimistic thinking about the self, the present and the future.

collective effort model People will only work hard on a collective task to the degree that they expect their efforts to be instrumental in leading to outcomes that they value personally.

collective unconscious According to Jung, the part of the unconscious that contains memories and ideas inherited from our ancestors over the course of evolution.

colour mixing The perception of two or more lights of different wavelengths seen together as light of an intermediate wavelength.

commitment The desire or intention to continue an interpersonal relationship.

commons dilemma Social dilemma in which cooperation by all benefits all, but competition by all harms all.

companionate love Love that is characterised by a deep, enduring affection and caring for another person, accompanied by a strong desire to maintain the relationship.

comparative psychology The branch of psychology that studies the behaviours of a variety of organisms in an attempt to understand the adaptive and functional significance of the behaviours and their relation to evolution.

competition A striving or vying with others who share the same ecological niche for food, mates and territory.

complementary medicine An alternative, unorthodox approach to treatment of illness that is not based on conventional medicine.

compliance Engaging in a particular behaviour at another person's request, not because you have an underlying attitude that favours the behaviour.

componential intelligence According to Sternberg, the mental mechanisms people use to plan and execute tasks; includes metacomponents, performance components, and knowledge acquisition components.

compulsion An irresistible impulse to repeat some action over and over even though it serves no useful purpose.

computerised tomography (CT) Technique that uses a special X-ray machine and a computer to produce images of the brain that appear as slices taken parallel to the top of the skull.

concept A category of objects or situations that share some common attributes.

concordance research Research that studies the degree of similarity between twins in traits expressed. Twins are said to be concordant for a trait if either both or neither twin expresses it and discordant if only one twin expresses it.

conditional response (CR) In classical conditioning, the response elicited by the CS.

conditional stimulus (CS) In classical conditioning, a stimulus which, because of its repeated association with the unconditional stimulus (UCS), eventually elicits a conditional response (CR).

conditioned emotional response A classically conditioned response produced by a stimulus that evokes an emotional response, in most cases including behavioural and physiological components.

conditioned flavour-aversion learning A type of learning in which a substance is avoided because its flavour has been associated with illness.

conditioned reinforcer (or punisher) A stimulus that acquires its reinforcing (or punishing) properties through association with a primary reinforcer (or punisher). Sometimes referred to as a secondary reinforcer (or punisher).

conditions of worth Conditions that others place on us for receiving their positive regard.

conduct disorder Impairment in the child's ability to inhibit its own antisocial and deviant behaviour.

cone A photoreceptor that is responsible for acute daytime vision and for colour perception.

confidentiality Privacy of participants and non-disclosure of their participation in a research project.

configural model Asch's gestalt-based model of impression formation, in which central traits have a disproportionate role in configuring the final impression.

confirmation bias A tendency to seek evidence that might confirm a hypothesis rather than evidence that might disconfirm it; a logical error.

conformity The adoption of attitudes and behaviours shared by a particular group of people – the internalisation of a group norm as a standard for one's own behaviour.

confounding of variables An inadvertent alteration of more than one variable during an experiment. The results of an experiment involving confounded variables permit no valid conclusions about cause and effect.

conjugate movement The cooperative movement of the eyes, which ensures that the image of an object falls on identical portions of both retinas.

connectionism The modelling of human cognitive function based on computer simulation.

conscience The internalisation of the rules and restrictions of society; it determines which behaviours are permissible and punishes wrongdoing with feelings of guilt.

consensual behaviour Behaviour that is shared by many people; behaviour that is similar from one person to the next. To the extent that different people engage in the same behaviour, their behaviour is consensual.

conservation Understanding that specific properties of objects (height, weight, volume, length) remain the same despite apparent changes in the shape or arrangement of those objects.

consistency The extent to which a person behaves the same way every time they are in the same situation.

consolidation The process by which information in short-term memory is transferred to long-term memory, presumably because of physical changes that occur in neurons in the brain.

consumer psychology The branch of psychology which studies the factors which influence consumer decision-making and preference.

contact hypothesis The view that prejudice will disappear if you bring people from different races together to interact with one another.

content word A noun, verb, adjective or adverb that conveys meaning.

context-dependent memory See place-dependent memory.

contextual intelligence According to Sternberg, intelligence that reflects the behaviours that were subject to natural selection: adaptation – fitting oneself into one's environment by developing useful skills and behaviours; selection – finding one's own niche in the environment; and shaping – changing the environment.

contingency theory Fiedler's interactionist theory that the effectiveness of particular leadership styles depends on situational and task factors.

contralateral Residing in the side of the body opposite the reference point.

control group A comparison group used in an experiment, the members of which are exposed to the naturally occurring or zero value of the independent variable.

conventional level Kohlberg's second level of moral development, in which people realise that society has instituted moral rules to maintain order and to serve the best interests of its citizenry.

convergence The result of conjugate eye movements whereby the fixation point for each eye is identical; feedback from these movements provides information about the distance of objects from the viewer.

conversation analysis In qualitative research, the process of analysing conversations for meaning, themes, and patterns (in speech and psychology).

conversion A defence mechanism that involves converting an intrapsychic conflict into a physical form, such as blindness, deafness, paralysis or numbness.

conversion disorder A somatoform disorder involving the actual loss of bodily function, such as blindness, paralysis and numbness, due to excessive anxiety.

conversion effect When minority influence brings about a sudden and dramatic internal and private change in the attitudes of a majority.

coordination loss Deterioration in group performance in comparison to individual performance due to problems in coordinating behaviour.

coping strategy A plan of action that a person follows to reduce the perceived level of stress, either in anticipation of encountering a stressor or in response to its occurrence.

cornea The transparent tissue covering the front of the eye.

coronary heart disease (CHD) The narrowing of blood vessels that supply nutrients to the heart.

corpus callosum A large bundle of axons ('white matter') that connects the cortex of the two cerebral hemispheres.

correctional mechanism In a regulatory process, the mechanism that is capable of restoring the system variable to the set point.

correlation coefficient A measurement of the degree to which two variables are related.

correlational study The observation of two or more variables in the behaviour or other characteristics of people or other animals.

counterbalancing A systematic variation of conditions in an experiment, such as the order of presentation of stimuli, so that different participants encounter them in different orders; prevents confounding of independent variables with time-dependent processes such as habituation or fatigue.

counter-transference The process by which the therapist projects their emotions onto the client.

covert sensitisation A method used by behavioural therapists in which a client imagines the aversive consequences of their inappropriate behaviour.

cranial nerve A bundle of nerve fibres attached to the base of the brain; conveys sensory information from the face and head and carries messages to muscles and glands.

creativity A process through which end products are created, usually in novel, unusual or unexpected ways.

cri-du-chat syndrome A genetic disorder arising from partial deletion of chromosome 5 which is associated with mental retardation and mewing sounds (hence cri-du-chat).

critical period A specific time in development during which certain experiences must occur for normal development to occur.

cross-cultural psychology The branch of psychology that studies and compares the effects of culture on behaviour.

crowd A group event involving a large number of people in the same place at the same time acting in a collective fashion.

CS pre-exposure effect The name given to the effect seen in latent inhibition – the phenomenon whereby a novel object is more successfully paired with a familiar one in conditioning.

cultural evolution The adaptive changes of cultures in response to environmental changes over time.

cultural psychology The branch of psychology which studies variations in behaviour within, but not necessarily across, cultures.

culture-bound syndrome Highly unusual mental disorders, similar in nature to non-psychotic mental disorders, that appear to be specific to only one or a few cultures.

cumulative recorder A mechanical device connected to an operant chamber for the purpose of recording operant responses as they occur in time.

cyclothymic disorder A less severe form of bipolar disorder.

cytoskeleton The skeletal structure of neurons.

D

dark adaptation The process by which the eye becomes capable of distinguishing dimly illuminated objects after going from a bright area to a dark one.

debriefing Full disclosure to research participants of the true nature and purpose of a research project after its completion.

deductive reasoning Inferring specific instances from general principles or rules.

deep dyslexia A severe inability to read; common words are sometimes read but are often replaced by semantically similar words.

deep processing The analysis of the complex characteristics of a stimulus, such as its meaning or its relationship to other stimuli.

defence mechanisms Mental systems that become active whenever unconscious instinctual drives of the id come into conflict with internalised prohibitions of the superego.

deferred imitation A child's ability to imitate the actions they have observed others perform. Piaget believed deferred imitation to result from the child's increasing ability to form mental representations of behaviour performed by others.

deferred imitation paradigm A child is exposed to an adult who is performing actions with a set of novel stimuli; after a delay, the child is then allowed to manipulate objects used by the experimenter. Identical use indicates a degree of imitation and learning.

deindividuation The loss of one's individuality and sense of personal responsibility in collective events.

delta activity The rhythmical activity of the electroencephalogram, having a frequency of less than 3.5 Hz, indicating deep (slow-wave) sleep.

delusions Beliefs that are obviously contrary to fact.

delusions of control The false belief that one's thoughts and actions are being controlled by other people or forces.

delusions of grandeur The false belief that one is famous, powerful or important.

delusions of persecution The false belief that other people are plotting against one.

dementia Cognitive deterioration associated with degenerative brain disorders.

dementia of the Alzheimer type (DAT) Cognitive impairment that arises from Alzheimer's disease.

dendrite A tree-like part of a neuron on which the terminal buttons of other neurons form synapses.

dependent variable The event whose value is measured in an experiment. Manipulation of independent variables demonstrates whether they affect the value of dependent variables.

depersonalisation The perception and treatment of self and others not as unique individual persons but as prototypical embodiments of a social group.

descriptive statistics Mathematical procedures for organising collections of data, such as determining the mean, the median, the range, the variance and the correlation coefficient.

detector In a regulatory process, a mechanism that signals when the system variable deviates from its set point.

determinant See causal event.

deuteranopia A form of hereditary anomalous colour vision; caused by defective 'green' cones in the retina.

developmental dyslexia A difficulty in learning to read despite adequate intelligence and appropriate educational opportunity.

developmental psychology The branch of psychology that studies the changes in behavioural, perceptual and cognitive capacities of organisms as a function of age and experience.

deviation IQ A procedure for computing the intelligence quotient; compares a child's score with those received by other children of the same chronological age.

Diagnostic and Statistical Manual IV (DSM-IV TR) A widely used manual for classifying psychological disorders.

diathesis model The notion that asymmetrical frontal cortex activation may predispose individuals to react negatively or positively to emotional stimuli.

diathesis-stress model A causal account of mental disorders based on the idea that mental disorders develop when a person possesses a predisposition for a disorder and faces stressors that exceed their abilities to cope with them.

dichotic listening A task that requires a person to listen to one of two different messages being presented simultaneously, one to each ear, through headphones.

dichromacy A deficit in colour vision in which a photopigment is missing.

difference threshold An alternative name for just-noticeable difference (jnd).

diffusion of responsibility An explanation of the failure of bystander intervention stating that, when several bystanders are present, no one person assumes responsibility for helping.

discourse analysis Qualitative method of analysis which involves the identification of themes, thoughts and ideas from transcripts of conversations or discussions.

discrimination (1) In operant conditioning, responding only when a specific discriminative stimulus is present but not when similar stimuli are present. (2) The differential treatment of people based on their membership in a particular group – discrimination is typically ‘against’ an out-group and in favour of the in-group. (3) In classical conditioning, the appearance of a conditioned response (CR) when one stimulus is presented (the CS+) but not another (the CS–).

discriminative stimulus In operant conditioning, the stimulus that sets the occasion for responding because, in the past, a behaviour has produced certain consequences in the presence of that stimulus.

disorganised schizophrenia A type of schizophrenia characterised primarily by disturbances of thought and a flattened or silly affect.

display rule A culturally determined rule that prescribes the expression of emotions in particular situations.

dispositional factors Individual personality characteristics that affect a person’s behaviour.

dissociative disorders A class of disorders in which anxiety is reduced by a sudden disruption in consciousness, which in turn produces changes in one’s sense of identity.

dissociative identity disorder A rare dissociative disorder in which two or more distinct personalities exist within the same person; each personality dominates in turn.

distinctive feature A physical characteristic of an object that helps distinguish it from other objects.

distinctiveness The extent to which a person engages in a particular behaviour in one situation but not in other situations.

divided attention Attention which is divided among two or more tasks.

dizygotic (DZ) twins Twins that are fertilised from different ova (and are, therefore, genetically different).

DNA ‘Deoxyribonucleic acid’. The DNA structure resembles that of a twisted ladder. Strands of sugar and phosphates are connected by rungs made from adenine and thymine and guanine and cytosine.

doctrine of apperception The belief that we do not see objects as separate elements but as wholes.

doctrine of specific nerve energies Johannes Müller’s observation that different nerve fibres convey specific information from one part of the body to the brain or from the brain to one part of the body.

doctrine of the association of ideas The belief that various associations are made between events and ideas, which allow meaningful thought to occur.

dominant allele The form of the gene that controls the expression of a trait. When a gene pair contains two dominant alleles or when it contains both a dominant and a recessive allele, the trait regulated by the dominant gene will be expressed.

door-in-the-face tactic Multiple-request technique to gain compliance, in which the focal request is preceded by a larger request that is bound to be refused.

dopamine hypothesis The hypothesis that the positive symptoms of schizophrenia are caused by overactivity of synapses in the brain that use dopamine.

double-aspect theory The belief that mental and physical events are characteristics of the same underlying entity.

double-bind The conflict caused for a child when they are given inconsistent messages or cues from a parent.

double-blind study An experiment in which neither the subject nor the experimenter knows the value of the independent variable.

Down syndrome A genetic disorder caused by a chromosomal aberration resulting in an extra twenty-first chromosome. People having Down syndrome are generally short, have broad skulls and round faces, and suffer impairments in physical, psychomotor and cognitive development.

drive A condition, often caused by physiological changes or homeostatic disequilibrium, that energises an organism’s behaviour.

drive reduction hypothesis The hypothesis that a drive (resulting from physiological need or deprivation) produces an unpleasant state that causes an organism to engage in motivated behaviours. Reduction of drive is assumed to be reinforcing.

DSM-IV TR See *Diagnostic and Statistical Manual IV*.

dual-action antidepressants Antidepressants which block certain serotonin receptors and inhibit its reuptake.

dual-route model of reading A model which proposes that there are two, non-semantic routes that take the reader from spelling to sound. The lexical route retrieves words from the mental lexicon; the sublexical route converts letters into sound using grapheme–phoneme correspondence rules.

dual-task methodology A protocol in attention research whereby the participant undertakes two tasks simultaneously in order to determine the degree to which the performance of one interferes with the other.

dualism or Cartesian dualism The philosophical belief that reality consists of mind and matter.

Duchenne smile The genuine smile of joy characterised by the activation of specific facial muscles.

dyslexia A disorder impaired reading ability.

dysthymic disorder A less severe form of depression.

E

echoic memory A form of sensory memory for sounds that have just been perceived.

eclectic approach A form of therapy in which the therapist uses whatever method they feel will work best for a particular client at a particular time.

educational psychology The branch of psychology which applies psychological principles to our understanding of the educational process and children’s learning and adjustment in education.

effortful processing Practising or rehearsing information through either shallow or deep processing.

ego The self. The ego also serves as the general manager of personality, making decisions regarding the pleasures that will be pursued at the id’s request and the moral dictates of the superego that will be followed.

egocentrism Self-centredness; preoperational children can see the world only from their own perspective.

ego-ideal The internalisation of what a person would like to be.

egoistic relative deprivation Sense of personally having less than one feels one is entitled to relative to one’s aspirations or to other individuals.

elaboration likelihood model A model that explains the effectiveness of persuasion. The central route requires the person to think critically about an argument, and the peripheral route entails the association of the argument with something positive.

elaborative rehearsal The processing of information on a meaningful level, such as forming associations, attending to the meaning of the material, thinking about it and so on.

Electra complex In Freudian thinking, a girl's attachment to her father; named after the mythical Electra who killed her mother and mother's lover in order to avenge her father's death.

electrocardiogram (ECG) The measurement and graphical presentation of the electrical activity of the heart, recorded by means of electrodes attached to the skin.

electroconvulsive therapy (ECT) Treatment of severe depression that involves passing small amounts of electric current through the brain to produce seizure activity.

electrodermal response (see galvanic skin response).

electroencephalogram (EEG) The measurement and graphical presentation of the electrical activity of the brain, recorded by means of electrodes attached to the scalp.

electroencephalography (EEG) A technique which measures the electrical activity of the brain using electrodes.

electromyogram (EMG) The measurement and graphical presentation of the electrical activity of muscles, recorded by means of electrodes attached to the skin above them.

electro-oculogram (EOG) The measurement and graphical presentation of the electrical activity caused by movements of the eye, recorded by means of electrodes attached to the skin adjacent to the eye.

elevation A monocular cue of depth perception; objects nearer the horizon are seen as farther from the viewer.

embryo stage The second stage of prenatal development, beginning two weeks and ending about eight weeks after conception, during which the heart begins to beat, the brain starts to function and most of the major body structures begin to form.

emotion A relatively brief display of a feeling made in response to environmental events having motivational significance or to memories of such events.

emotion-focused coping Any coping behaviour that is directed towards changing one's own emotional reaction to a stressor.

emotional disclosure A method by which trauma can be reduced by writing about that trauma and explaining why the response to trauma exists

emotional intelligence An understanding of the social and emotional components of interactions with others.

emotional stability The tendency to be relaxed and at peace with oneself.

empiricism The philosophical view that all knowledge is obtained through the senses.

encephalisation Increased brain size.

encoding The process by which sensory information is converted into a form that can be used by the brain's memory system.

encoding specificity The principle that how we encode information determines our ability to retrieve it later.

endocrine gland A gland that secretes a hormone.

enuresis Bed-wetting; a slow-wave sleep disorder.

enzymes Proteins that regulate the structure of bodily cells and the processes occurring within those cells.

epigenetics A field of study examining how experience and learning can alter gene expression.

epilepsy A seizure disorder which involves excessive and uncontrollable firing of neurons.

episodic memory A type of long-term memory that serves as a record of our life's experiences. Also called autobiographical memory.

ergonomics/human factors psychology The branch of psychology that studies the ways in which people and machines work together and helps design machines that are safer and easier to operate.

escape response An operant response acquired through negative reinforcement that terminates an aversive stimulus.

ethnolinguistic group Social group defined principally in terms of its language.

ethno-methodology Method devised by Garfinkel, involving the violation of hidden norms to reveal their presence.

ethology The branch of comparative psychology which studies the behaviour of animals and uses this information to draw conclusions about human behaviour and evolution.

event-related potential (ERP) A technique which records the brain's electrical activity across several presentations of the same stimuli.

evolutionary preparedness The notion that we are predisposed to fear certain objects and contexts.

evolutionary psychology The branch of psychology that studies the ways in which an organism's evolutionary history contributes to the development of behavioural patterns and cognitive strategies related to reproduction and survival during its lifetime.

exemplar A memory of particular examples of objects or situations that are used as the basis of classifying objects or situations into concepts.

exhibitionism Exposure of genitals in public for sexual gratification.

expectancy The belief that a certain consequence will follow a certain action.

experiential intelligence According to Sternberg, the ability to deal effectively with novel situations and to solve automatically problems that have been encountered previously.

experiment A study in which the experimenter changes the value of an independent variable and observes whether this manipulation affects the value of a dependent variable. Only experiments can confirm the existence of cause-and-effect relations among variables.

experimental brain lesion Deliberate damage to a particular region of the brain.

experimental group A group of participants in an experiment, the members of which are exposed to a particular value of the independent variable, which has been manipulated by the experimenter.

experimental psychology The experimental study of human behaviour, especially sensation and perception.

explicit memory Memory that can be described verbally and of which a person is therefore aware.

expressed emotion Expressions of criticism, hostility and emotional over-involvement by family members towards a person with schizophrenia.

externality effect In infancy, the idea that the child is more concerned with the contours of visual stimuli and rarely attends to internal features.

extinction In classical conditioning, the elimination of a response that occurs when the CS is repeatedly presented without being followed by the UCS. A decrease in the frequency of a previously reinforced response because it is no longer followed by a reinforcer.

extraversion The tendency to seek the company of other people, to be lively, and to engage in conversation and other social behaviours with them.

F

facial feedback hypothesis The notion that our awareness of facial expression influences the way we feel.

factor analysis A statistical procedure that identifies common factors among groups of data.

false consensus The tendency for a person to perceive their own behaviour as representative of general consensus of how other people behave.

family therapy A form of therapy in which the maladaptive relationships among family members is inferred from their behaviour and attempts are made to restructure these behaviours into more adaptive ones.

fast mapping The quick learning of new, content words by children.

female sexual dysfunction The inability to achieve orgasm.

fetish Unusual sexual attachment to objects such as articles of clothing, learned through classical conditioning.

fetishism The use of non-living things for sexual excitement.

field experiment An experiment that is conducted in a realistic environment and over which the experimenter has little experimental control.

fight or flight response Physiological reactions that help ready us to fight or to flee a dangerous situation.

figure A visual stimulus that is perceived as a self-contained object.

fissures Grooves between the bulges (gyri) of the cortex.

five-factor model A theory stating that personality is composed of five primary dimensions: neuroticism, extraversion, openness, agreeableness and conscientiousness. This theory was developed using factor analyses of ratings of the words that people use to describe personality characteristics.

fixation (1) A brief interval between saccadic eye movements during which the eye does not move; visual information is gathered during this time. (2) An unconscious obsession with an erogenous zone resulting from failure to resolve the crisis associated with the corresponding stage of psychosexual development.

fixation point The area in space where a gaze is fixed.

fixed-interval schedule A schedule of reinforcement in which the first response that is made after a fixed interval of time since the previous reinforcement (or the start of the session) is reinforced.

fixed-ratio schedule A schedule of reinforcement in which reinforcement occurs only after a fixed number of responses have been made since the previous reinforcement (or the start of the session).

flashbulb memory A lucid memory for an event or experience that occurred during a particularly emotional experience.

flooding The intense arousal of anxious patients, usually through exposure to the anxiety-provoking stimulus or context, which is intended to demonstrate that no harm comes from such exposure.

foetal alcohol syndrome A disorder that adversely affects an offspring's brain development that is caused by the mother's alcohol intake during pregnancy.

foetal learning The notion that the foetus is capable of rudimentary learning while in the womb.

foetal stage Third and final stage of prenatal development which lasts for about seven months, beginning with the appearance of bone tissue and ending with birth.

foot-in-the-door tactic Multiple-request technique to gain compliance, in which the focal request is preceded by a smaller request that is bound to be accepted.

forensic/criminological psychology The branch of psychology which uses psychological principles to study and assist in the legal and criminal process.

form constancy The tendency to perceive objects as having a constant form, even when they are rotated or their distance from the observer changes.

formal concept A category of objects or situations defined by listing their common essential characteristics, as dictionary definitions do.

fovea A small pit near the centre of the retina containing densely packed cones; responsible for the most acute and detailed vision.

fragile X A genetic disorder which leads to mental retardation. The X chromosome is fragile and easily broken.

fraternal twins See dizygotic (DZ) twins.

fraternalistic relative deprivation Sense that one's group has less than it is entitled to relative to its aspirations or to other groups.

free association A method of Freudian analysis in which an individual is asked to relax, clear their mind of current thoughts, and then report all thoughts, images, perceptions and feelings that come to mind.

free nerve ending An unencapsulated (naked) dendrite of somatosensory neurons.

frontal lobe The front portion of the cerebral cortex, including Broca's speech area and the motor cortex; damage impairs movement, planning and flexibility in behavioural strategies.

frotteurism Rubbing against a person in public for sexual gratification.

frustration-aggression hypothesis Theory that all frustration leads to aggression, and all aggression comes from frustration. Used to explain prejudice and intergroup aggression.

function word A preposition, article or other word that conveys little of the meaning of a sentence but is important in specifying its grammatical structure.

functional hemispheric asymmetry The idea that a function is located in one cerebral hemisphere.

functional magnetic resonance imaging (fMRI) A development of MRI which allows the observation of brain function and not just structure.

functionalism The strategy of understanding a species' structural or behavioural features by attempting to establish their usefulness with respect to survival and reproductive success.

fundamental attribution error The tendency to overestimate the significance of dispositional factors and underestimate the significance of situational factors in explaining other people's behaviour.

fundamental frequency The lowest, and usually most intense, frequency of a complex sound; most often perceived as the sound's basic pitch.

G

g factor According to Spearman, a factor of intelligence that is common to all intellectual tasks; includes apprehension of experience, education of relations and education of correlates.

gain–loss hypothesis Paradox of liking people more if they initially dislike us and then later like us; and of liking them less if the sequence is reversed.

galvanic skin response (GSR) A measure of the electrical activity of the skin.

ganglion cell A neuron in the retina that receives information from photoreceptors by means of bipolar cells and from which axons proceed through the optic nerves to the brain.

gaze Looking at someone's eyes.

gender schema theory Argues that children construct a 'schema' – a mental representation – of male and female and pay especial attention to features of their own sex.

general adaptation syndrome (GAS) The model proposed by Selye to describe the body's adaptation to chronic exposure to severe stressors. The body passes through an orderly sequence of three physiological stages: alarm, resistance and exhaustion.

general language discrimination hypothesis The notion that children can discriminate sentences from two languages based on extracting linguistic properties from these languages.

generalisation (1) The conclusion that the results obtained from a sample apply also to the population from which the sample was taken. (2) In classical conditioning, CRs elicited by stimuli that resemble the CS used in training. (3) In operant conditioning, the occurrence of responding when a stimulus similar (but not identical) to the discriminative stimulus is present.

generalised anxiety disorder (GAD) Excessive worry about all matters relating to the individual's life.

genes Small units of chromosomes that direct the synthesis of proteins and enzymes.

genetic counselling A form of counselling in which people receive information regarding their family history of genetic disorders.

genetic disorders Inherited disorders of behaviour that arise from faulty genetic material.

genetic epistemology The study of the origin of knowledge in the development of the child.

genetics The study of the genetic make-up of organisms and how it influences physical and behavioural characteristics.

genital stage The final of Freud's psychosexual stages (from puberty through adolescence). During this stage, the adolescent develops adult sexual desires.

genotype An organism's genetic make-up.

geon According to Biederman, an elementary shape that can serve as a prototype in recognising objects; a given object can consist of one or more individual geons.

gerontology The study of the process of ageing.

Gestalt psychology A school of psychology that asserts that the perception of objects is produced by particular configurations of the elements of stimuli; that cognitive processes can be understood by studying their organisation, not their elements.

gestalt therapy A form of therapy emphasising the unity of mind and body by teaching the client to 'get in touch' with unconscious bodily sensations and emotional feelings.

Gilles de la Tourette's syndrome A neurological disorder characterised by tics and involuntary utterances, some of which may involve obscenities and the repetition of others' utterances.

glia/glial cell A cell of the central nervous system that provides support for neurons and supplies them with some essential chemicals.

glucocorticoid A chemical, such as cortisol, that influences the metabolism of glucose, the main energy source of the body.

glucose A sugar which is the primary source of fuel for the body's cells.

glucostatic hypothesis The hypothesis that hunger is caused by a low level or low availability of glucose, a condition that is monitored by specialised sensory neurons.

glucostats Hypothetical entity which detects decreases in blood sugar.

glycogen An insoluble carbohydrate that can be synthesised from glucose or converted to it; used to store nutrients.

good continuation A Gestalt law of organisation; given two or more interpretations of elements that form the outline of the figure, the simplest interpretation will be preferred.

grapheme–phoneme correspondence (GPC) rules The rules used to convert written words into spoken sounds.

graphemes The smallest units of written words.

grey matter The portions of the central nervous system that are abundant in cell bodies of neurons rather than axons.

ground A visual stimulus that is perceived as a formless background against which objects are seen.

grounded theory A form of qualitative analysis which deliberately constructs theories on the basis of information derived from transcripts of conversations and discussions.

group A collection of individuals who have a shared definition of who they are and what they should think, feel and do – people in the same group generally have common interests and goals.

group polarisation The tendency for a group decision to be more extreme than the mean of its members' positions, in the direction favoured by the mean.

group psychotherapy Therapy in which two or more clients meet simultaneously with a therapist, discussing problems within a supportive and understanding environment.

groupthink The tendency to avoid dissent in the attempt to achieve group consensus in the course of decision-making.

gustation The sense of taste.

gyri Bulges in the surfaces of the cortex.

H

h The proportion of variance associated with genetic differences among individuals.

habituation The simplest form of learning; learning not to respond to an unimportant event that occurs repeatedly.

hallucinations Perceptual experiences that occur in the absence of external stimulation of the corresponding sensory organ.

handedness The degree to which an individual preferentially uses one hand for most activities.

haze A monocular cue of depth perception; objects that are less distinct in their outline and texture are seen as farther from the viewer.

health psychology The branch of psychology which applies psychological principles to health behaviour and illness prevention.

heredity The sum of the traits and tendencies inherited from a person's parents and other biological ancestors.

heritability The degree to which the variability of a particular trait in a particular population of organisms is a result of genetic differences among those organisms.

hertz (Hz) The primary measure of the frequency of vibration of sound waves; cycles per second.

heuristics Cognitive short-cuts that provide adequately accurate inferences for most of us most of the time.

'hidden observer' phenomenon The phenomenon whereby the hypnotist places a hand on the shoulder of the hypnotised and appears to be able to talk to a hidden part of the hypnotised person's body.

hippocampus A structure in the limbic system, located deep in the temporal lobe, which plays an important role in memory and learning.

homeostasis The process by which important physiological characteristics (such as body temperature and blood pressure) are regulated so that they remain at their optimum level.

hormone A chemical substance secreted by an endocrine gland that has physiological effects on target cells in other organs.

hue A perceptual dimension of colour, most closely related to the wavelength of a pure light.

human factors psychology See ergonomics.

humanistic approach An approach to the study of personality in which the emphasis is placed on the positive, fulfilling aspects of life.

humanistic psychology An approach to the study of human behaviour that emphasises human experience, choice and creativity, self-realisation, and positive growth.

humanistic therapy A form of therapy focusing on the person's unique potential for personal growth and self-actualisation.

Huntington's disease A genetic disorder caused by a dominant lethal gene in which a person experiences slow but progressive mental and physical deterioration.

hypnosis The process whereby verbal instructions can be acted on by another without conscious awareness of these instructions.

hypnotic analgesia The use of hypnosis to alleviate pain.

hypochondriasis A somatoform disorder involving persistent and excessive worry about developing a serious illness. People with this disorder often misinterpret the appearance of normal physical aches and pains.

hypothalamus A region of the brain located just above the pituitary gland; controls the autonomic nervous system and many behaviours related to regulation and survival, such as eating, drinking, fighting, shivering and sweating.

hypothesis A statement, usually designed to be tested by an experiment, that tentatively expresses a cause-and-effect relationship between variables.

hypothetico-deductive A methodological approach which sets hypotheses and then constructs experiments to test them.

I

iconic memory A form of sensory memory that holds a brief visual image of a scene that has just been perceived.

id The unconscious reservoir of libido, the psychic energy that fuels instincts and psychic processes.

idealism The belief that all ideas ultimately come from information from the senses.

idiot savants Autistic individuals who excel in specific abilities such as mental arithmetic, drawing, painting or music.

illusion of out-group homogeneity A belief that members of groups to which one does not belong are more similar to one another than are members of one's own group.

illusory correlation The perception of an apparent relation between two distinctive elements that does not actually exist or is enormously exaggerated.

immune system A network of organs and cells that protects the body from invading bacteria, viruses and other foreign substances.

immunoglobulins The antibodies that are released by B lymphocytes.

implicit association test (IAT) A test to measure the speed with which people unconsciously and automatically associate evaluative words with social categories – a measure of unconsciously held stereotypes.

implicit memory Memory that cannot be described verbally and of which a person is therefore not aware.

implosion therapy A form of therapy that attempts to rid people of fears by arousing them intensely until their responses diminish through habituation and they learn that nothing bad happens.

impression formation The way in which we form impressions of others and attribute specific characteristics and traits to them.

inattention blindness A perceptual phenomenon whereby a person fails to see particularly obvious or dramatic changes to a visual stimulus because their attention has been drawn to another aspect of it.

incest The mating of close relatives who share many of the same genes.

inclusive fitness The reproductive success of those who share common genes.

incongruence A discrepancy between a client's real and ideal selves.

independent groups design A design whereby each group in an experiment contains different participants. Also called between-groups design.

independent variable The variable that is manipulated in an experiment as a means of determining cause-and-effect relations. Manipulation of an independent variable demonstrates whether it affects the value of the dependent variable.

individual differences The branch of psychology concerned with the individual factors that make us different (such as personality, sex, race, etc.).

inductive reasoning Inferring general principles or rules from specific facts.

infantile amnesia Loss of memory for events that occur in infancy.

inferential statistics Mathematical procedures for determining whether relations or differences between samples are statistically significant.

inflection A change in the form of a word (usually by adding a suffix) to denote a grammatical feature such as tense or number.

information processing An approach used by cognitive psychologists to explain the workings of the brain; information received through the senses is processed by systems of neurons in the brain.

informational influence An influence to accept information from another as evidence about reality.

informed consent Agreement to participate as a subject in an experiment after being informed about the nature of the research and any possible adverse effects.

ingratiation Strategic attempt to get someone to like you in order to obtain compliance with a request.

inner speech To Vygotsky, the internalisation of words and the mental manipulation of words as symbols for objects in the environment.

insomnia Chronic and relentless inability to fall asleep at the appropriate times.

intelligence A person's ability to learn and remember information, to recognise concepts and their relations, and to apply the information to their own behaviour in an adaptive way.

intelligence quotient (IQ) A simplified single measure of general intelligence; by definition, the ratio of a person's mental age to their chronological age, multiplied by 100; often derived by other formulas.

interactionism The view that the mind and body are separate physical entities which interact.

intergroup relations Relations between groups or between individuals who are members of different groups and who are interacting in terms of their respective group memberships.

intermanual conflict The effect sometimes seen after split-brain surgery whereby one hand appears to behave in a contradictory way to the other.

intermittent reinforcement The occasional reinforcement of a particular behaviour; produces responding that is more resistant to extinction.

International Classification of Disorders 10 (ICD-10) A manual similar to DSM.

interneuron A neuron located entirely within the central nervous system.

interpersonal attraction People's tendency to approach each other and to evaluate each other positively.

interpersonal distance The distance apart at which people feel most comfortable in interacting in different situations, relationships and cultures.

interposition A monocular cue of depth perception; an object that partially occludes another object is perceived as closer.

interrater reliability The degree to which two or more independent observers agree in their ratings of another organism's behaviour.

intervening variables In behaviourism, the variables that modify the relationship between stimulus and response.

intraspecific aggression The attack by one animal upon another member of its species.

introspection Literally, 'looking within', in an attempt to describe one's own memories, perceptions, cognitive processes or motivations.

introversion The tendency to avoid the company of other people, especially large groups of people; shyness.

ion A positively or negatively charged particle; produced when many substances dissolve in water.

ion channel A special protein molecule located in the membrane of a cell; controls the entry or exit of particular ions.

ion transporter A special protein molecule located in the membrane of a cell; actively transports ions into or out of the cell.

iris The pigmented muscle of the eye that controls the size of the pupil.

isolation aphasia A language disturbance that includes an inability to comprehend speech or to produce meaningful speech accompanied by the ability to repeat speech and to learn new sequences of words; caused by brain damage to the left temporal/parietal cortex that spares Wernicke's area.

J

James–Lange theory A theory of emotion that suggests that behaviours and physiological responses are directly elicited by situations and that feelings of emotions are produced by feedback from these behaviours and responses.

just-noticeable difference (jnd) The smallest difference between two similar stimuli that can be distinguished. Also called difference threshold.

K

kin selection A type of selection that favours altruistic acts aimed at individuals who share some of the altruist's genes, such as parents, siblings, grandparents, grandchildren and, under certain conditions, distant relatives.

L

language acquisition device A hypothetical brain function which all children are said to have and which embodies the rules of universal grammar.

latency period The fourth of Freud's psychosexual stages, between the phallic stage and the genital stages during which there are no unconscious sexual urges or intrapsychic conflicts.

latent content The hidden message of a dream, produced by the unconscious.

latent inhibition The phenomenon whereby a novel object is more successfully paired with a familiar one in conditioning.

lateralisation Phenomenon whereby a function is the predominant responsibility of one side or part of the body or brain (e.g. speech production is lateralised in the left hemisphere).

law of attraction Byrne's theory that attraction towards a person bears a linear relationship to the proportion of attitudes associated with the person – the more similar you are to someone the more you like them.

law of closure A Gestalt law of organisation; elements missing from the outline of a figure are 'filled in' by the visual system.

law of effect Thorndike's observation that stimuli that occur as a consequence of a response can increase or decrease the likelihood of making that response again.

leader–member exchange (LMX) theory Theory that effective leadership rests on leaders developing personalised relationships with individual followers.

leakage A sign of expression of an emotion that is being masked.

learned helplessness A response to exposure to an inescapable aversive stimulus, characterised by reduced ability to learn a solvable avoidance task; thought to play a role in the development of some psychological disturbances.

learning An adaptive process in which the tendency to perform a particular behaviour is changed by experience.

lens The transparent organ situated behind the iris of the eye; helps to focus an image on the retina.

leptin Protein which is secreted by fat cells that have absorbed a large amount of triglyceride.

lexical awareness The ability to understand that speech and writing are composed of different, distinct elements called words.

libido An insistent, instinctual force that is unresponsive to the demands of reality; the primary source of motivation.

liking A feeling of personal regard, intimacy and esteem towards another person.

limbic cortex The cerebral cortex located around the edge of the cerebral hemispheres where they join with the brain stem; part of the limbic system.

limbic system A set of interconnected structures of the brain important in emotional and species-typical behaviour; includes the amygdala, hippocampus and limbic cortex.

linear perspective A monocular cue of depth perception; the arrangement or drawing of objects on a flat surface such that parallel lines receding from the viewer are seen to converge at a point on the horizon.

linguistic intergroup bias The use of concrete language that simply describes events when talking about positive out-group (and negative in-group) characteristics, and more general and abstract terms that relate to enduring traits when talking about negative out-group (and positive in-group) characteristics.

linguistic relativity The hypothesis that the language a person speaks is related to their thoughts and perceptions.

linguistics The study of the rules of language and the nature and meaning of written and spoken language.

lithium carbonate Drug used to treat bipolar disorder.

localisation of function The notion that functions may be localised in the brain at the neural, chemical or anatomical level.

locus of control An individual's beliefs that the consequences of their actions are controlled by internal person variables or by external environmental variables.

long-term memory Memory in which information is represented on a permanent or near-permanent basis.

long-term potentiation In learning and memory research, the strengthening of connections between neurons via repeated stimulation.

loving A combination of liking and a deep sense of attachment to, intimacy with, and caring for another person.

low-ball tactic Technique for inducing compliance in which a person who agrees to a request can feel committed even after finding that there is a hidden cost.

M

magnetic resonance imaging (MRI) Neuroimaging technique which allows neuropsychologists to observe the structure of the living brain by measuring the reverberation of hydrogen molecules in the brain as a magnetic field is passed over the head.

magnetoencephalography (MEG) A technique for measuring brain activation by detecting the activity of magnetic fields from a large number of neurons.

maintenance rehearsal The rote repetition of information; repeating a given item over and over again.

major depression Persistent and severe feelings of sadness and worthlessness accompanied by changes in appetite, sleeping and behaviour.

male sexual dysfunction The inability to achieve an erection.

mania Excessive emotional arousal and wild, exuberant, unrealistic activity.

manifest content The apparent storyline of a dream.

masking Attempting to hide the expression of an emotion.

matching A systematic selection of participants in groups in an experiment or (more often) a correlational study to ensure that the mean values of important subject variables of the groups are similar.

materialism A philosophical belief that reality can be known only through an understanding of the physical world, of which the mind is a part.

maturation Any relatively stable change in thought, behaviour or physical growth that is due to the ageing process and not to experience.

mean A measure of central tendency; the sum of a group of values divided by their number; the arithmetical average.

means-ends analysis An approach to problem-solving in which a person should look for differences between the current state and the goal state and seek ways to reduce these differences.

measure of central tendency A statistical measure used to characterise the value of items in a sample of numbers.

measure of variability A statistical measure used to characterise the dispersion in values of items in a sample of numbers.

median A measure of central tendency; the midpoint of a group of values arranged numerically.

medical model A perspective on mental illness which regards mental disorder as caused by specific abnormalities of the brain and nervous system.

medulla The part of the brain stem closest to the spinal cord; controls vital functions such as heart rate and blood pressure.

MEG See magnetoencephalography.

meiosis The form of cell division by which new sperm and ova are formed. The chromosomes within the cell are randomly rearranged so that new sperm and ova contain 23 individual chromosomes, or half of that found in other bodily cells.

memory The cognitive processes of encoding, storing and retrieving information.

meninges The three-layered set of membranes that enclose the brain and spinal cord.

menopause In women, the alternation in the endocrine system which leads to the pituitary gland and the hypothalamus releasing hormones that prevent the ovaries from controlling menstruation.

menstrual synchrony The phenomenon whereby menstrual cycles of more than one female become synchronous.

mental age A measure of a person's intellectual development; the level of intellectual development that could be expected for an average child of a particular age.

mental lexicon Hypothetical cognitive store of words and their meanings.

mental model A mental construction based on physical reality that is used to solve problems of logical deduction.

mental space (M-space) A hypothetical construct in Case's model of cognitive development similar to working memory, whose primary function is to process information from the external world.

mere exposure effect The formation of a positive attitude towards a person, place or thing, based solely on repeated exposure to that person, place or thing.

mesmerism Another word for hypnosis, named after Franz Anton Mesmer, an Austrian physician.

meta-analysis A statistical procedure by which the results of many studies are combined to estimate the magnitude of a particular effect.

metamemory Knowledge of the knowledge acquisition process.

method of loci A mnemonic system in which items to be remembered are mentally associated with specific physical locations or landmarks.

microtubules Parts of the neuron which perform specific functions.

midbrain The part of the brain stem just anterior to the pons; involved in control of fighting and sexual behaviour and in decreased sensitivity to pain during these behaviours.

minimal group paradigm Experimental methodology to investigate the effect of social categorisation alone on behaviour.

Minnesota Multiphasic Personality Inventory (MMPI) An objective test designed originally to distinguish individuals with different psychological problems from normal individuals. It has since become popular as a means of attempting to identify personality characteristics of people in many everyday settings.

minority influence Social influence processes whereby numerical or power minorities change the attitudes of the majority.

mirror neuron Neurons which fire when viewing an action as well as engaging in the same action

mnemonic system A special technique or strategy consciously employed in an attempt to improve memory.

mobile conjugate reinforcement paradigm An experimental method whereby a child learns that if it moves its foot, which is attached to a mobile, the mobile moves and, therefore, catches its attention.

mode The most frequently occurring number in a series of numbers.

model A relatively simple system that works on known principles and is able to do at least one of the things that a more complex system can do.

modelling A technique which has individuals modelling their behaviour on that of another.

modern racism Racist attitudes that are expressed in ways that do not immediately look like racism because on the surface they appear to reflect liberal values of egalitarianism, individualism, and so forth.

modularity The notion that the functions of the brain are organised by means of semi-independent and self-contained modules, each of which performs a specific function.

modulation An attempt to exaggerate or minimise the expression of an emotion.

monoamine oxidase inhibitors (MAOIs) Antidepressants which prevent enzymes at the synaptic gap from destroying amines.

monogamy The mating of one female and one male.

monozygotic (MZ) twins Twins that are fertilised from the same ovum (and are, therefore, genetically identical).

mood disorder A disorder characterised by significant shifts or disturbances in mood that affect normal perception, thought and behaviour. Mood disorders may be characterised by deep, foreboding depression, or a combination of the depression and euphoria.

moral realism The second stage of Piaget's model of moral development, which includes egocentrism and blind adherence to rules.

moral relativism The final of Piaget's stages of moral development in which the child becomes more flexible in interpreting moral issues, understands that moral responses are relative, that rules can be broken and that people are not always punished.

motion parallax A cue of depth perception. As we pass by a scene, objects closer to us pass in front of objects farther away.

motivated tactician A model of social cognition that characterises people as having multiple cognitive strategies available, which they choose among on the basis of personal goals, motives and needs.

motivation A general term for a group of phenomena that affect the nature, strength or persistence of an individual's behaviour.

motivation loss Deterioration in group performance in comparison to individual performance due to reduced motivation to perform.

motor association cortex Those regions of the cerebral cortex that control the primary motor cortex; involved in planning and executing behaviours.

motor neuron A neuron whose terminal buttons form synapses with muscle fibres. When an action potential travels down its axon, the associated muscle fibres will twitch.

muscle spindle A muscle fibre that functions as a stretch receptor; arranged parallel to the muscle fibres responsible for contraction of the muscle, it detects muscle length.

mutations Accidental alterations in the DNA code within a single gene. Mutations can either be spontaneous and occur naturally or be the result of environmental factors, such as exposure to high-energy radiation.

myelin The insulating material that encases most large axons.

N

narrative A mnemonic system in which items to be remembered are linked together by a story.

native language recognition hypothesis The notion that infants have the ability to identify words in their native language.

natural concept A category of objects or situations based on people's perceptions and interactions with things in the world; based on exemplars.

natural selection The consequence of the fact that organisms reproduce differentially, which is caused by behavioural differences among them. Within any given population, some animals – the survivors – will produce more offspring than will other animals.

naturalistic observation Observation of the behaviour of people or other animals in their natural environments.

need complementarity Winch's theory that we seek out apparent opposites, as they can best satisfy our needs.

negative after-image The image seen after a portion of the retina is exposed to an intense visual stimulus; a negative after-image consists of colours complementary to those of the physical stimulus.

negative allesthesia A decrease in the liking of food which is determined by internal, physiological signals.

negative feedback A process whereby the effect produced by an action serves to diminish or terminate that action. Regulatory systems are characterised by negative feedback loops.

negative reinforcement An increase in the frequency of a response that is regularly and reliably followed by the termination of an aversive stimulus.

negative symptoms Symptoms of schizophrenia that may include the absence of normal behaviour, flattened emotion, poverty of speech, lack of initiative and persistence, and social withdrawal.

neobehaviourism/radical behaviourism The strand of behaviourism developed by Skinner and others which described behaviour in terms of instrumental (or operant) learning.

nerve A bundle of nerve fibres that transmit information between the central nervous system and the body's sense organs, muscles and glands.

neural networks Computer models which hope to simulate the way in which the brain works.

neuroimaging Technique used to measure the anatomical structure and neural activity of the living human brain.

neuromodulator A substance secreted in the brain that modulates the activity of neurons that contain the appropriate receptor molecules.

neuron A nerve cell; consists of a cell body with dendrites and an axon whose branches end in terminal buttons that synapse with muscle fibres, gland cells or other neurons.

neuropsychological assessment Procedure whereby the effect of brain damage on cognitive, perceptual and emotional performance is evaluated by means of a single test or a collection of tests.

neuropsychological rehabilitation Process whereby brain-damaged individuals are trained to retrieve some of the functions lost through injury.

neuropsychology/neuroscience The study of central nervous system function.

neuroticism The tendency to be anxious, worried and full of guilt.

neurotransmitter A chemical released by the terminal buttons that causes the postsynaptic neuron to be excited or inhibited.

night terrors A children's disorder in which the child wakes up in absolute terror, usually after suddenly waking from stage 4 sleep; distinguishable from nightmares which are frightening dreams.

nominal fallacy The false belief that one has explained the causes of a phenomenon by identifying and naming it; for example, believing that one has explained lazy behaviour by attributing it to 'laziness'.

non-fluent (Broca's) aphasia Severe difficulty in articulating words, especially function words, caused by damage that includes Broca's area, a region of the frontal cortex on the left (speech-dominant) side of the brain.

non-verbal communication Transfer of meaningful information from one person to another by means other than written or spoken language (e.g. gaze, facial expression, posture, touch).

norm Data concerning comparison groups that permit the score of an individual to be assessed relative to their peers.

normative influence An influence to conform with the positive expectation of others, to gain social approval or to avoid social disapproval.

norms (in social psychology) Generally accepted rules and ways of behaving.

O

object permanence The idea that objects do not disappear when they are out of sight.

objective personality tests Tests for measuring personality that can be scored objectively, such as a multiple-choice or true/false test.

observational learning Learning through observing the kinds of consequence that others (called models) experience as a result of their behaviour.

obsession An involuntary recurring thought, idea or image.

obsessive-compulsive disorder Recurrent, unwanted thoughts or ideas and compelling urges to engage in repetitive ritual-like behaviour.

occipital lobe The rearmost portion of the cerebral cortex; contains the primary visual cortex.

occupational psychology See organisational psychology.

Oedipus complex In Freudian thinking, a boy's attachment to his mother; named after the mythical Greek king who unwittingly killed his father and married his mother.

oestrous cycle The ovulatory cycle in mammals other than primates; the sequence of physical and hormonal changes that accompany the ripening and disintegration of ova.

offender profiling A technique used by criminological psychologists which uses information about a criminal's behaviour to draw inferences about their personality.

olfaction The sense of smell.

olfactory bulbs Stalk-like structures located at the base of the brain that contain neural circuits that perform the first analysis of olfactory information.

olfactory mucosa The mucous membrane lining the top of the nasal sinuses; contains the cilia of the olfactory receptors.

operant chamber An apparatus in which an animal's behaviour can be easily observed, manipulated and automatically recorded.

operant conditioning A form of learning in which behaviour is affected by its consequences. Favourable consequences strengthen the behaviour and unfavourable consequences weaken the behaviour.

operational definition The definition of a variable in terms of the operations the experimenter performs to measure or manipulate it.

opioid A neuromodulator whose action is mimicked by a natural or synthetic opiate, such as opium, morphine or heroin.

opponent process The representation of colours by the rate of firing of two types of neurons: red/green and yellow/blue.

optic disc A circular structure located at the exit point from the retina of the axons of the ganglion cells that form the optic nerve.

optimal level of skill performance According to Fischer's skill model, the brain's maximal capacity for information processing.

optimum-level hypothesis The hypothesis that organisms will perform behaviour that restores the level of arousal to an optimum level.

oral stage The first of Freud's psychosexual stages, during which the mouth is the major erogenous zone – the major source of physical pleasure. Early in this stage, the mouth is used for sucking; later in the stage it is used for biting and chewing.

orbitofrontal cortex A region of the prefrontal cortex that plays an important role in recognition of situations that produce emotional responses.

organisational effect An effect of a hormone that usually occurs during prenatal development and produces permanent changes that alter the subsequent development of the organism. An example is androgenisation.

organisational/occupational psychology The branch of psychology concerned with the efficiency and effectiveness of organisation.

orienting response Any response by which an organism directs appropriate sensory organs (eyes, ears, nose) towards the source of a novel stimulus.

orthographic awareness The ability to recognise that writing systems have sets of rules that must be followed.

osmometric thirst The reduction in the concentration of sodium available across the membrane and the movement of water by osmosis dehydrates and shrinks the body's cells.

ossicle One of the three bones of the middle ear (the hammer, anvil and stirrup) that transmit acoustic vibrations from the eardrum to the membrane behind the oval window of the cochlea.

oval window An opening in the bone surrounding the cochlea. The stirrup presses against a membrane behind the oval window and transmits sound vibrations into the fluid within the cochlea.

overextension The use of a word to denote a larger class of items than is appropriate, for example, referring to the moon as a ball.

overtone A component of a complex tone; one of a series of tones whose frequency is a multiple of the fundamental frequency.

P

Pacinian corpuscle A specialised, encapsulated somatosensory nerve ending, which detects mechanical stimuli, especially vibrations.

paedophilia Sex with pre-pubescent children.

paleoanthropology The study of human evolution through interpreting fossil remains.

panic A feeling of fear mixed with hopelessness or helplessness.

panic disorder Unpredictable attacks of acute anxiety that are accompanied by high levels of physiological arousal and that last from a few seconds to a few hours.

papilla A small bump on the tongue that contains a group of taste buds.

parallel distributed processing A connectionist model devised by Seidenberg and McClelland to read regular, exception and non-words.

parallel processor The notion that the brain is composed of different modules which allow us to work simultaneously on more than one task.

paranoid schizophrenia A form of schizophrenia in which the person suffers from delusions of persecution, grandeur or control.

paraphilia Mental or behavioural disorder that has a sexual content.

parasympathetic branch The portion of the autonomic nervous system that activates functions that occur during a relaxed state.

parental investment The resources, including time, physical effort and risks to life, that a parent spends in procreation and in the feeding, nurturing and protecting of offspring.

parietal lobe The region of the cerebral cortex behind the frontal lobe and above the temporal lobe; contains the somatosensory cortex; is involved in spatial perception and memory.

passionate love An emotional, intense desire for sexual union with another person. Also called romantic love.

Pavlovian conditioning Similar to classical conditioning – the process by which a response normally elicited by one stimulus (the UCS) comes to be controlled by another stimulus (the CS) as well.

peg-word method A mnemonic system in which items to be remembered are associated with a set of mental pegs that one already has in memory, such as key words of a rhyme.

perception (1) A rapid, automatic, unconscious process by which we recognise what is represented by the information provided by our sense organs. (2) The detection of the more complex properties of a stimulus, including its location and nature; involves learning.

perceptual disorders Disorders in perception that tend to leave elementary sensation unimpaired.

period of concrete operations The third period in Piaget's theory of cognitive development during which children come to understand the conservation principle and other concepts, such as categorisation.

period of formal operations The fourth period in Piaget's theory of cognitive development during which individuals first become capable of more formal kinds of abstract thinking and hypothetical reasoning.

peripheral nervous system The cranial and spinal nerves; that part of the nervous system peripheral to the brain and spinal cord.

perseverance The tendency to continue to perform a behaviour even when it is not being reinforced.

perseveration Responding in a manner that was previously correct but is now inappropriate.

person variables Individual differences in cognition, which, according to Mischel, include competences, encoding strategies and personal constructs, expectancies, subjective values, and self-regulatory systems and plans.

personal constructs Idiosyncratic and personal ways of characterising other people.

personality A particular pattern of behaviour and thinking prevailing across time and situations that differentiates one person from another.

personality disorders Abnormalities in behaviour which impair social or occupational function.

personality trait An enduring personal characteristic that reveals itself in a particular pattern of behaviour in a variety of situations.

personality types Different categories into which personality characteristics can be assigned based on factors such as developmental experiences or physical characteristics.

phallic stage The third of Freud's psychosexual stages. During this stage, the primary erogenous zone is the genital area. At this time, children not only wish to stimulate their genitalia but also become attached to the opposite-sex parent.

phantom limb Sensations that appear to originate in a limb that has been amputated.

phenotype The outward expression of an organism's genotype; an organism's physical appearance and behaviour.

phenylketonuria (PKU) A genetic disorder caused by a particular pair of homozygous recessive genes and characterised by the inability to break down phenylalanine, an amino acid found in many high protein foods. The resulting high blood levels of phenylalanine cause mental retardation.

pheromone A chemical secreted by the body which induces stereotypical behaviour in the perceiving organism.

phi phenomenon The perception of movement caused by the turning on of two or more lights, one at a time, in sequence; responsible for the apparent movement of images in movies and television.

phobia Unreasonable fear of specific objects or situations, such as insects, animals or enclosed spaces, learned through classical conditioning.

phoneme The minimum unit of sound that conveys meaning in a particular language, such as /p/.

phonetic reading Reading by decoding the phonetic significance of letter strings; 'sound reading'.

phonological awareness The capacity to appreciate the sounds of words and be able to identify letters with sounds.

phonological dyslexia A reading disorder in which people can read familiar words but have difficulty reading unfamiliar words or pronounceable non-words because they cannot sound out words.

phonological loop See articulatory loop.

photopigment A complex molecule found in photoreceptors; when struck by light, it splits apart and stimulates the membrane of the photoreceptor in which it resides.

photoreceptor A receptive cell for vision in the retina; a rod or a cone.

physiological psychology The branch of psychology that studies the physiological basis of behaviour.

pituitary gland An endocrine gland attached to the hypothalamus at the base of the brain.

place-dependent memory Description of greater success in retrieval of material when acquisition and retrieval of information occur in the same location.

placebo An inert substance that cannot be distinguished from a real medication by the patient or subject; used as the control substance in a single-blind or double-blind experiment.

planned behaviour (theory of) Modification by Ajzen of the theory of reasoned action. It suggests that predicting a behaviour from an attitude measure is improved if people believe that they have control over that behaviour.

planum temporale Structure found in the primary auditory cortex which seems to be larger in the left than right hemisphere.

pleasure principle The rule that the id obeys: obtain immediate gratification, whatever form it may take.

polyandry The mating of one female with more than one male.

polygynandry The mating of several females with several males.

polygyny The mating of one male with more than one female.

pons The part of the brain stem just anterior to the medulla; involved in control of sleep.

positive brain allometry An increase in brain size relative to body size

positive reinforcement An increase in the frequency of a response that is regularly and reliably followed by an appetitive stimulus.

positive symptoms Symptoms of schizophrenia that may include thought disorder, hallucinations or delusions.

positivism The school of thought which states that all meaningful ideas can be reduced to observable material.

positron emission tomography (PET) Technique used to measure the degree of blood flow or oxygen consumption in the living brain as it engages in activity.

postconventional level Kohlberg's third and final level of moral development, in which people come to understand that moral rules include principles that apply across all situations and societies.

posterior Towards the back.

posterior part of the parietal cortex (PPC) Part of the brain responsible for the ability to locate objects in space.

posthypnotic amnesia A failure to remember what occurred during hypnosis; induced by suggestions made during hypnosis.

posthypnotic suggestibility The tendency of a person to perform a behaviour suggested by the hypnotist some time after the person has left the hypnotic state.

postsynaptic neuron A neuron with which the terminal buttons of another neuron form synapses and that is excited or inhibited by that neuron.

post-traumatic stress disorder (PTSD) Anxiety which follows a traumatic event.

preconventional level Kohlberg's first level of moral development, which bases moral behaviour on external sanctions, such as authority and punishment.

prefrontal cortex The anterior part of the frontal lobe; contains the motor association cortex.

prejudice An attitude or evaluation, usually negative, towards a group of people defined by their racial, ethnic or religious heritage or by their gender, occupation, sexual orientation, level of education, place of residence or membership of a particular group.

premotor stage of moral development First of Piaget's stages of moral development in which the child shows little understanding of rules or principles governing moral behaviour or understanding.

prenatal period The nine months between conception and birth. This period is divided into three developmental stages: the zygote, the embryo and the foetal stages.

preoperational period The second of Piaget's periods, which represents a 4–5 year transitional period between first being able to think symbolically and then being able to think logically. During this stage, children become increasingly capable of speaking meaningful sentences.

preoptic area A region at the base of the brain just in front of the hypothalamus; contains neurons that appear to control the occurrence of slow-wave sleep.

presynaptic neuron A neuron whose terminal buttons form synapses with and excite or inhibit another neuron.

primacy effect (1) The tendency to remember initial information. In the memorisation of a list of words, the primacy effect is evidenced by better recall of the words early in the list. (2) The tendency to form impressions of people based on the first information we receive about them.

primary appraisal In anxiety research, the initial evaluation of the environment as neutral, positive or negative.

primary auditory cortex The region of the cerebral cortex that receives information directly from the auditory system; located in the temporal lobes.

primary motor cortex The region of the cerebral cortex that directly controls the movements of the body; located in the back part of the frontal lobes.

primary punisher A biologically significant aversive stimulus, such as pain.

primary reinforcer A biologically significant appetitive stimulus, such as food or water.

primary somatosensory cortex The region of the cerebral cortex that receives information directly from the somatosensory system (touch, pressure, vibration, pain and temperature); located in the front part of the parietal lobes.

primary visual cortex (V1) The region of the cerebral cortex that receives information directly from the visual system; located in the occipital lobes.

principle of common fate States that elements that move in the same direction will be perceived as belonging together and forming a figure.

prisoner's dilemma Two-person game in which both parties are torn between competition and cooperation and, depending on mutual choices, both can win or both can lose.

proactive interference Interference in recall that occurs when previously learned information disrupts our ability to remember newer information.

problem-focused coping Any coping behaviour that is directed at reducing or eliminating a stressor.

process schizophrenia According to Bleuler, a form of schizophrenia characterised by a gradual onset and a poor prognosis.

progressive relaxation technique A relaxation technique involving three steps: (1) recognising the body's signals that indicate the presence of stress; (2) using those signals as a cue to begin relaxing; and (3) relaxing groups of muscles, beginning with those in the head and neck and then those in the arms and legs.

projection A defence mechanism in which one's unacceptable behaviours or thoughts are attributed to someone else.

projective tests Unstructured personality measures in which a person is shown a series of ambiguous stimuli, such as pictures, inkblots or incomplete drawings. The person is asked to describe what they 'see' in each stimulus or to create stories that reflect the theme of the drawing or picture.

proprioception Our sense of bodily position and movement.

prosocial behaviour Acts that are positively valued by society.

prosody The use of changes in intonation and emphasis to convey meaning in speech besides that specified by the particular words; an important means of communication of emotion.

prosopagnosia A form of visual agnosia characterised by difficulty in the recognition of people's faces; caused by damage to the visual association cortex.

prospective memory Remembering to perform an activity planned in the future.

protanopia A form of hereditary anomalous colour vision; caused by defective 'red' cones in the retina.

protective factor A factor – psychological or physiological – which can assist in the prevention of disease.

prototype A hypothetical idealised pattern that resides in the nervous system and is used to perceive objects or shapes by a process of comparison; recognition can occur even when an exact match is not found.

protoword A unique string of phonemes that an infant invents and uses as a word.

proximate causes Immediate environmental events and conditions that affect behaviour.

proximity principle See adjacency principle.

pseudohomophone A word which is legally spelled, is not a real word but sounds like a real word (e.g. 'phicks' sounds like 'fix').

pseudoword A word that is legally spelled but is not a real word.

psychiatry A branch of medicine concerned with the diagnosis and treatment of mental illness.

psychoactive substance use disorders Mental disorders that are characterised by addiction to drugs or by abuse of drugs.

psychoanalysis A form of therapy aimed at giving the client insight into their unconscious motivations and impulses; a branch of thinking which argues that behaviour can be explained by unconscious desires and impulses.

psychobiology See physiological psychology.

psychodynamic A term used to describe the Freudian notion that the mind is in a state of conflict among instincts, reasons and conscience.

psychodynamic therapy Therapy based on the understanding that unconscious drives, desires and impulses manifest themselves in behaviour.

psychogenic amnesia A dissociative disorder characterised by the inability to remember important events or personal information.

psychogenic fugue Amnesia with no apparent organic cause accompanied by a flight away from home.

psycholinguistics A branch of psychology devoted to the study of verbal behaviour.

psychological universal A psychological phenomenon that is seen across all peoples and cultures.

psychology The scientific study of the causes of behaviour; also, the applications of the findings of psychological research to the solution of problems.

psychoneuroimmunology Study of the interactions between the immune system and behaviour as mediated by the nervous system.

psychophysics A branch of psychology that measures the quantitative relation between physical stimuli and perceptual experience.

psychophysiology The measurement of physiological responses, such as blood pressure and heart rate, to infer changes in internal states, such as emotions.

psychosurgery Unalterable brain surgery used to relieve the symptoms of psychological disorders.

psychoticism The tendency to be aggressive, egocentric and antisocial.

puberty The period during which people's reproductive systems mature, marking the beginning of the transition from childhood to adulthood.

punishment A decrease in the frequency of a response that is regularly and reliably followed by an aversive stimulus.

pure word deafness The ability to hear, to speak and (usually) to write, without being able to comprehend the meaning of speech; caused by bilateral temporal lobe damage.

purposive behaviourism A variation on behaviourism proposed by Tolman which argued that variables intervening between stimulus and response were important and gave behaviour its purpose.

pursuit movement The movement that the eyes make to maintain an image of a moving image upon the fovea.

Q

q methodology In qualitative research methods, a complex procedure in which the person, not their responses, is treated as the variable.

qualitative analysis An approach to research which focuses on the ways in which people use words, express feelings and arguments. Themes and ideas can be interpreted from transcripts of these discussions.

quantitative research The methodological approach which regards human behaviour as measurable and subject to statistical analysis.

R

radical behaviourism See neobehaviourism.

random assignment An assignment of participants to the various groups of an experiment by random means, thereby ensuring comparable groups.

range The difference between the highest score and the lowest score of a sample.

rapid eye movement (REM) sleep A period of sleep during which dreaming, rapid eye movements, and muscular paralysis occur and the EEG shows beta activity.

ratio IQ A formula for computing the intelligence quotient; mental age divided by chronological age, multiplied by 100.

rational-emotive therapy Therapy based on the belief that psychological problems are caused not by upsetting events but by how people think about them.

rationalisation A defence mechanism that justifies an unacceptable action with a more acceptable, but false, excuse.

reaction formation A defence mechanism that involves behaving in a way that is the opposite of how one really feels because the true feelings produce anxiety.

reactive schizophrenia According to Bleuler, a form of schizophrenia characterised by rapid onset and brief duration; he assumed the cause was stressful life situations.

realistic conflict theory Sherif's theory of intergroup conflict that traces the complexion of intergroup behaviour to the nature of goal relations between groups.

reality principle The tendency to satisfy the id's demands realistically, which almost always involves compromising the demands of the id and superego.

reasoned action (theory of) Fishbein and Ajzen's model of the links between attitude and behaviour. A major feature is the proposition that the best way to predict a behaviour is to ask whether the person intends to do it.

receiver operating characteristic (ROC) curve A graph of hits and false alarms of subjects under different motivational conditions; indicates people's ability to detect a particular stimulus.

recency effect The tendency to recall later information. In the memorisation of a list of words, the recency effect is evidenced by better recall of the last words in the list.

receptive field That portion of the visual field in which the presentation of visual stimuli will produce an alteration in the firing rate of a particular neuron.

receptor cell A neuron that directly responds to a physical stimulus, such as light, vibrations or aromatic molecules.

receptor molecule A special protein molecule located in the membrane of the postsynaptic neuron that responds to molecules of the transmitter substance. Receptors such as those that respond to opiates are sometimes found elsewhere on the surface of neurons.

recessive allele The form of the gene that does not influence the expression of a trait unless it is paired with another recessive allele.

reciprocal altruism Altruism in which people behave altruistically towards one another because they are confident that such acts will be reciprocated towards either them or their kin.

reciprocal determinism The idea that behaviour, environment and personal variables, such as perception, interact to determine personality.

reciprocity The tendency to return, in kind, favours that others have done for us.

recovered memories Memories (usually negative) that are thought to be repressed in very early childhood and which access consciousness during therapy.

referent informational influence An influence to conform with a self-referent group norm that defines oneself as a group member.

reflex An automatic response to a stimulus, such as the blink reflex to the sudden approach of an object towards the eyes.

regulatory behaviour A behaviour that tends to bring physiological conditions back to normal, thus restoring the condition of homeostasis.

regulatory focus theory Higgins's theory of individual differences in whether people have a promotion (approach) or a prevention (avoidance) orientation to life.

rehabilitation In neuropsychology, the procedure whereby a person with brain injury is taught to re-learn cognitive and social functions and skills lost through the injury.

reification Assuming that your subject matter is real and concrete and actually exists in substance.

relationship dissolution model Duck's proposal of the sequence through which most long-term relationships proceed if they finally break down.

relative deprivation Sense of having less than that to which one feels entitled.

reliability The repeatability of a measurement; the likelihood that if the measurement was made again it would yield the same value.

REM sleep behaviour disorder A neurological disorder characterised by absence of the paralysis that normally occurs during REM sleep; the patient acts out their dreams.

remember-to-know shift Period when remembered information is transferred into long-term memory and becomes permanent knowledge.

repeated measures design A design whereby the same participants take part in each condition of an experiment. Also called within-groups design.

replication Repetition of an experiment or observational study to see whether previous results will be obtained.

representativeness heuristic A general rule for social judgement by which people classify a person, place or thing into the category to which it appears to be the most similar.

repression The mental force responsible for actively keeping memories, most of which are potentially threatening or anxiety provoking, from being consciously discovered.

reproductive strategies Different systems of mating and rearing offspring. These include monogamy, polygyny, polyandry and polygynandry.

reproductive success The number of viable offspring an individual produces relative to the number of viable offspring produced by other members of the same species.

resistance A development during therapy in which the client becomes defensive, unconsciously attempting to halt further insight by censoring their true feelings.

resistant attachment A kind of attachment in which infants show mixed reactions to their mothers. They may approach their mothers upon their return but, at the same time, continue to cry or even push their mothers away.

response bias Tendency to say yes or no when unsure whether a stimulus was detected.

response cost A decrease in the frequency of a response that is regularly and reliably followed by the termination of an appetitive stimulus.

retention interval Period between the acquisition and retrieval of material.

retina The tissue at the back inside surface of the eye that contains the photoreceptors and associated neurons.

retinal disparity The fact that points on objects located at different distances from the observer will fall on slightly different locations on the two retinas; provides the basis for stereopsis, one of the forms of depth perception.

retrieval The active processes of locating and using stored information.

retrieval cues Contextual variables, including physical objects or verbal stimuli, that improve the ability to recall information from memory.

retroactive interference Interference in recall that occurs when recently learned information disrupts our ability to remember older information.

retrograde amnesia The loss of the ability to retrieve memories of one's past, particularly memories of episodic or autobiographical events.

retrospective study A research technique that requires participants to report what happened in the past.

reuptake The process by which a terminal button retrieves the molecules of transmitter substance that it has just released; terminates the effect of the transmitter substance on the receptors of the postsynaptic neuron.

rhodopsin The photopigment contained by rods.

right shift theory The theory which suggests that a single gene shifts dominance to one hand (usually the right).

rod A photoreceptor that is very sensitive to light but cannot detect changes in hue.

role-playing A technique which requires an individual to act out or rehearse skills by adopting the identity of another.

Rorschach Inkblot Test A projective test in which a person is shown a series of symmetrical inkblots and asked to describe what he or she thinks they represent.

round window An opening in the bone surrounding the cochlea. Movements of the membrane behind this opening permit vibrations to be transmitted through the oval window into the cochlea.

S

s factor According to Spearman, a factor of intelligence that is specific to a particular task.

saccadic movement The rapid movement of the eyes that is used in scanning a visual scene, as opposed to the smooth pursuit movements used to follow a moving object.

sample A selection of items from a larger population, for example a group of participants selected to participate in an experiment.

Sapir-Whorf hypothesis The idea that language can determine thought.

saturation A perceptual dimension of colour, most closely associated with purity of a colour.

scatterplot A graph of items that have two values; one value is plotted against the horizontal axis and the other against the vertical axis.

schema A mental framework or body of knowledge that organises and synthesises information about a person, place or thing.

schemata Mental representations or sets of rules that define a particular category of behaviour. Schemata include rules that help us to understand current and future experiences.

schizophrenia A serious mental disorder characterised by thought disturbances, hallucinations, anxiety, emotional withdrawal and delusions.

scientific method A set of rules that govern the collection and analysis of data gained through observational studies or experiments.

sclera The tough outer layer of the eye; the 'white' of the eye.

script The characteristics (events, rules and so on) that are typical of a particular situation; assists the comprehension of verbal discourse.

seasonal affective disorder A mood disorder characterised by depression, lethargy, sleep disturbances and craving for carbohydrates. This disorder generally occurs during the winter, when the amount of daylight is low. This disorder can be treated with exposure to bright lights.

secondary appraisal In anxiety research, the individual's ability to evaluate how best to cope with an environment and what strategies can facilitate coping.

secondary reinforcer (or punisher) See conditioned reinforcer (or punisher).

secretory immunoglobulin A (sIgA) A type of antibody which is secreted by and covers the mucosal surfaces.

secure attachment A kind of attachment in which infants use their mothers as a base for exploring a new environment. They will venture out from their mothers to explore a strange situation but return periodically.

segmentation The breaking up of words in order to make them more pronounceable.

selective attention The process that controls our awareness of, and readiness to respond to, particular categories of stimuli or stimuli in a particular location.

self-actualisation The realisation of one's true intellectual and emotional potential.

self-awareness Being consciously aware of oneself as an object.

self-categorisation theory Turner and associates' theory of how the process of categorising oneself as a group member produces social identity and group and intergroup behaviours.

self-concept One's knowledge, feelings and ideas about one's self.

self-control The tendency to be kind, considerate and obedient of laws and rules.

self-discrepancy theory Higgins's theory about the consequences of making actual-ideal and actual-'ought' self comparisons that reveal self-discrepancies.

self-efficacy The expectations of success; the belief in one's own competences.

self-esteem Feelings about and evaluations of oneself.

self-fulfilling prophecy A stereotype that causes a person to act in a manner consistent with that stereotype.

self-perception theory The theory that we come to understand our attitudes and emotions by observing our own behaviour and the circumstances under which it occurs.

self-schema A mental framework that represents and synthesises information about one's self; a cognitive structure that organises the knowledge, feelings and ideas that constitute the self-concept.

self-serving bias The tendency to make attributions that protect or enhance our self-esteem and self-image.

semantic memory A type of long-term memory that contains data, facts and other information, including vocabulary.

semantic priming A facilitating effect on the recognition of words having meanings related to a word that was presented previously.

semantics The meanings and the study of the meanings represented by words.

semicircular canal One of a set of three organs in the inner ear that responds to rotational movements of the head.

semi-structured interview A flexible form of the structured interview which requests responses to specific pre-set questions but allows the interviewer the scope to ask participants to develop their answers further.

sensation The detection of the elementary properties of a stimulus.

sensorimotor period This first period in Piaget's theory of cognitive development, lasting from birth to 2 years. It is marked by an orderly progression of increasingly complex cognitive development: reflexes, permanence, a rough approximation of causality, imitation and symbolic thinking.

sensory association cortex Those regions of the cerebral cortex that receive information from the primary sensory areas.

sensory memory Memory in which representations of the physical features of a stimulus are stored for very brief durations.

sensory neuron A neuron that detects changes in the external or internal environment and sends information about these changes to the central nervous system.

sensory-specific satiety The decrease in the pleasantness and consumption of food after eating it to satiety.

separation anxiety A set of fearful responses, such as crying, arousal and clinging to the carer, that the infant exhibits when the carer attempts to leave the infant.

serotonin-specific reuptake inhibitors (SSRIs) Antidepressants which block the reuptake of serotonin in nerve cells.

serum cholesterol A fat-like chemical found in the blood. One form (LDL) promotes the formation of atherosclerotic plaques. Another form (HDL) may protect against coronary heart disease.

set point The optimum value of the system variable in a regulatory mechanism. The set point for human body temperature, recorded orally, is approximately 98.6°F.

sex chromosomes The chromosomes that contain the instructional code for the development of male or female sex characteristics.

sex-influenced gene A gene which can occur in both sexes but the phenotype is more common in one sex.

sex-linked gene A gene that resides only on the sex chromosome.

sex role Cultural expectations about the ways in which men and women should think and behave.

sex stereotypes Beliefs about differences in the behaviours, abilities and personality traits of males and females.

sexual identity One's private sense of being male or female.

sexual masochism Sexual gratification from being made to suffer.

sexual sadism Sexual gratification from inflicting suffering.

sexual selection Selection for traits specific to sex, such as body size or particular patterns of behaviour.

shading A monocular cue of depth perception; determines whether portions of the surface of an object are perceived as concave or convex.

shadowing The act of continuously repeating verbal material as soon as it is heard.

shallow processing The analysis of the superficial characteristics of a stimulus, such as its size or shape.

shaping The reinforcement of behaviour that successively approximates the desired response until that response is fully acquired.

short-term memory An immediate memory for stimuli that have just been perceived. It is limited in terms of both capacity (7 ± 2 pieces of information) and duration (less than 20 seconds).

signal detection theory A mathematical theory of the detection of stimuli, which involves discriminating a signal from the noise in which it is embedded and which takes into account subjects' willingness to report detecting the signal.

similarity principle A Gestalt principle of organisation; similar elements are perceived as belonging to the same figure.

simulation An attempt to express an emotion that one does not actually feel.

single-blind study An experiment in which the experimenter but not the subject knows the value of the independent variable.

single-case study research An experiment or correlational study concerning the behaviour of individual participants rather than comparisons of the average performance of groups of participants.

situational factors Environmental stimuli that affect a person's behaviour.

sleep apnoea The inability to sleep and breathe at the same time.

sleepwalking Literally, talking in one's sleep.

sleepwalking Literally, walking while asleep.

slow-wave sleep Sleep other than REM sleep, characterised by regular, slow waves on the electroencephalograph.

social cognition The processes involved in perceiving, interpreting, storing and acting on social information.

social comparison theory Theory of the process of comparing one's behaviours and opinions with those of others in order to establish the correct or socially approved way of thinking or behaving.

social compensation Increased effort on a collective task in order to compensate for other group members' actual, perceived or anticipated lack of effort or ability.

social decision schemes Explicit or implicit decision-making rules that relate individual opinions to a final group decision.

social desirability The desire to be seen as competent, cooperative and sociable by the experimenter.

social dilemmas A general class of situations in which long-term gains are best served by short-term losses.

social dominance theory Individual differences in people's preference for their own group to be dominant over and superior to other groups, and their rejection of egalitarian ideologies and acceptance of myths that legitimise hierarchy and discrimination.

social facilitation The enhancement of task performance caused by the mere presence of others.

social identity That part of the self-concept that derives from membership of social groups and is associated with group, as opposed to interpersonal, behaviours.

social identity perspective See social identity theory.

social identity theory Theory of group membership and intergroup relations based on self-categorisation, social comparison and the construction of a shared self-definition in terms of in-group defining properties.

social judgeability Perception of whether it is socially acceptable to judge a specific person.

social learning theory The idea that both consequences of behaviour and an individual's beliefs about those consequences determine personality.

social loafing A reduction in effort when people perform a task collectively with other people.

social markers Features of speech style that convey information about mood, context, status and group membership.

social norms Informal rules defining the expected and appropriate behaviour in specific situations.

social phobia A mental disorder characterised by an excessive and irrational fear of situations in which the person is observed by others.

social psychology The branch of psychology that studies our social behaviour – how the actual, imagined or implied presence of other people influences our thoughts, feelings and behaviours.

social representations Collectively elaborated explanations of unfamiliar and complex phenomena that transform them into a familiar and simple form.

sociobiology The study of the genetic bases of social behaviour; the branch of biology which seeks to explain behaviour in terms of adaptation and evolution.

soma A cell body; the largest part of a neuron.

somatic marker hypothesis The idea that the ability to make decisions leading to positive or potentially negative consequences depends on the activation of somatic (bodily) states.

somatisation disorder A class of somatoform disorder, occurring mostly among women, that involves complaints of wide-ranging physical ailments for which there is no apparent biological cause.

somatoform disorder A mental disorder involving a bodily or physical problem for which there is no physiological basis.

somatosense Bodily sensations; sensitivity to such stimuli as touch, pain and temperature.

source memory Recall of the context in which an event occurred, rather than of the content/knowledge of the event.

spatial neglect A perceptual disorder in which the patient neglects (or fails to attend to) one side of the body, usually the left.

species-typical behaviour A behaviour seen in all or most members of a species, such as nest building, special food-getting behaviours or reproductive behaviours.

specific language impairment Difficulty in producing or understanding spoken language in the absence of known brain injury.

specific phobia An excessive and irrational fear of specific things, such as snakes, darkness or heights.

speech accommodation theory Modification of speech style to the context (e.g. listener, situation) of a face-to-face inter-individual conversation.

speech style The way in which something is said (e.g. accent, language), rather than the content of what is said.

spinal cord A long, thin collection of nerve cells attached to the base of the brain and running the length of the spinal column.

split brain The consequence of surgical excision of the fibres connecting the two cerebral hemispheres of the brain.

split-brain surgery A surgical procedure that severs the corpus callosum, thus abolishing the direct connections between the cortex of the two cerebral hemispheres.

split-half reliability The degree to which two halves or portions of the same measure correlate.

spontaneous recovery After an interval of time, the reappearance of a response that had previously been extinguished.

sport and exercise psychology The branch of psychology concerned with studying the effect of sport and exercise on behaviour and with

applying psychological principles to our understanding of sport-related behaviour.

standard deviation A statistic that expresses the variability of a measurement; square root of the sum of the squared deviations from the mean.

Stanford–Binet Scale An intelligence test that consists of various tasks grouped according to mental age; provides the standard measure of the intelligence quotient.

state-dependent memory The tendency to recall information better when our mental or emotional state at retrieval matches that during encoding.

statistical significance The likelihood that an observed relation or difference between two variables is not due to chance factors.

stereopsis A form of depth perception based on retinal disparity.

stereotaxic apparatus A device used to insert an electrode into a particular part of the brain for the purpose of recording electrical activity, stimulating the brain electrically, or producing localised damage.

stereotype A shared, often unfavourable, generalisation held by members of one group about members of another group.

stereotype threat Feeling that one will be judged and treated in terms of negative stereotypes of one's group, and that one will inadvertently confirm these stereotypes through one's behaviour.

stigma Possession of some attribute, or characteristic, which conveys a social identity that is devalued in a particular social context.

stimulus equivalence A type of learning in which stimuli become equivalent even though the organism has never observed a relation between them; may be involved in learning how to read and manipulate symbols.

storage The process of maintaining information in memory.

Strange Situation A test of attachment in which an infant is exposed to different stimuli that may be distressing.

stranger anxiety The wariness and fearful responses, such as crying and clinging to their carers, that the infant exhibits in the presence of strangers.

stress A pattern of physiological, behavioural and cognitive responses to stimuli (real or imagined) that are perceived as endangering one's well-being.

stress inoculation training The stress management programme developed by Meichenbaum for teaching people to develop coping skills that increase their resistance to the negative effects of stress.

stressors Stimuli that are perceived as endangering one's well-being.

striving for superiority The motivation to seek superiority. Adler argued that striving for superiority is born out of our need to compensate for our inferiorities.

stroke A cerebrovascular accident; damage to the brain caused by a blood clot in a cerebral artery or rupture of a cerebral blood vessel.

Stroop effect A phenomenon whereby a well-practised memory is difficult to suppress and is retrieved automatically (e.g., if participants are asked to name the colours of words and see the word red written in the colour blue, they are likely to say 'red' rather than 'blue').

structuralism Wundt's system of experimental psychology; it emphasised introspective analysis of sensation and perception.

structured interview Predefined format for interviewing participants in research which allows little deviation from the questions set.

subjective ethnolinguistic vitality Individual group members' representation of the objective ethnolinguistic vitality of their group.

sublimation A defence mechanism that involves redirecting pleasure-seeking or aggressive instincts towards socially acceptable goals.

subliminal perception The perception of a stimulus, as indicated by a change in behaviour, at an intensity insufficient to produce a conscious sensation.

subordinate concept A concept that refers to types of items within a basic-level category.

subvocal articulation Uttering words inaudibly.

superego The repository of an individual's moral values, divided into the conscience – the internalisation of a society's rules and regulations – and the ego-ideal – the internalisation of one's goals.

superordinate concept A concept that refers to collections of basic-level concepts.

superstitious behaviour A behaviour that occurs in response to the non-contingent occurrence of an appetitive stimulus; appears to cause a certain event but in reality does not.

supervisory attentional system (SAS) A cognitive system, proposed by Norman and Shallice, which is responsible for the conscious attentional control needed to regulate behaviour.

suprachiasmatic nucleus (SCN) Structures located in the posterior of the hypothalamus which are thought to regulate circadian rhythms.

surface dyslexia A reading disorder in which people can read words phonetically but have difficulty reading irregularly spelled words by the whole-word method.

symbolic play Name given by Piaget to a certain type of play because infants used objects to symbolise other objects or were used to symbolise other activities.

sympathetic branch The portion of the autonomic nervous system that activates functions that accompany arousal and expenditure of energy.

symptom substitution The Freudian notion that the removal of one symptom will lead to its replacement by another.

synaesthesia Phenomenon where the stimulus in one sensory modality evokes a sensation in another.

synaesthete A person who experiences synaesthesia.

synapse The junction between the terminal button of one neuron and the membrane of a muscle fibre, a gland or another neuron.

synaptic cleft A fluid-filled gap between the presynaptic and postsynaptic membranes; the terminal button releases transmitter substance into this space.

syntax Grammatical rules for combining words to form phrases, clauses and sentences.

system variable The variable controlled by a regulatory mechanism; for example, temperature in a heating system.

systematic desensitisation A method of treatment in which the client is trained to relax in the presence of increasingly fearful stimuli.

T

T lymphocytes Cells that develop in the thymus gland that produce antibodies which defend the body against fungi, viruses and multicellular parasites.

taboo A societal rule prohibiting the members of a given culture from engaging in specific behaviours.

tachistoscope A device that can present visual stimuli for controlled (usually very brief) durations of time.

tardive dyskinesia A serious movement disorder that can occur when a person has been treated with antipsychotic drugs for an extended period.

target cell A cell whose physiological processes are affected by a particular hormone; contains special receptor molecules that respond to the presence of the hormone.

taste bud A small organ on the tongue that contains a group of gustatory receptor cells.

tectorial membrane A membrane located above the basilar membrane; serves as a shelf against which the cilia of the auditory hair cells move.

template A hypothetical pattern that resides in the nervous system and is used to perceive objects or shapes by a process of comparison.

temporal coding A means by which the nervous system represents information; different features are coded by the pattern of activity of neurons.

temporal lobe The portion of the cerebral cortex below the frontal and parietal lobes and containing the auditory cortex.

teratogens Drugs or other substances that can cause birth defects.

terminal button The rounded swelling at the end of the axon of a neuron; releases transmitter substance.

test-retest reliability The degree to which scores on one test correlate with the same test undertaken on another occasion.

texture A monocular cue of depth perception; the fineness of detail present in the surfaces of objects or on the ground or floor of a scene.

thalamus A region of the brain near the centre of the cerebral hemispheres. All sensory information except smell is sent to the thalamus and then relayed to the cerebral cortex.

Thematic Apperception Test (TAT) A projective test in which a person is shown a series of ambiguous pictures that involve people. The person is asked to make up a story about what the people are doing or thinking. The person's responses are believed to reflect aspects of their personality.

theory A set of statements designed to explain a set of phenomena; more encompassing than a hypothesis.

theory of mind The understanding of others' mental events.

theory of reasoned action The notion that behaviour follows from an intention to act and that these intentions are based on beliefs, feelings and attitudes.

theta activity EEG activity of 3.5–7.5 Hz; occurs during the transition between sleep and wakefulness.

thought disorder A pattern of disorganised, illogical and irrational thought that often accompanies schizophrenia.

threat gesture A stereotyped gesture that signifies that one animal is likely to attack another member of the species.

three-term contingency The relation among discriminative stimuli, behaviour and the consequences of that behaviour. A motivated organism emits a specific response in the presence of a discriminative stimulus because, in the past, that response has been reinforced only when the discriminative stimulus is present.

threshold The point at which a stimulus, or a change in the value of a stimulus, can just be detected.

timbre A perceptual dimension of sound, determined by the complexity of the sound, for example as shown by a mathematical analysis of the sound wave.

tip-of-the-tongue phenomenon An occasional problem with retrieval of information that we are sure we know but cannot immediately remember.

token economy A programme often used in institutions in which a person's adaptive behaviour is reinforced with tokens that are exchangeable for desirable goods or special privileges.

tolerance The decreased sensitivity to a drug resulting from its continued use.

top-down processing A perception based on information provided by the context in which a particular stimulus is encountered.

transactional theories of leadership Theories that attribute effective leadership to mutually beneficial exchange relations between leaders and followers.

transactive memory Shared system for encoding, storing and retrieving information in a group.

transcranial magnetic stimulation (TMS) A technique which modulates cortical activity by passing alternating magnetic fields across the scalp. (rTMS = repetitive transcranial magnetic stimulation.)

transduction The conversion of physical stimuli into changes in the activity of receptor cells of sensory organs.

transference The process by which a client begins to project powerful attitudes and emotions onto the therapist.

transformational leadership Effective leaders' transactions with followers are characterised by charisma, inspirational motivation, intellectual stimulation, and individualised consideration, which motivate followers to work for group goals that transcend immediate self-interest.

transvestic fetishism Dressing in the clothes normally associated with the opposite sex.

triarchic theory A theory of intelligence which posits that intelligence is made of componential, experiential and contextual elements.

trichromatic theory The theory that colour vision is accomplished by three types of photoreceptor, each of which is maximally sensitive to a different wavelength of light.

tricyclic antidepressants The earliest known antidepressants, so called because of their chemical three-ring structure.

tritanopia A form of hereditary anomalous colour vision; caused by a lack of 'blue' cones in the retina.

Turner's syndrome Genetic disorder in which all or a part of the X chromosome is missing; intelligence is within the normal range but individuals have problems with social adjustment.

two-point discrimination threshold The minimum distance between two small points that can be detected as separate stimuli when pressed against a particular region of the skin.

type A pattern A behaviour pattern characterised by high levels of competitiveness and hostility, impatience and an intense disposition; supposedly associated with an increased risk of coronary heart disease.

type B pattern A behaviour pattern characterised by lower levels of competitiveness and hostility, patience and an easygoing disposition; supposedly associated with a decreased risk of coronary heart disease.

type C (cancer-prone) personality A behaviour pattern marked by cooperativeness, unassertiveness, patience, suppression of negative emotions, and acceptance of external authority; supposedly associated with an increased likelihood of cancer.

tyramine cheese reaction A potentially fatal reaction to eating certain foods in individuals taking MAOIs.

U

UCR See unconditional response.

UCS See unconditional stimulus.

UCS pre-exposure effect A phenomenon in which conditioning is weak because the organism has already been exposed to a novel UCS before it is used in the conditioning experiment.

ultimate attribution error The tendency to attribute in-group failures and out-group successes externally, and in-group successes and out-group failures internally.

ultimate causes Evolutionary conditions that have slowly shaped the behaviour of a species over generations.

unconditional positive regard According to Rogers, the therapeutic expression that a client's worth as a human being is not dependent on anything that they do, say, feel or think.

unconditional response (UCR) In classical conditioning, a response, such as salivation, that is naturally elicited by the UCS.

unconditional stimulus (UCS) In classical conditioning, a stimulus, such as food, that naturally elicits a reflexive response, such as salivation.

unconscious The inaccessible part of the mind.

unconscious inference A mental computation of which we are unaware that plays a role in perception.

underextension The use of a word to denote a smaller class of items than is appropriate, for example referring only to one particular animal as a dog.

undifferentiated schizophrenia A type of schizophrenia characterised by fragments of the symptoms of different types of schizophrenia.

V

validity The degree to which the operational definition of a variable accurately reflects the variable it is designed to measure or manipulate.

variable A measure capable of assuming any of several values.

variable error An error caused by random differences in experimental conditions, such as the subject's mood or changes in the environment.

variable-interval schedule A schedule of reinforcement similar to a fixed-interval schedule but characterised by a variable time requirement having a particular mean.

variable-ratio schedule A schedule of reinforcement similar to a fixed-ratio schedule but characterised by a variable response requirement having a particular mean.

variance The square of the standard deviation.

variation The differences found across individuals of any given species in terms of their genetic, biological (size, strength, physiology) and psychological (intelligence, sociability, behaviour) characteristics.

vertebrae Bones that encase the spinal cord and constitute the vertebral column.

vestibular apparatus The receptive organs of the inner ear that contribute to balance and perception of head movement.

vestibular sac One of a set of two receptor organs in each inner ear that detect changes in the tilt of the head.

visual agnosia The inability of a person who is not blind to recognise the identity or use of an object by means of vision; usually caused by damage to the brain.

visuospatial scratchpad The component of working memory that stores visuospatial information.

voice onset time The delay between the initial sound of a voiced consonant (such as the puffing sound of the phoneme /p/) and the onset of vibration of the vocal cords.

volumetric thirst Thirst provoked by a reduction in the volume of blood plasma.

voyeurism Looking at people while they are undressing or having sex, without their knowledge.

W

waist-to-chest ratio In men, the ratio between size of waist and chest, which determines attractiveness

waist-to-hip ratio In women, the ratio between size of hips and waist, which determines attractiveness

wavelength The distance between adjacent waves of radiant energy; in vision, most closely associated with the perceptual dimension of hue.

Weber fraction The ratio between a just-noticeable difference and the magnitude of a stimulus; reasonably constant over the middle range of most stimulus intensities.

Wechsler Adult Intelligence Scale (WAIS) An intelligence test for adults devised by David Wechsler; contains eleven subtests divided into the categories of verbal and performance.

Wechsler Intelligence Scale for Children (WISC) An intelligence test for children devised by David Wechsler; similar in form to the Wechsler Adult Intelligence Scale.

Wernicke's aphasia A disorder caused by damage to the left temporal and parietal cortex, including Wernicke's area; characterised by deficits in the perception of speech and by the production of fluent but rather meaningless speech.

Wernicke's area A region of auditory association cortex located in the upper part of the left temporal lobe; involved in the recognition of spoken words.

white matter The portions of the central nervous system that are abundant in axons rather than cell bodies of neurons. The colour derives from the presence of the axons' myelin sheaths.

whole-word reading Reading by recognising a word as a whole; 'sight reading'.

withdrawal symptom An effect produced by discontinuance of use of a drug after a period of continued use; generally opposite to the drug's primary effects.

within-groups design See repeated measures design.

working memory A short-term memory system which allows the retention and processing of information concurrently.

Z

zone of proximal (or potential) development According to Vygotsky, the range of tasks or skills that a child is unable to master alone but can with the assistance of adults or their peers.

zygote stage The first stage of prenatal development, during which the zygote divides many times and the internal organs begin to form.
